Short interfering RNA (siRNA) is a double stranded RNA (dsRNA) consisting of 21 nucleotides. siRNA inhibits gene expression specifically by binding and inducing target mRNA degradation. These mechanisms occur within a cell so vectors are important for siRNA delivery into cell. Chitosan (CS) is a biodegradable polymer with high positive charge and can be used as a vector in siRNA delivery. However the major drawback of CS is low solubility in neutral pH and low transfection efficiency. To improve the solubility and transfection efficiency, CS salt forms were used in this experiment. The purpose of this study was to investigate the effect of salt forms of CS (CS-hydrochloride (CS-H), CS-lactate (CS-L), CS-aspartate (CS-A) and CS-glutamate (CS-G)) and molecular weight (MW) of CS (20, 45, 200 and 460 kDa) and N/P ratio (charge ratio between amino groups of CS and phosphate groups of siRNA) for siRNA gene silencing efficiency and cytotoxicity. The human cervical carcinoma stable cells (HeLa stable cells), constitutively expressing green fluorescent protein (GFP) gene were used to study the delivery of siRNA targeting GFP. The results revealed that all CS salt forms were able to silence the GFP gene. The silencing efficiency depend on MW. The low MW CS (20 and 45 kDa) showed higher gene silencing efficiency than the high MW (200 and 460 kDa), observed in CS-H, CS-A and CS-G with an exception of CS-L which had low gene silencing efficiency in all MW and CS-H MW 45 show comparable efficiency to CS-H MW 460. In comparison to CS salt forms, the maximum gene silencing efficiency was found in different N/P ratios. CS-H/siRNA, CS-L/siRNA, CS-A/siRNA and CS-G/siRNA complexes showed maximum gene silencing efficiencies at N/P ratios of 8 ($34.2 \pm 0.5\%$), 16 ($14.6 \pm 1.5\%$), 64 ($32.4 \pm 4.7\%$) and 64 ($25.8 \pm 1.1\%$), respectively. Cytotoxicity results showed that all CS/siRNA complexes had cytotoxicity lower than polyethylenimine (PEI, 25 kDa).

ACKNOWLEDGEMENTS

This thesis would not have been successful without the support from my advisors, Assistant Professor Dr. Sunee Techaarpornkul, Associate Professor Dr. Auayporn Apirakamwong and Associate Professor Dr. Praneet Opanasopit. I am indebted for their valuable advice, encouragement, patience, helpful guidance and kindness given to me during my study.

I would like to appreciate for Assistant Professor Dr. Theerasak Rojanarata for his helpful guidance and worth comment.

I would like to thank to Associate Professor Dr. Jurairat Nunthanid for providing chitosan salt form.

I would like to thank to Dr. Uracha Ruktanonchai of Nanotechnology Center (NANOTEC) for help with Zetasizer Nano ZS and atomic force microscopy (AFM) measurement.

I am grateful to acknowledge the financial support that has enabled me to proceed with this research from National Center for Genetic Engineering and Biotechnology (BIOTEC), Thailand.

I would like to sincerely thank to all teachers, fellow graduate students and the staff in Faculty of Pharmacy, Silpakorn University, for giving me the place, equipments, knowledge and friendship.

Finally, I would like to express my deep gratefulness and appreciation to my parents and lovely friend for their encouragement, helpful and support with never-failing in my life.

CHAPTER I

INTRODUCTION

1. Statement and significance of the research problem

A short interfering RNA (siRNA) was originally identified as an intermediate in the RNA interference pathway (RNAi). siRNA consisting of 21-23 nucleotides can regulate gene expression in mammalian cells through RNAi. (Fire et al. 1998 : 806-811; Hannon 2000 : 244-251) siRNA guides sequence-specific degradation of the homologous mRNA, thus producing "knock-down" gene. Because of the high knockdown efficiency and specificity, it has been employed as a powerful tool for curing disease by blocking the expression of a defective gene or a viral gene including cancer, viral infections and autoimmune disorders. siRNA shows many advantages over oligonucleotide antisense in terms of higher resistance to nuclease degradation and longer therapeutic effect. However, siRNA suffers particular problems including poor cellular uptake, rapid degradation by ubiquitous nucleases in blood circulation.

Basically, there are two main types of vectors that are used in siRNA delivery based on viral or non-viral vector. The viral vector shows a high transfection yield but it has many disadvantages such as oncogenic effect and immunogenicity. (Mansouri et al. 2004 : 1-8) Therefore, non-viral vector has been more attractive, as they are simple to prepare, rather stable, easy to modify and relatively safe, compared to viral vectors. Unfortunately, they also suffer from low transfection efficiency. Polycation such as chitosan, polyethylenimine (PEI), dendrimers, etc. and cationic liposomes are non- viral vectors that are widely used to deliver nucleic acids, including plasmid

DNA, antisense oligonucleotide and the more recently siRNA. (Sung and Chong 2007 : 3360-3368)

Chitosan is a copolymer of N-acetyl-glucosamine and glucosamine. This polymer is a weak base with a pK_a value of the glucosamine residue of ~ 6.2 to 7.0 . Therefore, it is insoluble at neutral and alkaline pH values including pH 7.2 - 7.4 of body. To improve its solubility, chitosan is made salts form with inorganic and organic acid such as hydrochloric acid, lactic acid, glutamic acid and aspartic acid which allows it to be soluble in water. The properties of chitosan (e.g. pK_a and solubility) can be modified by changing the degree of deacetylation (DD). Chitosan is a good candidate for gene delivery due to its low toxicity, biodegradability and low immunogenicity. At acidic pH, below pK_a , the primary amines in the chitosan backbone become positively charged. These protonated amines enable chitosan to bind to negatively charged DNA or siRNA and condense it into complexes.

Few researches using chitosan or chitosan salt as siRNA carriers have been done successfully. The effects of molecular weight (MW) and DD of chitosan and the N/P ratio (ratio of positive charged chitosan to negatively charged siRNA) on the complex physicochemical properties and their transfection efficiency were studied. However, the effect of salt form of CS has not been investigated. In this study we compared different CS salt including chitosan hydrochloride (CS-H), chitosan lactate (CS-L), chitosan aspartate (CS-A) and chitosan glutamate (CS-G) for their ability to form complexes with siRNA and their gene silencing efficiencies in HeLa cells, stably expressing green fluorescent protein (EGFP). Particle size and zeta potential of CS/siRNA complexes were evaluated. In addition, the cytotoxicity of CS/siRNA complexes formulated with various CS was investigated in the stable HeLa cells.

2. Objective of this research

- 2.1 To study the factor affecting the gene silencing efficiencies of CS/siRNA such as the salt form and molecular weight (MW) of CS and the N/P ratio.
- 2.2 To study the physicochemical properties of CS/siRNA complexes such as particle size, zeta-potential and morphology.
- 2.3 To study the cytotoxicity of CS/siRNA complexes formulated with various CS in HeLa cell.

3. The research hypothesis

- 3.1 Different CS salts significantly influence on the gene silencing efficiencies.
- 3.2 Different molecular weight of CS significantly influence on the gene silencing efficiencies.
- 3.3 Different N/P ratio of CS/siRNA complexes significantly influence on gene silencing efficiencies.

CHAPTER II

LITERATURE REVIEW

1. Membrane transport

The plasma membranes are a phospholipids bilayer (Figure 1). The hydrophobic lipid tails are oriented inwards and the hydrophilic phosphate groups are aligned toward the aqueous cytosol or the outside environment. The plasma membrane serves as a semi-porous barrier. It is permeable to specific molecules and allows nutrients and other essential elements to enter the cell and waste materials to leave the cell as summarized in Figure 2. The hydrophobic interior of the lipid bilayer creates a barrier to passage of most hydrophilic molecules, including ions. Electrically-neutral and small molecules such as oxygen, carbon dioxide, and water are able to pass freely across the membrane but the passage of charge and large molecules, such as amino acids and sugars are carefully regulated.

Cell is able to internalize large particles such as protein and nucleotide from the outside by adsorptive endocytosis. Endocytosis is a process where cells absorb material from the outside by engulfing it with their cell membrane which, occur first buds inward and then pinches off to form an vesicle that is called “early endosome” then, the early-endosome fuse with lysosome, resulting in the formation of “late endosome”, in which the pH of late endosomes has acidified condition. Subsequently the material is digested and released into cytosol. The adsorptive endocytosis is commonly divided into two types; phagocytosis and pinocytosis. Phagocytosis, as cell-eating, involves the ingestion of large particles, such as microorganisms and cell

debris via large vesicles called phagosomes (generally >250 nm in diameter). Pinocytosis, as cell-drinking, involves the ingestion of fluid and molecules via small vesicles (<150 nm in diameter).

Figure 1 Schematic drawings showing the two and three-dimensional view of a cell membrane.

Source: Alberts et al, Molecular Biology of the Cell, Third edition (N.Y.: Garland Publishing, 1994), 477.

Another cell endocytosis occurs by the inward budding of plasma membrane vesicles containing proteins with receptor sites specific to the molecules being internalized that is called receptor-mediated endocytosis in which clathrin and cargo molecules are assembled into clathrin-coated pits on the plasma membrane together

with an adapter complexes called AP-2. Subsequently mature clathrin-coated vesicles are actively uncoated and transported to early endosome (Figure 3).

Available from http://www.wormbook.org/chapters/www_intracellulartrafficking/txt

A number of factors influence on the cellular uptake via endocytosis including particle size, shape and surface charge. It has been reported that particles in the nanometer size have a relatively higher intracellular uptake compared to microparticles. (Zauner et al. 2001 : 39-51) Moreover, the surface charges of particles are also very important because positively charged particles interact with the cell surface by an electrostatic interaction with anionic substances on the cell surface. Negatively charged nanoparticles showed an inferior rate of endocytosis and do not utilize the clathrin-mediated endocytosis pathway. Whereas positively charged nanoparticles internalized rapidly via the clathrin-mediated pathway. (Harush-Frenkle et al. 2007 : 26-32) Therefore, gene therapy and drug delivery in nanosize particles with positive charge are considered attractive owing to their minor toxic effect and their ability to associate and internalize into mammalian cells.

2. Transfection

Transfection is a delivery of foreign genes such as DNA (deoxyribonucleic acid), RNA (ribonucleic acid) and siRNA (small interfering RNA) into eukaryotic cells. Popularly, lipofectamine 2000TM (Invitrogen, USA) has been deliver siRNA into mammalian cells. Transfection has becomes a powerful tool for the study of siRNA delivery.

For successful transfection it is essential to maintain aseptic technique when working with cell cultures. The presence of microorganisms can inhibit growth, kill cells, and lead to inconsistent results. The routes of contamination are numerous such as media and reagents, instruments and pipettes, incubators and refrigerators, the worker, the hood, and incoming cells etc. Bacteria, yeasts, fungi, molds, and

mycoplasmas are common contaminants in tissue culture. Use healthy cells at optimal density. Cells should be 70–80% confluent and be used at a passage number that is well characterized. Handling of cell culture in a suitable condition is necessary for good transfection. Several stressful conditions injure cells and cause low transfection efficiency. These include frequent temperature and pH changes, inadequate nutrition from medium depletion in overgrown cultures, instability from subculturing at too low cell density, extended exposure to trypsin, exposure to shear forces from vigorous pipetting or centrifugation, and mycoplasma contamination.

3. siRNA and RNAi

3.1 History of RNAi

RNA interference (RNAi) is a post-transcriptional regulation that specifically inhibits gene expression. RNAi is generally found in all eukaryotic cells including plants and animals. RNAi has proven to be important for cellular defense against foreign genetic element such as viral genes and transposons. RNAi was first reported in 1998 by Mello and Fire et al. They found a potent gene silencing effect after injecting double stranded RNA into *Caenorhabditis elegans* (*C. elegans*) to investigate the regulation of muscle protein production, they observed that neither antisense nor sense RNA injections had an effect on protein production, but it was double-stranded RNA that successfully silenced the targeted gene. As a result of this work, they coined the term RNAi. (Fire et al. 1998 : 806-811; Hannon 2000 : 244-251)

3.2 Mechanism of RNAi

RNAi initiates when the host cell encounters a long dsRNA from a virus or an endogenous source. These long dsRNA are cleaved by dicer which is a ribonuclease III enzyme, into shorter dsRNA of 21-23 nt containing 5' phosphate and 3' hydroxyl termini of both strands, with 2-nt overhang at both 3' end (Figure 4). siRNA is incorporated into a nuclease complex called RNA-induced silencing complex (RISC). One of the siRNA strand, an antisense strand remaining on the RISC complex binds to the homologous nucleotide sequences within the target mRNA and induces cleavage of the mRNA, thereby preventing its translation into protein. The sense strand is removed and degraded by a helicase associated with the RISC. (Aigner 2006 : 12-25) (Figure 5).

siRNA can be exogenously introduced into cells by various form including a long dsRNA or a plasmid containing a pol III promoter that drives expression of siRNA. In mammalian cell, introduction of long dsRNA (>30 nucleotides) activated the interferon, a RNA-binding protein kinase, which induces non-specific degradation of RNA causing cell apoptosis. (Gil et al. 2000 : 107-114) Elbashir et al. succeeded in inducing RNAi machinery in mammalian cells without a non-specific response by transfecting siRNA directly into cell. (Elbashir 2001 : 494-498)

Figure 4 Schematic representation of a siRNA molecule, OH: 3' hydroxyl.

Figure 5 Mechanism of siRNA for specific gene silencing

Source : Achim Aigner, "Gene silencing through RNA interference (RNAi) in vivo: Strategies based on the direct application of siRNAs," Journal of Biotechnology 124 (2006) : 14.

3.3 Application of siRNA

Any gene of which sequence is known can be targeted based on sequence complementarity with an appropriate siRNA. This has made siRNA a powerful tool for gene therapy, analyzing gene function and drug target validation. siRNA targets to viral gene or a defective gene that causes diseases has been employed for gene therapy for chronic diseases including viral infection, cancer and autoimmune disorder. At present, there are no marketed siRNA drugs but a number of siRNAs are investigated in clinical trials such as siRNA-based treatment for age-related macular degeneration is going to clinical trial at level three (Sirna therapeutics, Inc.).

For gene function study, the expression of a targeted gene can be knocked down by siRNA and the phenotypic change can be observed as compared to the normal cell. This technique provides much simple and rapid method for the loss-of-function study compared with the conventional knockout animal technique.

3.4 Introduction of an exogenous siRNA into cell

3.4.1 Preparation of artificial siRNA

Three methods for producing synthetic siRNA are including chemical synthesis, *in vitro* transcription and siRNA expression vector. Firstly, chemical synthesis allow obtainable high purity siRNA but expensive and it is not useful for long term study. Secondly *in vitro* transcription using synthetic DNA oligonucleotide as templates. It is less expensive than the synthesis one but requires more hands-on time, high variability in yield and quality of the products. Finally, siRNA can be expressed in form of shRNA inside the cells by transfecting plasmids that consist of sequence encoding a short hairpin RNA (shRNA) under the control of an RNA polymerase III promoter. shRNA is cleaved by the cellular nuclease into siRNA. This

system provides long term target gene knock down but effective concentration of the shRNA can not be controlled.

To introduce siRNA into cell. It is advised to use high quality siRNA at the lowest effective concentration. siRNA should be free of reagents carried over from synthesis (e.g., ethanol, salts, and proteins). Double-stranded RNA contaminants longer than 30 bp can alter gene expression by activating the nonspecific interferon response, resulting in cytotoxicity.

3.4.2 Obstacle for siRNA delivery

In order for siRNA to work inside cells, they must be internalized into individual cell and access the target mRNA so the delivery of siRNA into cells, tissues or organs remain to be a big obstacle for its applications due to biophysical characteristics that frustrating the intracellular delivery of siRNA are that it is polyanionic, usually one phosphate group per residue, and macromolecular. The polyanionic character of siRNA may limit its interaction with the cell membrane to internalization via adsorptive endocytosis in regions of the cell membrane which are negatively charged under physiological condition. Consequently, the macromolecular nature of siRNA restricts its passive diffusion through the cell membrane. Furthermore, In cytosol has ubiquitous nucleases that occurring rapid degradation. Therefore, siRNA must be enclosed in carriers to allow cellular uptake, to protect siRNA from nuclease digestion and to escape endosome and release of siRNA into the cytosol where the RNAi occurs.

3.4.3 Vector used for siRNA delivery

Basically, there are two main types of vectors that are used in siRNA delivery based on viral or non-viral vector. The viral vectors show a high transfection

yield but they have many disadvantages such as oncogenic effect and immunogenicity. Therefore, non-viral vectors have attracted great interest, as they are simple to prepare, rather stable, easy to modify and relatively safe, compared to viral vectors.

Among the nonviral vector, cationic polymer and lipid-based siRNA vectors have been shown to enter cells and mediate specific RNA interference *in vitro* and *in vivo*. Cationic liposomes including lipofectamine2000 and DOPA provides high efficient siRNA transport although showing some cytotoxicity. Two cationic polymers including the natural polymers such as chitosan and its derivatives and the synthetic polymers eg. poly-L-lysine (PLL), polyethyleneimine (PEI) and dendrimers also has been used for siRNA delivery. Although they do not give as high efficiency as the cationic liposomes, in general they show lower cellular toxicity.

4. Transfection of siRNA using viral vector

There are 5 main classes of viruses used in the delivery of nucleotides to cells, including the retrovirus, lentivirus, adenovirus, baculovirus, and adeno-associated-virus (AAV). RNAi induced by viral delivery was demonstrated first using retroviral vectors based on the mouse stem cell virus (MSCV) and the moloney murine leukemia virus (MoMLV). (Brummelkamp et al. 2002 : 243-247) Despite the relative ease of use *in vitro*, use of the retrovirus *in vivo* has safety concerns and significant limitations. Retroviruses integrate their DNA into the hosts genomic DNA, bringing with it, the risk of mutagenesis and carcinogenesis. Another problem is that retroviral transduction is limited to actively dividing cells, which means that the majority of mammalian cells will not receive the siRNA. Lentiviral vectors are a promising

subclass of retroviruses that lack the risk of insertional mutagenesis and are able to transduce primary and non-dividing cells. Several studies have demonstrated the use of lentiviral vectors to deliver RNAi to target cells. Lentiviral vectors that contain Pol III siRNA-expression cassettes have been used to transfect a number of cell lines *in vitro*, including HeLa, HEK293, mouse embryonic fibroblasts, primary T cells and hematopoietic stem cells. (Stewart et al. 2003 : 493-501) Because retroviruses such as MOMLV and lentivirus integrate into the host genome, they can be used to generate stable knockdown cell lines with relatively high efficiency. At third, Adenoviral vectors are commonly used in gene therapy trials. Since the adenovirus does not integrate DNA into the hosts genome, the effects are short-lived, usually lost after several cell divisions. For this reason, the adenovirus is used when a short duration of action is sufficient or desirable, such as tumor-targeting therapy. The lack of genomic integration also provides a clear safety advantage to adenoviral vectors. Despite the lowered risk of insertional mutagenesis, the adenovirus is associated with significant dose-dependent liver toxicity that can severely limit therapy. Another major disadvantage of adenoviral vectors is the dependence on specific surface receptors on the target cell which are often absent, rendering transduction impossible in many case. Several studies have reported success in delivering siRNA to cells with an adenoviral vector using local injection. At forth, Baculoviruses are insect viruses that can carry large quantities of genetic information. This may allow their use for combined RNAi therapy and gene therapy. Safety concerns are less prominent with these vectors since the virus is unable to replicate or express proteins in mammalian cells. The last, Adeno-associated viruses (AAV) are another possible vector for siRNA. These viruses do not appear to be pathogenic and can transducer non-dividing cells. Raghvis

et al. demonstrated the ability of the modified AVV vector to delivery efficiently siRNA into HeLa S3 cells and down regulate p53 and caspase 8 expression. (Raghuvis et al. 2003 : 5712-5715)

5. Transfection of siRNA using non-viral vector

The use of viral vectors, such as retrovirus and adenovirus, to delivery siRNA has shown effective gene silencing *in vitro* and *in vivo*. (Barton 2002 : 14943-14945)

Although the viral vectors show a high transfection yield but it has many disadvantages such as oncogenic effect and immunogenicity. Therefore, non-viral vectors have attracted great interest more in comparison to viral vectors due to the advantages of non-viral vectors such as simple to prepare, rather stable, easy to modify, low immune response and unrestricted gene materials size in addition to potential benefits in terms of safety. Really, siRNA is a nucleic acid, the basic principles that underlie the design of transfection reagents to delivery siRNA are similar to those used to design delivery agents for other nucleic acid, most notably plasmid DNA. Nucleic acid transfection reagents have two basic properties. First, they must interact in some manner with the nucleic acid cargo. Most often this involves electrostatic forces, which allow the formation of nucleic acid complexes. Formation of complexes ensures that the nucleic acid and transfection reagent are presented simultaneously to the cell membrane. Complexes can be divided into three classes, based on the nature of the delivery reagent : lipoplexes; polyplexes and lipopolyplexes. Lipoplexes are formed by the interaction of anionic nucleic acids with cationic lipids, polyplexes by interaction with cationic polymers, and lipopolyplexes by interaction with both cationic lipids and cationic polymers. (Felgner et al. 1997 :

511-512) Cationic lipids and cationic polymers such as chitosan, polyethylenimine (PEI) and dendrimers are non-viral vectors that are widely used to deliver nucleic acids, including DNA, antisense oligonucleotides, and ribozymes, therefore widely believed to be useful siRNA delivery reagents since siRNA, like other material genetics specially ribozymes, has negatively charged phosphate groups that allow electrostatic complexation. Furthermore, size of siRNA, near ribozymes, consist short chain of ribonucleotide sequence.

5.1 Cationic liposomes (Lipoplexes)

Many cationic liposomes/lipid-based products are commercially available, including lipofectamine2000, N-[1-(2,3-Dioleoyloxy) propyl]-N,N,N-trimethylammonium methylsulfate (DOTAP) and N-[1-(2,3-dioleoyloxy) propyl]-N,N,N-trimethylammonium chloride (DOTMA). As early as the late 1980s, DOTMA was the first liposome that was used to transfer DNA and RNA. (Malone 1989 : 6077-6081) Lipofectamine2000 is a cationic liposome based reagent that provides high transfection efficiency for both DNA and siRNA in a range of mammalian cell types *in vitro*. Lipofectamine2000 has also been used successfully to transfect synthetic siRNA into mammalian cells for RNAi studies. Dalby et al. used lipofectamine2000 to investigate the effect of these factors on its transfection efficiency to siRNA. (Dalby 2004 : 95-103) Khoury et al. demonstrated cationic lipid 2-(3-[bis-(3-amino-propyl)-amino]-propylamino)-N-ditetradecylcarbamoylme-thyl-acetamide combined with L-alpha-Dioleoyl Phosphatidylethanolamine (DOPE) can be efficient to deliver siRNAs designed to silence tumor necrosis factor α (TNF- α) in collagen-induced arthritis (CIA). (Khoury 2006 : 1867-1877)

5.2 Cationic polymers (Polyplexes)

5.2.1 Polyethylenimine (PEI)

Polyethylenimine (PEI) is a polymer with high positive charge density of amine groups. It can form electrostatically complex with the negatively charged phosphate groups of nucleic acid to produce a neutral or positively charged complex to allow intracellular delivery of the genetic material. PEI is also believed to facilitate nucleic acid delivery through a proton sponge mechanism wherein the osmotic pressure at acidic pH is enhanced causing rupture and release of nucleic acid within endosomal vesicle. (Akinc et al. 2005 : 657-663) PEI exists in two principal forms, branched (25 and 800 kDa) and linear (25 kDa) (Figure 6), have been successfully used as transfection agents. Recently, application of linear PEI or low molecular PEI as an siRNA delivery vector has been becoming a hot research subject. Grayson et al. evaluated the efficacy of different PEI structures for siRNA delivery in the HR5-CL11 cell line stably expressing luciferase. Only 25 K B-PEI was found to successfully mediate siRNA delivery and occurred only when an N/P ratio of 6:1 or 8:1 was used with an siRNA concentration of 200 nM. The zeta potential and size of the complexes correlated to transfection efficacy for complexes formed from the 25 K B-PEI and 800 B-PEI, but not the 22 K L-PEI. Other factor, such as the relative stability of the complexes, may also play a role in determining the transfection efficacy of a given PEI structure. The ability of PEI to transfer siRNA into cells is surprisingly dependent on its biophysical and structure characteristics when compared to its relative simple for DNA delivery. Therefore, siRNA transfection is apparently different from DNA transfection. (Grayson et al. 2006 : 1868-1876) Werth et al. showed that PEI F25-LMW (PEI 25 K, low molecular weight, fresh complexes) was

able to complex and fully protected siRNA against nucleolytic degradation, and delivered siRNAs into PC-3 cells (prostate carcinoma cells) where they displayed bioactivity. Upon lyophilization and reconstitution of the complexes, siRNAs were still able to efficiently induce RNAi. (Werth et al. 2006 : 257-270)

5.2.2 Dendrimers

Polycationic dendrimers such as poly (amidoamine) (PAMAM) dendrimers are known to be efficient nucleic acid delivery system. These dendrimers bear primary amine groups on their surface, while having tertiary amine groups inside. The primary amine groups participate in DNA binding, compact DNA into nanoscale particles and promote the cellular uptake of DNA, while the buried tertiary amine groups act as a proton sponge in endosomes and enhance the release of DNA into the cytoplasm. All these features of dendrimers could also be used for RNA delivery. Zhou et al reported that PAMAM dendrimers show strong binding affinity for RNA molecules. They developed dendrimers with the triethanolamine as core has the branching unit starting 10 successive bonds from the center amine (Figure 7). Dendrimers used in this study are referred as G_n (n: dendrimer generation number). The first studied the ability of dendrimers to form self-assembled complexes with siRNA by performing agarose gel electrophoresis. Dendrimers with amine end groups were able to almost completely retard siRNA in the gels at N/P ratios > 2.5 . Moreover, the ability of siRNA/dendrimer complexes to deliver siRNA to A549Luc cells stably expressing the GL3 luciferase gene was tested using a model of endogenous gene knockdown. Efficient gene silencing was observed with the specific GL3Luc siRNA- G_7 complexes, while neither the naked siRNA nor the nonspecific GL2Luc siRNA- G_7 complex showed any gene silencing effect. These results are a

consequence of efficient dendrimers-mediated siRNA delivery. The conclusion, the effective siRNA delivery system based on structure flexible polycationic PAMAM dendrimers. These genuine, nondegraded dendrimers condense siRNA into nanoparticles. They protect siRNA from enzymatic degradation and achieve substantial release of siRNA over an extended period of time for efficient gene silencing. Taken together, these findings suggest that flexible polycationic dendrimers may have great potential for *in vitro* (functional genomics) and possibly *in vivo* (therapeutic) applications. (Zhou et al. 2006 : 2362-2364)

6. Chitosan

Chitosan (CS), a (1→4) 2-amino-2-deoxy-β-D-glucan, is a linear cationic aminopolysaccharide derived by partial alkaline deacetylation of chitin Figure 8. (Skaugrud 1989 : 31-35), a polymer abundant in nature. Chitin is mostly obtained from exoskeletons of crustacean; main sources are shell wastes of shrimp and crab. Chitin also exists naturally in some microorganisms and fungi such as yeast. The backbone of the copolymer consists of two subunits, D-glucosamine and *N*-acetyl-D-glucosamine, which are linked by 1→4 glycosidic bonds. The process of deacetylation involves the removal of acetyl groups from the molecular chain of chitin, leaving behind a compound (chitosan) with a high degree chemical reactive amino group (-NH₂). Molecular weight of native chitin is usually larger than one million Daltons (Da) while commercial chitosan products have the molecular weight

range of 10,000-1,000,000 Daltons, depending on the process and grades of the product. These two characteristics are important because of their heavy impact on the physicochemical, biological and the formulation properties of chitosan.

6.1 Properties of chitosan

Chitosan is weak base with a pKa value of approximately 6.2-7.0 on the amino groups; it is insoluble at neutral and alkaline pH values. However, it can form water-soluble salts with acids such as hydrochloric, lactic, glutamic and aspartic acid, which products were called “chitosan salt form”. Upon dissolution in acid media, the free amino groups (controlled by degree of acetylation) become protonated, resulting in a high charge density and a fully extended, flexible conformation of the chitosan backbone. (Harish Prashanth and Tharanathan 2007 : 117-131) The characteristics of glucosamine unit and acid used to form salt form was presented in Table 1.

Figure 8 Primary structure of (a) chitin and (b) chitosan

Source : Harish Prashanth and Tharanathan, “Chitin/chitosan : modifications and their unlimited application potential-an overview,” Trends in food science & technology 18 (2007) : 119.

The viscosity of chitosan solutions varies from low to high depending on factors such as the molecular weight (MW), degree of deacetylation, pH, ionic strength and temperature. (Wang 1994 :149-152) Protonated chitosan can form gels with polyanions, a property that was exploited in the development of controlled-release formulations of various drug.

The possibility of chemical modification of chitosan, for instance, by introducing chemical groups to its backbone structure through covalent binding has resulted in a series of versatile chitosan derivatives with improved physicochemical properties and transfection efficiency such as quaternized CS have been synthesized in order to free amine groups of CS can form ammonium salts with inorganic and organic acids. Reaction of CS with excess of methyl iodide in alkaline condition give *N*-trimethyl CS derivative. Such quaternary CS derivatives are useful for enhance solubility. (Thanou 2002 : 153-159)

Chitosans, except for high molecular weight chitosans of specific salt forms, are generally shown to be nontoxic (LD50 in rats of 16g/kg) (Borchard and Bivas-Benita, in Amiji 2004 : 301-310), partially due to their biodegradability. Chitosan is degraded by lysozymes into a common amino sugar, which is incorporated into the synthetic pathway of glycoproteins, and is subsequently excreted as carbon dioxide.

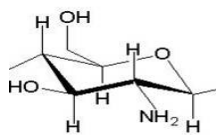

6.2 Applications of chitosan

The application potential of chitosan is abundance such as in food and nutrition, biotechnology, material science, drugs and pharmaceutics, agriculture and environmental protection, and recently in gene therapy as well. Examples of potential applications of chitosan in conventional pharmaceutical include its use as binder, disintegrant and coating material. Because of its unique polymeric character, gel-

forming properties and property for degradation, chitosan-based controlled and targeted delivery systems have also been developed and examined. Several reports have confirmed the absorption enhancing characteristics of chitosan formulations following nasal administration of vaccines, peptides, proteins and low molecular weight drugs. (Davis et al. 2003 : 1107-1128)

In recent years, chitosan-based carriers are one of the non-viral vectors that have gained increasing interest as a safer and cost-effective delivery system for gene materials including plasmid DNA (pDNA), antisense, oligonucleotides and siRNA. At acidic pH, the primary amine functions are protonated, resulting in a cationic polymer of high charge density, which can easily form stable complexes with negatively charged nucleotides by electrostatic interaction, partially protecting genetic material from nuclease degradation.

Table 1 Characteristics of acid and glucosamine unit of chitosan salt.

Acid	M.W.	bp (°C)	mp (°C)	pK _a	Chemical structure
L-Aspartic	133.10			3.65	COOH HC-NH_2 CH_2 COO^-
L-Glutamic	147.13		160	4.25	COOH HC-NH_2 CH_2 CH_2 COO^-
Lactic	90.08	122	17	3.86	CH_3 HC-OH COO^-
Hydrochloric	36.4	110			Cl^-
Chitosan	161.16			6.3 – 7

6.3 The complex formation between CS and siRNA

Katas et al. was the first group to investigate the use of chitosan to deliver siRNA *in vitro*. They used 2 MW of CS-H and CS-G to form CS/siRNA complexes by three methods; simple complexation, ionic gelation by siRNA entrapment in chitosan-tripolyphosphate (CS-TPP) nanoparticles and by adsorption of siRNA onto the surface of preformed CS-TPP nanoparticles. These complexes were evaluated for their physicochemical properties and their siRNA delivery efficiency. They found that siRNA CS-TPP entrapment in nanoparticles showed higher transfection efficiency than those prepared by the other two methods possibly due to their high binding and loading efficiency. (Katas and Alpar 2006 : 216-225) Liu et al. studied the gene silencing activity and the physicochemical properties (size, zeta potential, morphology and complexes stability) of the CS/siRNA complexes. (Liu et al. 2007 : 1280-1288) The chitosan properties that have effect on the gene silencing activity and the physicochemical properties of the particles include molecular weight (MW), degree of deacetylation (DDA) and N/P ratio.

6.3.1. The effect of MW and DD

The molecular weight and degree of deacetylation of chitosan are important factors that determine siRNA compaction, the nuclease resistance of the complexes and the dissociation of siRNA from chitosan. The higher MW CS are longer and more flexible molecules whereas the lower MW CS are shorter and have stiffer molecular chains. The DD value determines the positive charge density when chitosan is dissolved in acidic conditions. Higher DD results in increased positive charge enabling a greater siRNA binding capacity.

Liu et al. investigated the effects of MW and DD of CS on physicochemical properties of CS/siRNA complexes and gene silencing efficiency. They formulated siRNA/chitosan nanoparticles at N:P 50 using different chitosan samples (MW range was 8.9-173 kDa and DDA range was 54- 95%) as shown in Table 2 .

Table 2 Chitosan samples with different MW and DD

Simple	C9-95 ^a	C12-77	C65-78	C114-84	C170-84	C173-54
MW (kDa)	8.9	11.9	64.8	114.2	170	173
DD (%)	95	77	78	84	84	54
SIZE	3500	500	200	200	200	200

^aNumbers indicate MW (molecular weight, kDa) and DD (degree of deacetylation, %).

The result showed that the size of nanoparticles formed with chitosan C9-95 (low MW and high DD) was ~3500 nm and decreased to ~500 nm with chitosan C12-77 (low MW and medium DD). All other chitosan samples (C65-78, C114-84, C170-84, and C173-54) resulted in particles with a size of approximately 200 nm. The zeta potential for all formulations was in the range of 10-20 mV, suggesting a net positive surface charge due to excess chitosan. The charge increased slightly with MW, with the exception of C173-54 which was reduced due to the relative low DD value.

Study of gel retardation assay and in vitro transfection in EGFP stably expressing human lung carcinoma cells (H1299) revealed that low MW CS ~10 kDa even with DD as high as 95% cannot form complex and show low or no gene silencing whereas the high MW CS ~64-170 kDa with medium DD (77-84%) can

form stable complex resulting in 45-65% gene silencing efficiency. The high MW CS with low DD of 54% form unstable complex with lower positive charge and lower gene silencing efficiency than those CS with higher DD. (Liu et al. 2007 : 1280-1288)

Katas et al. studied 2 chitosan salt with 86% DDA: chitosan hydrochloride and chitosan glutamate. The result showed that smaller particle size was obtained with the lower MW (CS-H 110 kDa versus CS-H 270 kDa, and CS-G 160 kDa versus CS-G 460 kDa) or the lower concentration of chitosan. They explained that due to the decreased viscosity of the lower MW and concentration of chitosan which resulted in better solubility and generated its molecular character as a polyelectrolyte material that allows more efficient interaction between negatively charged siRNA and the cationic chitosan. (Katas and Alpar 2006 : 216-225)

6.3.2 The effect of N/P ratio

The transfection efficiencies were significantly influenced by the N/P ratios, which defined as the theoretical charge ratio of chitosan amino groups (N) to siRNA phosphate groups (P). The N/P ratio can be used to control the characteristics of the formed complexes such as condensation, stability, zeta-potential, size and transfection efficiency of complexes. Liu et al. showed that the complex stability and the level of EGFP knockdown increased at higher N:P ratio formulations compared to lower N:P formulations. Nanoparticles of siRNA and high MW CS with 84% DD formed at N:P 150 showed the greatest level (~80%) of EGFP knockdown. Nevertheless, the high N/P ratio formulations show slightly increase in cytotoxicity which may be due to the increased level of free excess CS in the system. (Liu et al. 2007 : 1280-1288)

6.4 The mechanism of gene silencing via chitosan/siRNA complexes

In general, it is thought that the intracellular trafficking of siRNA occurs by endocytosis, followed by release from the endosome, and silencing messenger RNA (mRNA) that it recognizes as having the complimentary sequence. The siRNA/chitosan complexes consists of the negatively charged active siRNA sequences that are designed to “silence” target gene. These siRNA sequences are complexed through electrostatic bonds with the chitosan cationic polymer. Previously, it has been well accepted that the siRNA/chitosan complexes absorb to the cell surface through electrostatic interactions and internalized into the cells by endocytosis. Recently, there have been several evidences suggesting that chitosan interacts with cell membranes not only by electrostatic forces, but also by interactions with carbohydrate moieties on cell membranes. These interactions lead to a disturbance of the bilayer structure. (Borchard and Bivas-Benita, in Amiji 2004 : 301-310)

After the siRNA/chitosan complexes have already been internalized into cell, they must be escape from endosomal vesicle to avoid lysosomal degradation into the cytoplasm. Exactly what happens inside the endosome to release the nanoparticles is still not fully understood, even for delivery of pDNA. What is known is that following endocytosis, nanoparticles are sequestered in vesicle inside the endosome where enzymes and the acidic pH (~5.5) can either degrade or swell polymers, depending on their chemistry. This step may help to release the nucleic acid from the nanoparticles, but if the naked DNA or siRNA remain inside the endosome for too long, it will also be degraded. (Bettinger et al. 2001 : 3882-3891) Katas et al. reported that the siRNA/chitosan nanoparticle complex significantly protected siRNA from nuclease

activity. In this study siRNA/CS-TPP complex up to 72 h in 5% serum and 7 h in 50% serum whereas naked siRNA was degraded after 48 h of incubation in 5% serum and instantly degraded in 50% serum. (Katas and Alpar 2006 : 216-225)

Finally, siRNA which escapes from the late endosome, was released into the cytosol where RNA-Induced Silencing Complex (RISC) was activated. RISC encountered siRNA, unwinded it leaving only the antisense strand then bound and located to target messenger RNA (mRNA) with homologous nucleotide sequences and induced cleavage specific of mRNA.

7. Establishing a stable cell line constitutive expressing EGFP gene

Green fluorescent protein (GFP) from the bioluminescent jellyfish *Aequorea Victoria*. GFP is unique among various light-emitting proteins in being autofluorescent. i.e. it does not required substrate or cofactors to emit light. Moreover, mutants of GFP can be generated to increase fluorescence intensity and shift wavelengths of excitation and emission. A plasmid encoding enhanced green fluorescent protein (EGFP) gene was used to generate a stable cell line producing EGFP. This stable cell line can be uses as a model to test for specific eGFP gene silencing activity and the cytotoxicity of the complexes containing siRNA targeting EGFP.

The pEGFP-C2 plasmid DNA (Figure 9), Genbank accession #: U55761, encodes a red-shifted variant of wild-type GFP which has been optimized for brighter fluorescence and higher in expression in mammalian cells. (Excitation maximum = 488 nm; emission maximum = 507 nm.). The plasmid contains neomycin/kanamycin resistant gene as a selectable marker for selection of transfectants using a

commercially available G418 antibiotic. Cells that have successfully integrated the transfected pEGFP-2 into their chromosomal DNA will form clones of stable cell lines expressing EGFP gene constitutively when growing in a complete medium with G418.

CHAPTER III

MATERIALS AND METHODS

1. Materials

1.1 siRNA-EGFP(+) targeted to position 124-145 of the *eGFP* open reading frame (sense: 5' –AAG CUG ACC CUG AAG UUC AUC-3', antisense: 3' –CGA CUG GGA CUU CAA GUA GAA-5') and non-silencing control, siRNA-EGFP(-), (sense: 5' –AAG CAC CGC UUA CGU GAU ACU-3', antisense: 3' –CGU GGC GAA UGC ACU AUG AAA-5'), 5 nmol each, were purchased from Ambion, USA (Silencer[®] GFP (eGFP) siRNA, Catalog # : AM 4626)

1.2 Chitosan (CS) MW of 20, 45, 200 and 460 kDa with 85% degree of deacetylation (Seafresh company, Thailand)

1.3 The HeLa cell line was obtained from Nanotec Thailand (American Type Culture Collection Catalog No. CCL-2[™]) at passage number 77.

- Tissue culture reagents including Minimum Eagle Medium (MEM), Fetal bovine serum EU approved, origin L-Glutamine, MEM non-essential amino acids, trypan blue stain 0.4% and 0.25% Trypsin-EDTA were purchased from GIBCO[™], USA

1.4 Plasmid encoding green fluorescence protein (pEGFP-C2) and materials for purification of plasmid

1.5 *Escherichia coli* DH5- α

1.6 All other chemicals

Geneticin (G418) (Invitrogen , USA)

Lipofectamine 2000TM (Invitrogen, USA)

Diethylpyrocarbonate (DEPC) (Bio basic INC, Canada)

GenePure LE Agarose (ISC BioExpress[®], USA)

Sodium bicarbonate (Fisher Scientific, USA)

3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT) (Sigma-chemical company, USA)

2. Equipment

1. Spray dryer (Minispray Dryer, Büchi 190, Postfach, Switzerland)
2. Atomic force microscopy (SPI4000-SPA400, Seiko Instruments, Chiba, Japan)
3. Spectrophotometer (Agilent Technologies, Waldbronn, Germany)
4. Zetasizer 3000 (Malvern Instruments, Southborough, MA, USA)
5. CO₂ Incubator (Contherm, Lower Hutt, New Zealand)
6. Laminar hood (Holten, Nino-lab, Sweden)
7. Optical microscope (Nikon, eclipse TE2000-S, Tokyo, Japan)

8. Incubator shaker (GFL, Burgwedel, Germany)
9. Microplate reader (Universal Microplate Analyzer, AOPUS01 and AI53601, Packard Biosciences, Meriden, CT, USA)
10. Gel electrophoresis set (Alphaimager 2200, Alpha-Innotech, CA, USA)
11. Cell culture plate/ dish / flask (Corning, NY, USA)
12. pH meter (Horiba, Kyoto, Japan)

3. Methods

3.1 Preparation of plasmid

One hundred nanogram of plasmid pEGFP-C2 was transformed into *Escherichia coli* DH5- α (*E. Coli*), plated on LB agar supplemented with 50 $\mu\text{g/ml}$ of Kanamycin (Invitrogen, USA) and incubated overnight at 37 °C. A single colony of transformant was grown in 100 ml of LB medium at 37 °C with vigorous shaking at 200 rpm. The cells were harvested by centrifugation at 6000 g for 15 minute at 4°C. The plasmid was isolated from the pellet using QIAGEN[®] Plasmid Midi Kits (QIAGEN, USA), according to the manufacturer's directions. The concentration of prepared plasmid was determined by spectrophotometry (Biometra[®], USA) at wavelength 260 nm and 280 nm. The concentration of plasmid was calculated using follow equation:

$\text{Plasmid concentration} = 50 \mu\text{g/ml} \times \text{OD}_{260\text{nm}} \times \text{DF}$

- A solution of 50 $\mu\text{g/ml}$ of an average double-stranded DNA has an $\text{OD}_{260 \text{ nm}}$ of 1.
- $\text{OD}_{260 \text{ nm}}$ is the optical density from the absorbance reading
- DF is the dilution factor

3.2 Preparation of Chitosan salts

Chitosan base (CS) with MW of 20, 45, 200 and 460 kDa and 85% degree of deacetylation (DD) was dissolved in dilute acid solutions of hydrochloric acid, lactic acid, glutamic acid and aspartic acid in certain molar ratio (Table 3). These solutions were adjusted with distilled water to make 1% w/w solutions and stirred for at least 12 h, filtered and then spray-dried at a feed rate of 5 ml/min under the following conditions: inlet temperature of 125 ± 2 °C and outlet temperature of 65 ± 2 °C using a spray dryer (Minispray Dryer, Büchi 190, Switzerland). The obtained powders (CS-H, CS-L, CS-G and CS-A) were stored in a dessicator containing dry silica gel prior to use in each experiment. (Nunthanid et al. 2004: 15-26)

Table 3. Molar ratio of D-glucosamine unit : acids

Materials	Molar ratio	Chitosan salts
chitosan: aspartic acid	1:0.850	CS-A
chitosan: hydrochloric acid	1:0.800	CS-H
chitosan: glutamic acid	1:0.825	CS-G
chitosan: lactic acid	1:0.775	CS-L

3.3 Preparation of complete growth medium

The process of preparation of 1X complete culture medium is shown as follows: fetal bovine serum (FBS) was heat-inactivated by incubating for 30 min in a 56°C water bath. To prepare 1 litre of medium, MEM medium powder (GIBCO,

USA) was dissolved in 300 ml of sterile water with gentle stirring and 2.0 g of NaHCO_3 was added and the pH was adjusted to 7.4-7.5 using 1 M HCl or 1 M NaOH before adding more sterile water to adjust the volume to 1L. The medium was sterilized immediately by 0.22 μm membrane filtration. Then the medium was supplemented with: 1% v/v L-Glutamate, 1% v/v Non-essential amino acid and 10% v/v heat- inactivated FBS.

3.4 Establishing stable cell lines

HeLa cells were transfected with complexes of 0.8 μg of pEGFP-C2 plasmid DNA (Clontech , USA) and 2.0 μl of lipofectamine2000TM (Invitrogen, USA) according to the manufacturer's instructions. Briefly, the day before transfection, cells were seeded 1×10^5 cells into each of one well of a 24-well plate and incubated at 37 °C with 5% CO_2 . Prior to transfection, medium was removed and washed one time with PBS then added with a mixture of 100 μl of complexes and 500 μl of serum free medium then incubated at at 37 °C with 5% CO_2 incubator for 12 hours then the medium was removed and was added fresh medium and further incubation until cell grew 100 % confluent. Cells were trypsinized and aliquot into a 100 mm cell culture dishes and added with selective medium, a MEM supplemented with 10% FBS and 0.5 mg/ml of G418 (Geneticin® Invitrogen Corp, USA) which is used to select and maintain for EGFP gene expression. Later, the cells were maintained in selective media to get single clone of a few hundreds cells (Figure 10-11). Media were changed every 3 days. Individual clones were isolated and transferred into each of 24-well plate and cultured in MEM supplemented with 10% FBS and 0.1 mg/ml of

G418. The cells were subpassaged and expanded in separate wells of 6-well plate. Cryostocks of each clone were collected from 100% confluent cell culture.

3.4.1 The cultivation of HeLa stable cells

HeLa stable cells were grown in 250 ml tissue culture flask containing complete growth medium (MEM) in a humidified air atmosphere (5% CO₂, 95% RH, 37 °C). Cultivated cell were visualized using an inverted microscope to detect cross-contamination or visible microbial contamination. The cells were subpassage every 3-5 days as spit ratio of 1:5 to 1 :10.

Figure 10 Cultivated HeLa cells on 24-well plate. image 10x objective using an inverted microscope.

Figure 11 Cultivated HeLa stable cells on 24-well plate. image 10x objective using fluorescent microscope.

3.4.2 Thawing frozen cell

Thaw the frozen cells in a vial by gentle agitation in a 37 °C water bath. Thawing should be rapid and transfer the vial contents to a sterilized tube containing 10 ml complete medium. The cells were briefly centrifuged at 1,000 rpm for 1 min at 4 °C to remove DMSO containing medium that can be toxic to cell. The medium was removed and the cell pellet in complete growth medium was resuspended gently. The cell suspension was diluted to appropriate concentration, and transferred into a tissue culture flask.

3.4.3 Subculturing

The cells were subpassaged when reaching 80-100% confluency. The medium was aspirated and the cells were rinsed one time with PBS before adding 1

ml of 0.25% trypsin/EDTA solution (GIBCO, USA) and incubating at 37°C for approximately 5 minutes or until the cells detach and float. This can be confirmed by periodic visual inspection of flasks or observing cells under an inverted microscope. Inactivate trypsin/EDTA by adding excess serum-containing medium. Cell suspension was removed to a conical tube and pellet by centrifugation at 1,000 rpm for 1 minute. 5 ml of complete culture medium was added and the cells were resuspended gently by pipette up and down. For spit ratio 1:5, 1 ml of the cell suspension were added to a new 75 cm² TC flask and 15 ml of complete culture medium was added. The cell culture was then placed in the incubator.

3.4.4 Frozen culture

For one 75 cm² cell culture flask, cells were trypsinized, pelleted and resuspended in 5 ml of complete culture medium. The cell suspension tube and 5 labeled cryotubes were pre-cooled on ice for 5 minutes before adding 250 µl of DMSO into the suspension cell and mixing gently. 1 ml of cell suspension was transferred into each cryoprotective tubes. The cryostocks were stored at -80°C for overnight then transferred into liquid nitrogen tank for long term storage.

3.5 Calculation of N/P ratio

The N/P ratio is theoretical charge ratio between amino groups of chitosan and phosphate groups of siRNA. Amino groups have the positive charge but phosphate groups have the negative charge. The N/P ratio was appropriated that enhance efficiency transfection. The N/P ratio was calculated using follow equation:

$$\text{N/P ratio} = \frac{\text{nmoles N}}{\text{nmoles P}}$$

$$\text{nmoles N of chitosan} = \frac{\text{amount of CS } (\mu\text{g})}{\text{MW of (N) CS}}$$

$$\text{nmoles P of siRNA} = \frac{\text{amount of siRNA } (\mu\text{g})}{\text{MW of (P) siRNA}}$$

$$\text{Average M.W. of (P) siRNA} = 333 \text{ g/mole}$$

$$\text{Average M.W. of (N) chitosan} = 161 \text{ g/mole}$$

In this study, the amount of siRNA was fixed as 25 pmol/well in 25 μl of complexes

$$\text{Stock of siRNA} = 2 \mu\text{M}$$

$$\text{Stock of chitosan} = 0.44 \text{ mg/ml}$$

Table 4. The amount of CS and siRNA per well used to form complexes at various N/P

N/P	siRNA (μl) (2 μM)	CS (μl) (0.44 mg/ml)	water (μl) (DEPC)
8	12.5	3.25	9.25
16	12.5	6.25	6.25
32	12.5	12.5	-
64	12.5	12.5*	-

* CS 0.88 mg/ml

3.6 Preparation of CS/siRNA complexes

The CS/siRNA complexes were formed in DEPC water at various N/P of 8, 16, 32 and 64 by adding the siRNA solution into an equal volume of various salt form of

CS solution (Table 4). The complexes were pipetted up and down. They were then incubated for 30 min at room temperature to allow complex formation.

3.7 Characterization of CS/ siRNA complexes

3.7.1 Agarose gel electrophoresis

2% agarose gel was prepared by dissolving 0.5 g of agarose in 25 ml of Tris-borate-EDTA (TBE) (0.1 M Tris HCl, 0.09 M boric acid, 2 nM EDTA) buffer, pH 8.3. The gel solution was warmed up in order to dissolve the agarose. 15 μ l of 1 mg/ml ethidium bromide was added into the gel solution before the gel was congealed. The CS/siRNA complexes were formulated as described in section 3.6 (Table 5). CS/siRNA complexes and naked siRNA were loaded into the agarose gel in TBE buffer, pH 8.3. The volume of the sample loaded in the well was 10 μ l of CS/siRNA complex solution containing 5 pmol of siRNA. The electrophoresis was carried out at 100 V for 20 min. UV transillumination of the gel was employed to visualize siRNA and the transilluminated gel was photographed using a gel documentation analyzer (AlphaImager 2200, Alpha-Innotech, CA, USA).

Table 5. The amount of CS and siRNA per well used to form 10 μ l of complexes at various N/P for gel electrophoresis.

N/P	siRNA (μ l) (0.4 μ M)	CS (μ l) (0.1 mg/ml)	water (μ l) (DEPC)
8	5	1.25	3.75
16	5	2.49	2.51
32	5	4.98	0.02
64	5	4.98*	0.02

* CS 0.88 mg/ml

3.7.2 Particle size and zeta-potential of the siRNA/CS complexes

The mean particle size and surface charge of the CS/siRNA complexes were determined by using the Zetasizer Nano ZS (Malvern instrument Ltd., Malvern, UK) at room temperature. To obtain the optimum scattering intensity, the CS/siRNA complexes were formed for 30 minutes and the complex were diluted with PBS/DEPC solution pH 7.2. All samples were measured in triplicate.

3.7.3 Morphology

The morphology of the CS/siRNA complexes was determined by Atomic Force Microscope (AFM) using tapping-mode AFM in air. The complexes were diluted with 0.1% DEPC water that was passed through 0.22 μm membrane filter prior to use. These samples were dropped immediately onto freshly cleaved mica and air-dried. (Wu et al. 2004 : 294-295)

3.7.4 *In vitro* transfection

In vitro transfections were performed in adherent HeLa stable cells. Briefly, the day before transfection, 8×10^3 cells in 100 μl of growth medium were plated into sterile opaque 96-well plates. Prior to transfection, the culture medium was removed from each well and the cells were washed once with PBS and the mixture of 25 μl of CS/siRNA complexes at various N/P of 8, 16, 32 and 64 and 100 μl of MEM without serum, was added onto each well and cells were incubated at 37°C with 5% CO₂. The GFP cell fluorescence was measured before and every 24 hour after transfection using a spectrofluorophotometer (model no: AOPUS01 and A153601; A Packard bioscience company, USA) with an emission and excitation wavelength at 488 and 510 nm. respectively. The transfection efficiency was calculated from the

fluorescence intensity of siRNA(+) transfected cells and siRNA(-) transfected cells performed in parallel using the following equations:

$$\% \text{ seeding variation} = \frac{(I_{\text{average,day0}} - I_{n,\text{day0}}) \times 100}{I_{\text{average,day0}}} \quad \text{Eq.1}$$

$$\text{Adjusted fluorescent intensity } (I_{\text{ad}}) = \frac{I_{n,d1-5} + (I_{n,d1-5}) \times (\% \text{ seeding variation})}{100} \quad \text{Eq.2}$$

$$\% \text{inhibition of gene expression} = \frac{(I_{\text{averagead,siRNA(-)}} - I_{\text{ad,siRNA(+)}}) \times 100}{I_{\text{average ad,siRNA(-)}}} \quad \text{Eq.3}$$

where $I_{\text{average,day0}}$ is the average fluorescent intensity of all wells at before transfection (day 0), $I_{n,\text{day0}}$ is the fluorescent intensity of individual well at day 0, $I_{n,d1-5}$ is the fluorescent intensity at day 1-5 of each well, I_{ad} is adjusted fluorescent intensity, $I_{\text{ad,siRNA(+)}}$ is adjusted fluorescent intensity of the cell with CS/siRNA (+) complexes, and $I_{\text{average ad,siRNA(-)}}$ is an average (n=3-5) adjusted fluorescent intensity of the cell with CS/siRNA (-) complexes.

3.7.5 Cytotoxicity of the siRNA/CS complexes

In vitro cytotoxicity test were performed in HeLa stable cells. Briefly, the day before transfection, plate 8×10^3 cells in 100 μl of growth medium into sterile 96-well plates. Prior to transfection, the culture medium was removed from each well and the cells were rinsed one time with PBS. The mixture of 25 μl of CS/siRNA complexes at various N/P of 8, 16 32 and 64 and 100 μl of MEM with no serum, was

added onto each well and the cells were incubated at 37°C and 5% CO₂. 24 post-transfection, the medium was removed and 20 µl of MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide, 5 mg/ml) in serum free-medium was added to each well and the cells were incubated for 4 h to allow formation of formazan, then the medium was removed and 100 µl of DMSO was added to dissolve the formazan crystals. The absorbance of formazan was measured at 540 nm using a microplate reader (Universal Microplate Analyser, Model AOPUS01 and A1536601, Packard bioscience company, USA). The relative cell viability was calculated by using the follow equation:

$$\% \text{ cell viability} = \frac{[\text{OD}]_{\text{test}} - [\text{OD}]_{\text{DMSO}}}{[\text{OD}]_{\text{control}} - [\text{OD}]_{\text{DMSO}}} \times 100$$

[OD]_{test} ; value that got from wavelength 540 nm of cell which were also added siRNA /CS complexes at various N/P

[OD]_{DMSO} ; value that got from wavelength 540 nm of cell which were also added DMSO

[OD]_{control} ; value that got from wavelength 540 nm of cell which were not added siRNA /CS complexes

3.7.6 Statistical analysis

All experimental measurements were collected in triplicate. Result values were expressed as mean value ± standard deviation (SD).

CHAPTER IV

RESULTS AND DISCUSSION

1. Results

1.1 Complex formation of CS salt form with siRNA

Complex formation between siRNA and various CS salt forms were confirmed by gel retardation assay. When the concentration of CS gradually increased, the siRNA showed gradual retardation within the gel. The migration of siRNA on an agarose gel was retarded and depended on molecular weight and size enlargement and reduction of negative charge of chitosan/siRNA complexes (CS/siRNA) as compared to those of the free siRNA.

Figure 12 illustrated the gel retardation assay of CS-H/siRNA complexes of various MW of CS. The result showed that CS with different MW started binding to siRNA at different N/P ratio. The CS-H MW 20, CS-H MW 45, CS-H MW 200 and CS-H MW 460 showed initial binding to siRNA at N/P ratios of 8 (Figure 12a, Lane 5), 16 (Figure 12b, Lane 6), 4 (Figure 12c, Lane 4) and 32 (Figure 12d, Lane 7), respectively. The migration of siRNA in these complexes retarded as compared to the migration of unbound siRNA. (Figure 12a-d lane 1) Some of them show smear band in 2 % agarose gel due to their size variation of the CS/siRNA complexes.

Figure 13 illustrated the gel retardation assay of CS-L/siRNA complexes of various MW of chitosan. The result showed that CS-L with MW of 20 and 200 kDa showed retardation in migration. The CS-L MW 20 and 200 kDa started retardation in migration at N/P ratios of 32 (Figure 13a, Lane 7) and 8 (Figure 13c, Lane 5),

respectively, whereas the CS-L with MW of 45 and 460 kDa showed no retardation (Figure 13b, Figure 13d).

Figure 14 illustrated the gel retardation assay of CS-A/siRNA complexes of various MW of chitosan. The result showed that each of MW of CS started retardation in migration at different N/P ratio. The CS-A MW 45, 200 and 460 kDa showed at N/P ratios of 8 (Figure 14b, Lane 5), 4 (Figure 14c, Lane 4) and 4 (Figure 14d, Lane 4), respectively, whereas the CS-A MW 20 kDa showed no binding to siRNA and therefore displayed no retardation (Figure 14a).

Figure 15 illustrated the gel retardation assay of CS-G/siRNA complexes of various MW of chitosan. The result showed that each of MW of CS started retardation in migration at different N/P ratio. The CS-G MW 20, 45 and 200 kDa showed at N/P ratios of 32 (Figure 15a, Lane 7), 8 (Figure 15b, Lane 5) and 64 (Figure 15c, Lane 8), respectively, whereas the CS-G MW 460 kDa showed no binding to siRNA and therefore displayed no retardation (Figure 15d).

Figure 15 Gel retardation assay of CS-G/siRNA complex on 2% agarose gel. (lane 1) siRNA-GFP (lane 2-8) N/P ratio of 1, 2, 4, 8, 16, 32 and 64 respectively. (a) MW 20 kDa (b) MW 45 kDa (c) MW 200 kDa (d) MW 460 kDa.

1.2 The particle size and zeta-potential of the CS/siRNA complexes

1.2.1 The particle size and zeta-potential of the CS-H/siRNA complexes

The particle size and zeta-potential of the CS-H/siRNA complexes of various MW (20, 45, 200 and 460 kDa) at N/P ratio 8, 16, 32 and 64 are shown in Figure 16. MW of CS did not significantly affect the particle size and zeta potential. The zeta-potential of all CS-H/siRNA complexes slightly increased toward positive charge with an increasing N/P ratio. At the N/P ratio 8 and 16, the complexes had negative surface charge, whereas the complexes at N/P ratio 32 and 64 had neutral to slightly positive surface charge. The particle sizes of all complexes were in nanometer (less than 500 nm).

1.2.2 The particle size and zeta-potential of the CS-L/siRNA complexes

The particle size and zeta-potential of the CS-L/siRNA complexes of various MW (20, 45, 200 and 460 kDa) at N/P ratio 8, 16, 32 and 64 are shown in Figure 17. MW of CS did not significantly affect the particle size and zeta potential. The zeta-potential of all CS-L/siRNA complexes slightly increased toward positive charge with an increasing N/P ratio. At the N/P ratio 8 and 16, the complexes had negative surface charge. Whereas the complexes at N/P ratio 32 and 64 had neutral to slightly positive surface charge. The particle sizes of all complexes were in nanometer (less than 600 nm).

1.2.3 The particle size and zeta-potential of the CS-A/siRNA complexes

The particle size and zeta-potential of the CS-A/siRNA complexes of various MW (20, 45, 200 and 460 kDa) at N/P ratio 8, 16, 32 and 64 are shown in Figure 18. MW of CS did not significantly affect the particle size and zeta potential. The zeta-potential of all CS-A/siRNA complexes slightly increased toward positive charge with an increasing N/P ratio. At the N/P ratio 8 and 16, the complexes had negative surface charge. Whereas the complexes at N/P ratio 32 and 64 had neutral to slightly positive surface charge. The particle sizes of all complexes were less than 500 nm except the CS-A/siRNA complexes at N/P ratio 16 of CS MW 460 kDa was 879 nm.

1.2.4 The particle size and zeta-potential of the CS-G/siRNA complexes

The particle size and zeta-potential of the CS-G/siRNA complexes of various MW (20, 45, 200 and 460 kDa) at N/P ratio 8, 16, 32 and 64 are shown in Figure 19. MW of CS did not significantly affect the particle size and zeta potential. The zeta-potential of all CS-G/siRNA complexes slightly increased toward positive charge with an increasing N/P ratio. At the N/P ratio 8 and 16, the complexes had negative surface charge. Whereas the complexes at N/P ratio 32 and 64 had neutral to slightly positive surface charge. The particle sizes of all complexes were less than 600 nm except for the CS-G/siRNA complexes at N/P ratio 32 of CS MW 20 kDa was 850 nm.

Figure 16 Particle size (◆) and zeta potential (●) of CS-H/siRNA complex of CS various MW (a) MW 20 kDa (b) MW 45 kDa (c) MW 200 kDa and (d) MW 460 kDa at varying N/P ratios.

1.3 Morphology

The morphology of CS/siRNA complexes formed at N/P ratio 16 and 32 using CS-H with MW 20 kDa was studied by atomic force microscopy (AFM). The AFM images revealed that the complexes were spherical shape with size in nanometer and heterogeneity (Figure 20 A-B).

Figure 20 A The planar and three-dimensional AFM images of complexes between CS-H MW 20 KDa and siRNA at N/P ratio 16 (a) planar images; (b) three-dimensional image.

Figure 20 B The planar and three-dimensional AFM images of complex between CS-H MW 20 KDa and siRNA at N/P ratio 32 (a) planar images; (b) three-dimensional image.

1.4 *In vitro* transfection

To investigate the CS salts mediated *in vitro* siRNA transfection efficiency, siRNA transfection assay was performed in HeLa cells stable expressing green fluorescent protein (EGFP). The inhibition of GFP gene expression level was affected by transfection of CS/siRNA complexes into the stable cells. We measured EGFP expression by using Fusion Force Microscope Analyzer. Polyethyleneimine (PEI, 25 KDa) was used as a positive control. In this study, the factors including salt

form, MW and N/P ratio affecting on *in vitro* transfection efficiency were investigated.

1.4.1 Effect of CS MW and N/P ratio

1.4.1.1 CS-H

CS-H/siRNA complexes were formulated with CS-H of various MWs (20, 45, 200 and 460 kDa) in order to investigate the effect of MW on gene silencing efficiency. The gene silencing efficiencies of CS-H/siRNA complexes are shown in Figure 22. The gene silencing efficiencies of CS-H with MW 20, 45, 200 and 460 kDa were 41.2 ± 0.9 %, 23.4 ± 0.1 %, 14.6 ± 0.5 % and 24.3 ± 0.8 %, respectively. The complex formed by each MW of CS-H at various N/P ratios gave comparable gene silencing efficiency. The gene silencing efficiency of the CS-H/siRNA complexes had a tendency to decrease as the N/P ratio increased. The low MW of CS-H showed higher gene silencing efficiency than the high MW of CS-H. CS-H MW 460 kDa gave the similar gene silencing efficiency to CS-H MW 45 kDa. The maximum gene silencing efficiency was found in different N/P ratios studied. The CS-H/siRNA complexes of MW 20, 45, 200 and 460 kDa showed maximum gene silencing efficiency at N/P ratios of 8, 8, 16 and 8, respectively.

Figure 21 Effect of MW of CS and N/P ratio of CS-H/siRNA complexes on gene silencing efficiency in HeLa stable cells (n=4).

1.4.1.2 CS-L

CS-L/siRNA complexes were formulated with CS-L of various MWs (20, 45, 200 and 460 kDa) in order to investigate the effect of MW on gene silencing efficiency. The gene silencing efficiencies of CS-L/siRNA complexes are shown in Figure 23. The maximum gene silencing efficiencies of CS-L with MW 20, 45, 200 and 460 kDa were $17.0 \pm 5.1\%$, $12.4 \pm 4.4 \%$, $6.9 \pm 1.6 \%$ and $13.0 \pm 3.4 \%$, respectively. The complex formed by each MW of CS-L at various N/P ratios gave comparable gene silencing efficiency.

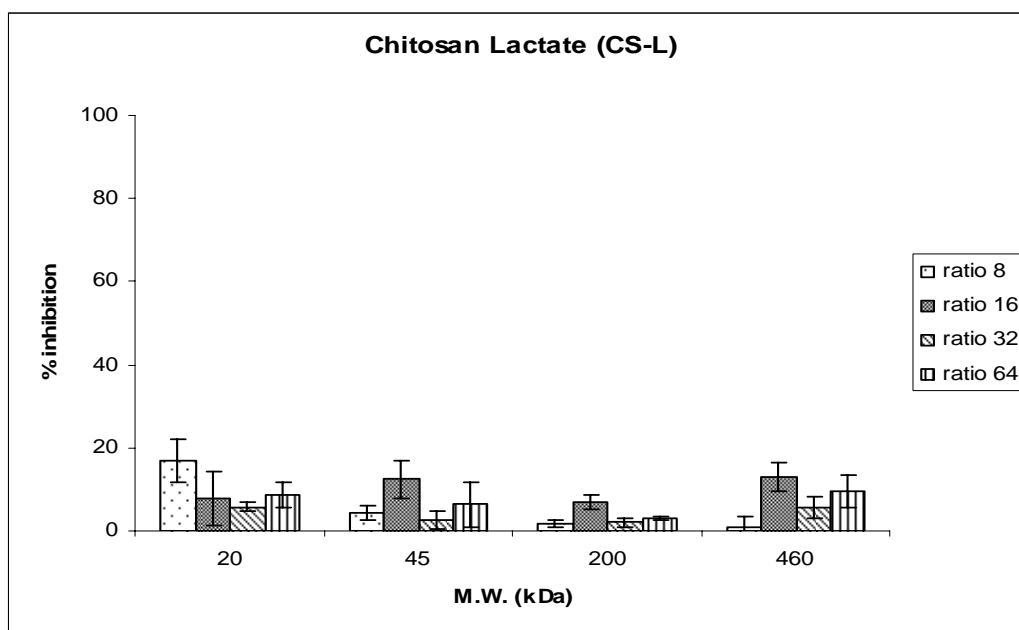

Figure 22 Effect of MW of CS and N/P ratio of CS-L/siRNA complexes on gene silencing efficiency in HeLa stable cells (n=4).

1.4.1.3 CS-A

CS-A/siRNA complexes were formulated with CS-A of various MWs (20, 45, 200 and 460 kDa) in order to investigate the effect of MW on gene silencing efficiency. The gene silencing efficiencies of CS-A/siRNA complexes are shown in Figure 24. The maximum gene silencing efficiency of CS-A/siRNA complexes were ranked as CS-A 20 kDa ($48.8\% \pm 2.3$) > 45 kDa ($42.8\% \pm 1.6$) > 200 kDa ($12.7\% \pm 3.1$) > 460 ($6.8\% \pm 2.1$) kDa. The gene silencing efficiency had a tendency to increase as the N/P ratio increased. All MW of CS-A had maximum gene silencing efficiency at N/P ratio 64, except for MW 200 kDa had maximum gene silencing efficiency at N/P ratio 16.

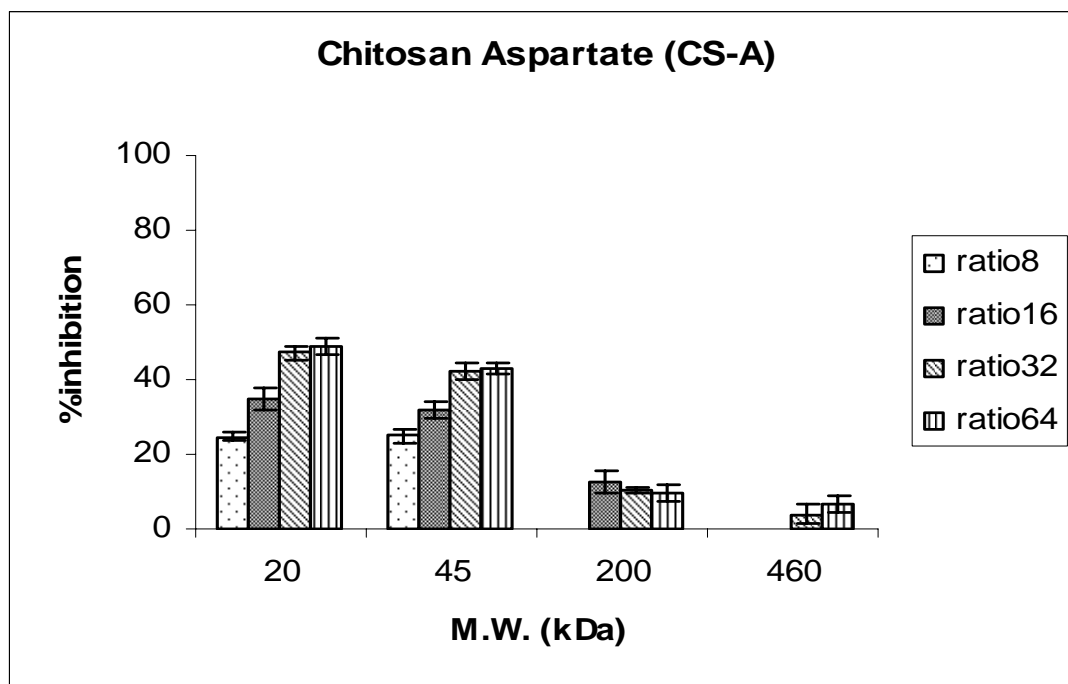

Figure 23 Effect of MW of CS and N/P ratio of CS-A/siRNA to gene silencing efficiency in HeLa stable cells (n=5).

1.4.1.4 CS-G

CS-G/siRNA complexes were formulated with CS-G of various MWs (20, 45, 200 and 460 kDa) in order to investigate the effect of MW on gene silencing efficiency. The gene silencing efficiencies of CS-G/siRNA complexes are shown in Figure 25. The gene silencing efficiency of CS-G/siRNA complexes were ranked as CS-G 20 kDa ($24.8\% \pm 1.5$) > 200 kDa ($20.0\% \pm 2.7$) > 460 kDa ($17.2\% \pm 1.5$) > 45 ($13.4\% \pm 4.2$) kDa. The gene silencing efficiency had a tendency to increase as the N/P ratio increased. All MW of CS-G had maximum gene silencing efficiency at N/P ratio 64.

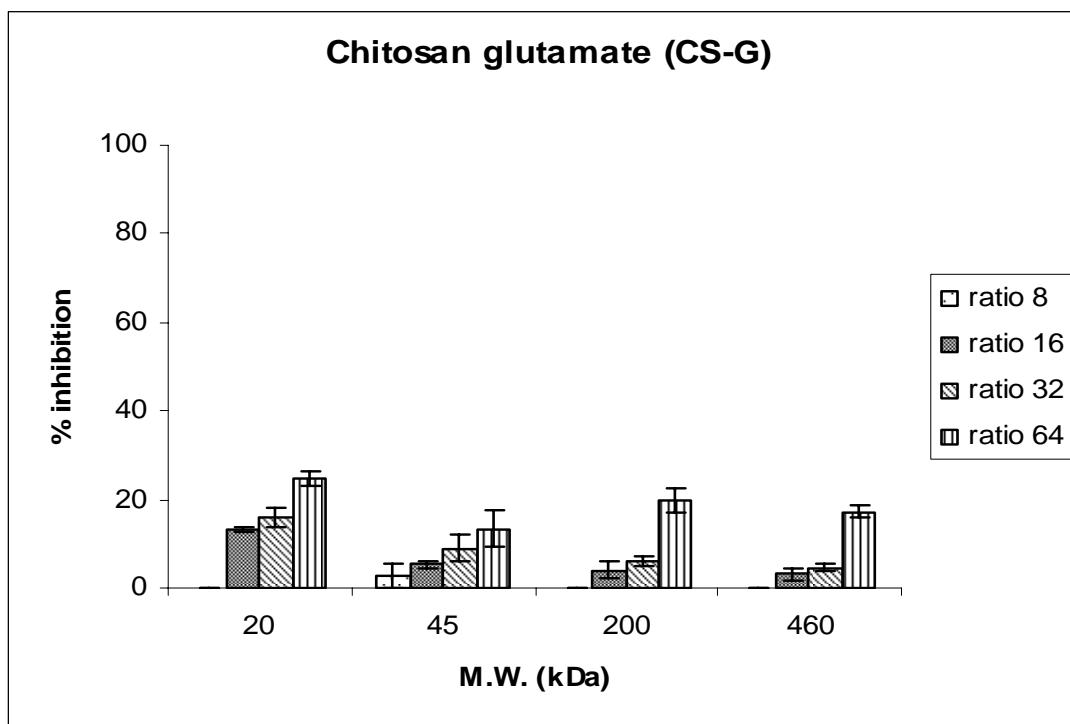

Figure 24 The effect of MW of CS and N/P ratio of CS-G/siRNA to gene silencing efficiency in HeLa stable cells (n=5).

1.4.2 The effect of chitosan salt form

In order to investigate the effect of salt form of CS on transfection efficiency, the CS/siRNA complexes were formulated with CS MW 20 kDa of 4 salt form including CS-H, CS-L, CS-A and CS-G at N/P ratio of 8, 16, 32 and 64. PEI was used as a positive control. The gene silencing efficiency of CS/siRNA complexes and PEI/siRNA complexes were shown in Figure 21. The maximum gene silencing efficiency of PEI/siRNA complexes at an N/P ratio of 32 was $31.7 \pm 1.1\%$. The maximum gene silencing efficiency of each CS salt was found in different N/P ratios.

CS-H/siRNA, CS-L/siRNA, CS-A/siRNA and CS-G/siRNA complexes showed maximum gene silencing efficiencies at N/P ratios of 8 ($34.2 \pm 0.5\%$), 16 (14.6 ± 1.5), 64 (32.4 ± 4.7) and 64 (25.8 ± 1.1), respectively. The gene silencing efficiency of CS-H and CS-L tended to decrease when increasing N/P ratio. On the other hand, the gene silencing efficiency of CS-A and CS-G increased when increasing N/P ratio.

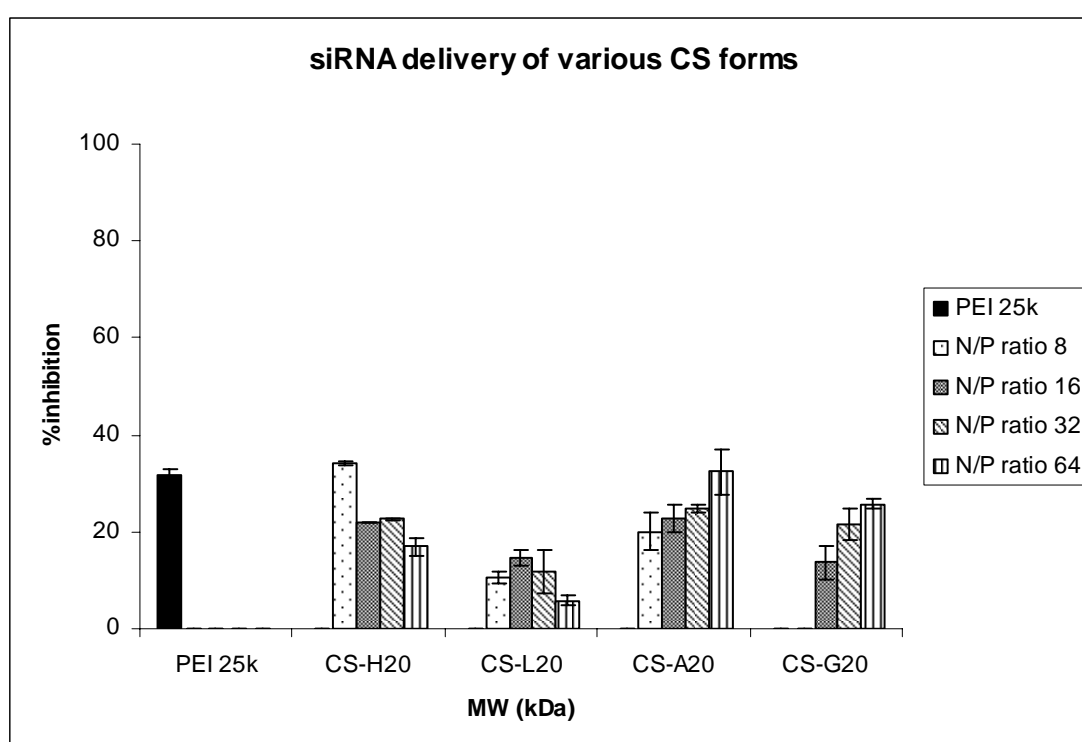

Figure 25 Percentage of GFP inhibition of CS/siRNA complexes formulated with CS MW 20 kDa of different salts in HeLa stable cells. Each value represents the mean \pm S.D. of four wells.

1.5 Effect of chitosan/siRNA complexes on cell viability

A cytotoxicity assay was performed in order to evaluate the potential of CS as a vector for a safe gene delivery. Therefore, the cytotoxicity of CS-H/siRNA, CS-L/siRNA, CS-A/siRNA and CS-G/siRNA complexes at various N/P ratios was examined in HeLa stable cells. The cell viability was determined by MTT assays. Cells without treatment of the CS/siRNA complexes were considered as a control with a cell viability of 100%. The effect of CS/siRNA complexes with various CS salts, MW and N/P ratios on cell viability were shown in Figure 26-29. Over 90% average cell viability was observed for CS-H/siRNA complexes. Over 80% average cell viability was observed for CS-L/siRNA complexes. Over 75% average cell viability was observed for CS-A/siRNA and CS-G/siRNA complexes. On the other hand, the PEI 25 K/siRNA complexes have over 34% average cell viability was observed at N/P ratio 32 (Figure 30). The results showed that all CS/siRNA complexes formulated with various CS and MW were less toxic than PEI 25 K/siRNA complexes at N/P ratio 32.

Figure 26 Effect of CS-H/siRNA complexes formulated with CS-H of different MWs (20, 45, 200 and 460 kDa) on HeLa stable cell viability (* indicated that complexes showed a significant difference from the untreated cell $p < 0.05$).

Figure 27 Effect of CS-L/siRNA complexes formulated with CS-L of different MWs (20, 45, 200 and 460 kDa) on HeLa stable cell viability (* indicated that complexes showed a significant difference from the untreated cell $p < 0.05$).

Figure 28 Effect of CS-A/siRNA complexes formulated with CS-A of different MWs (20, 45, 200 and 460 kDa) on HeLa stable cell viability (* indicated that complexes showed a significant difference from the untreated cell $p < 0.05$).

Figure 29 Effect of CS-G/siRNA complexes formulated with CS-G of different MWs (20, 45, 200 and 460 kDa) on HeLa stable cell viability (* indicated that complexes showed a significant difference from the untreated cell $p < 0.05$).

Figure 30 Effect of PEI 25k/siRNA complexes at various N/P ratio on HeLa stable cell viability (* indicated that complexes showed a significant different from the untreated cell $p < 0.05$).

2. Discussion

Binding of siRNA with 4 CS salt forms (CS-H, CS-L, CS-A and CS-G) and 4 MW (20, 45, 200 and 460) was investigated by gel retardation assay in 2% agarose. The migration of CS/siRNA complexes were slow down as compared to the migration of the unbound siRNA due to the size enlargement and the negative charge reduction.

Salt form and MW of CS have some effect on the interaction with siRNA. For example, CS-H with MW 20 started binding to siRNA at N/P 8 whereas CS-A with MW 20 of all N/P ratio showed no binding to siRNA. Moreover, the same CS salt with different MW start forming stable complex at different N/P ratio. For example, CS-H MW 20, CS-H MW 45, CS-H MW 200 and CS-H MW 460 showed initial binding to siRNA at N/P ratio of 8 (Figure 12a, Lane 5), 16 (Figure 12b, Lane 6), 4 (Figure 12c, Lane 4) and 32 (Figure 12d, Lane 7), respectively.

The complexes of CS/siRNA in this experiment run through 2% agarose gel as smear bands whereas the complex of CS/plasmid which remain in the well. Moreover, CS with all MW and salt forms show no binding with siRNA at N/P ratio lower than 4 indicating that siRNA required large number of CS to compact into stable complexes. This was contrary to plasmid that formed complete complex with CS at N/P ratio as low as 3 to 5. (Weecharangsan et al. 2008 : 161-168) The short length (21 bp) and the linearity of siRNA might explain the difference. This observation is in agreement with previous studies by Katas et al. and Liu et al. (Katas and Alpar 2006 : 216-225 ; Liu et al. 2007 : 1280-1288)

The effective diameters and zeta-potential of complexes formed by siRNA and various CS salt forms, MW and N/P ratios were measured. The zeta-potential of all complexes was found to increase with an increasing N/P ratio (Figure 16-19). The

increment was due to the increase in the number of positive charges which counteracts with negative charged of siRNA as the amount of siRNA was fixed. The increase in zeta-potential of CS/siRNA complexes with increasing N/P ratio or concentration of CS was also observed by Katas et al. (Katas 2006 : 216-225) A positive surface charge of complexes is necessary for binding to anionic cell surfaces by electrostatic interaction, consequently facilitating uptake of the complexes by cell. (Harush-Frenkel 2007 :26-32) While the size of all CS/siRNA complexes were in the nanometer range that had a relatively higher intracellular uptake compared to micrometer range. (Zauner 2001 : 39-51) Study in DNA, nanoparticles was advantageous in gene transfer because of enhancement of cellular uptake of the CS/DNA complexes and facilitating its subsequent release from the endo-lysosome pathway. Similar to DNA, it appeared that fine balance between the two steps of siRNA complex can enhance transfection efficiency. (Huang 2005 : 391-406)

The planar and three dimensional figure of the complexes formed by siRNA and CS-H with MW 20 at N/P ratio 16 and 32 were illustrated by AFM image (Figure 20A and 20B). The complexes were in nanometer range with size heterogeneity corresponding to the result of particle size measurement and the gel retardation assay. The complex with N/P ratio 16 showed relatively larger and less compact than the complex with N/P ratio 32 implying that siRNA bind CS looser at lower N/P ratio. The less condense complex that show weak interaction between siRNA and CS may result in better release of siRNA in the cytosol. This might partially explain the higher gene silencing activity of CS-H/siRNA complex formed at low N/P ratio (Figure 21).

Transfection of complexes of siRNA targeting EGFP gene and various CS into HeLa stable cells line expressing green fluorescent protein (EGFP) was used to

investigate the gene silencing efficiency of the various CS/siRNA complexes. The MW and N/P ratio of CS/siRNA complexes was one of the important formulation parameters that affect transfection efficiency. In the study of the effect of MW on gene silencing efficiency, CS-H/siRNA, CS-A/siRNA and CS-G/siRNA complexes of low MW chitosan of 20 kDa gave higher transfection efficiencies than the complexes of high MW chitosan of 45, 200 and 460 with an exception of CS-L. (Figure 21, 22, 23 and 24) This could be due to these low MW of CS provided an efficient balance between appropriate protection (association at outer cell) and release (dissociation at inside cell), resulting in high in vitro gene silencing efficiency. The short chain of low MW CS resulted in loose binding siRNA, therefore siRNA could escape the endosomal vesicle into the cytosol where RNAi occurred. This observation was in agreement with previous study by Liu et al. (Liu et al. 2007 : 1280-1288) It was not clear why the complexes of all lactate salts showed very low gene silencing efficiency. The only explanation could be the impurity and solubility of CS-L as gel forming was observed during the complex formation step.

The gene silencing efficiency of CS-A/siRNA and CS-G/siRNA complexes increased when increasing N/P ratio. This might be because of the larger amount of CS at higher N/P ratios yields a higher amount of positively charged complexes to successfully transfect cells. This observation was in agreement with the previous studies. The gene silencing efficiency increased at high N/P ratios (Liu et al. 2007 : 1280-1288) whereas the CS-H/siRNA complexes showed that the N/P ratio did not significantly influence the gene silencing efficiency. However, the reason for this result was not clear.

The acids used to form CS in this study can be classified into two groups; strong acid (hydrochloric acid, 100% dissociation) and weak acid (glutamic acid, pK_a 4.25 and lactic acid, pK_a 3.86 and aspartic acid, pK_a 3.65). The maximum gene silencing efficiency of each CS salt was found in different N/P ratios. CS-H/siRNA, CS-L/siRNA, CS-A/siRNA and CS-G/siRNA complexes showed maximum gene silencing efficiencies at N/P ratios of 8, 16, 64 and 64, respectively. (Figure 25) This might be resulted by the difference structure of counter ions of each salt forms that give steric hindrance to siRNA binding to CS backbone. The CS-H/siRNA complexes showed maximum gene silencing at N/P ratios less than the CS-A/siRNA complexes and the CS-G/siRNA complexes because a hydrochloric ion is smaller than an aspartic and a glutamic ion.

A good gene carrier should have low or no cytotoxicity. In this study, a standard MTT assay was used to test for cell toxicity. In principle, MTT was changed to a formazan complex by a reductase enzyme in mitochondria of a viable cell. The amount of solubilized formazan complex measured by spectrophotometry was corresponded to the number of viable cell. The cytotoxicity of cationic polymer was probably caused by polymer aggregation on cell surfaces. This impaired the important membrane function. (Jiang et al. 2007 : 273-280) The CS-H/siRNA complexes showed lower cytotoxicity than the CS-L/siRNA, CS-A/siRNA and CS-G/siRNA complexes (Figure 26-29). The difference in cytotoxic level of complexes of each salt form leave no explanation since all salt forms were naturally found inside a cell. The complexes of all CS salt forms had lower cytotoxicity than the complex of PEI 25 K (Figure 30). This might be the result of biodegradable property of CS that lead to lower cytotoxicity. (Wong et al. 2006 : 152-158)

CHAPTER V

CONCLUSIONS

The CS salt forms were successfully used for improve solubility of CS. These CS salt forms were used to assess their gene silencing efficiency and cytotoxicity on HeLa stable cells. The effect of MW, N/P ratio and type of salt form of CS on silencing efficiency and cytotoxicity were determined. The resulted of this study could be concluded as follow:

1. Physiochemical properties of CS/siRNA complexes

1.1 Complex formation of CS salt forms

Gel retardation illustrated that CS salt forms were able to form complex with siRNA. MW and salt forms of CS affected the started binding between CS and siRNA at different N/P ratio; CS-H 20 N/P ratio 8, CS-H 45 N/P ratio 16, CS-H 200 N/P ratio 4, CS-H 460 N/P ratio 4, CS-L 20 N/P ratio 32, CS-L 45 no retardation, CS-L 200 N/P ratio 8, CS-L 460 no retardation, CS-A 20 no retardation, CS-A 45 N/P ratio 8, CS-A 200 N/P ratio 4, CS-A 460 N/P ratio 4, CS-G 20 N/P ratio 32, CS-G 45 N/P ratio 8, CS-A 200 N/P ratio 64 and CS-G 460 no retardation.

Particle size and surface charge of the CS/sRNA complexes

The CS salt forms can form complex with siRNA in nano size range. The zeta potential of all complexes at N/P ratio 32 and 64 were neutral to slightly positively surface charge.

1.2 Morphology by AFM

The morphology of CS-H/siRNA complexes at N/P ratio 16 and 32 was determined by using AFM. The AFM image showed that the complexes were spherical in shape and nano size range.

2. *In vitro* gene silencing efficiency

2.1 N/P ratio

The gene silencing efficiency of CS/siRNA complexes was significantly influenced by N/P ratio. By increasing N/P ratios, gene silencing efficiency of the CS-A/siRNA and CA-G/siRNA complexes had a tendency to increase. Whereas the gene silencing efficiency of the CS-H/siRNA and CS-L/siRNA complexes had a tendency to decrease as the N/P ratio increased.

2.2 Effect of Molecular weight

The gene silencing efficiency of CS/siRNA complexes was significantly influenced by MW of CS. CS-H, CS-A and CS-G showed that low MW CS (20 kDa) gave a higher gene silencing efficiency than at high MW of CS. Whereas MW of CS-L was not affected gene silencing efficiency.

2.3 Effect of salt form

The gene silencing efficiency of CS/siRNA complexes was significantly influenced by type of CS salt form. The maximum gene silencing efficiency was ranked as CS-H ~ CS-A > CS-G > CS-L.

3. Cytotoxicity

The cytotoxicity of CS/siRNA complexes can be ranked as CS-H/siRNA < CS-L/siRNA < CS-A/siRNA ~CS-G/siRNA < PEI 25 K.

BIOGRAPHY

NAME Sirirat Wongkupasert, Miss

DATE of BIRTH 9 November 1979

PLACE OF BIRTH Bangkok, Thailand

INSTITUTION ATTENDED

Silpakorn University, 1999 – 2003 :

Bachelor of Science (Biology)

Silpakorn University, 2006- 2008 :

Master of Pharmacy (Biopharmaceutical sciences)

PRESENTATION

1. **Sirirat Wongkupasert**, Sunee Techaarpornkul, Auayporn Apirakaramwong, Praneet Opanasopit, Jurairat Nunthanid. Characterization of lipofectamine and polyethylenimine-mediated siRNA delivery in vitro. 23th Annual meeting of the faculty of pharmaceutical sciences Chulalongkorn University and JSPS 1st Medicinal chemistry seminar of asia/africa scientific program December 14-15, 2006; Bangkok, Thailand.
2. Praneet Opanasopit, **Sirirat Wongkupasert**, Sunee Techaarpornkul, Auayporn Apirakaramwong, Jurairat Nunthanid. Chitosan-Mediated siRAN Delivery in Vitro: Effect of Polymer Molecular Weight and Salt Forms. 34th Annual meeting of the controlled release society July 7-11, 2007; Long Beach Convention Center, Long Beach, California, USA.
3. **Sirirat Wongkupasert**, Sunee Techaarpornkul, Praneet Opanasopit, Auayporn Apirakaramwong, Jurairat Nunthanid and Uracha Ruktanonchai

“Chitosan lactate as siRNA delivery in stable and constitutive EGFP-expressing cells” Proceedings of the 5th Pharma-Indochina conference in Pharmacy for sustainable development, November 21-24, 2007 Bangkok, Thailand.

4. Praneet Opanasopit, Sunee Techaarpornkul, **Sirirat Wongkupasert**, Auayporn Apirakaramwong, Jurairat Nunthanid and Mitsuru Hashida. Galactosylated chitosan for siRNA delivery in stable constitutive eGFP-HepG2 cells. 3rd Asian association of Schools of pharmacy (AASP) conference October 25th-28th 2007 at the Renaissance Makati City Hotel, Makati City, Philippines.
