THESIS

EFFECTS OF WATER TO BINDER RATIO AND SLAG FINENESS  
ON THE PROPERTIES OF SLAG MORTAR

The logo of Kasetsart University is a large, light green circular emblem. It features a central figure, likely a deity or a personification of knowledge, surrounded by intricate patterns. The text "KASETSART UNIVERSITY" is written in a semi-circle at the top, and "1943" is at the bottom. Two small floral motifs are positioned on the left and right sides of the emblem.

Muhammad Ilyas 2011: Effects of Water to Binder Ratio and Slag Fineness on the Properties of Slag Mortar. Master of Engineering (Civil Engineering), Major Field: Civil Engineering, Department of Civil Engineering.  
Thesis Advisor: Associate Professor Prasert Suwanvitaya, Ph.D. 97 pages.

This research addresses the compressive strength and porosity when granulated blast-furnace slag (GBFS) was used as a supplementary cementitious material (SCM) to make mortar, and discusses in detail the parameters affecting the compressive strength and porosity of mortar cubes and pastes, respectively. The effects of fineness, water-binder ratio, replacement percentage, curing methods and age on the strength and porosity, and hydration products of mortars containing GBFS were studied. The cubes were conventionally-cured and steam-cured to correlate between curing methods and eventually their effects on compressive strength and porosity of mortars. The results showed that finer GBFS had the higher value of compressive strength and lower porosity when steam-cured ones. The increase in water-binder ratio reduced the strength and increased the porosity of mortars as expected.

## ACKNOWLEDGEMENTS

I am greatly indebted and grateful to my supervisor Dr. Prasert Suwanvitaya who provided me with the opportunity to work with him and guide me throughout my whole research. His impeccable guidance, continuous encouragement and great patience constituted into the most essential foundation of this thesis. I am also grateful to Dr. Trakool Aramraks for his useful suggestions and help throughout the development of this research thesis at the International Graduate Program of Civil Engineering, Kasetsart University.

I also appreciate the financial support from the Thailand International Development Cooperation Agency (TICA) who sponsored my research. Sincere thanks to the In-charge Research and Development Department, at the Pakistan Steel for extending all assistance during the procurement of granulated blast-furnace slag. Sincere thanks to the Chairman of Department of Civil Engineering, NED University of Engineering and Technology, Karachi, Pakistan for all of their assistance during the experimental work.

Finally, I owe the most to my family, especially to my parents for being the driving force, support and inspiration during my educational endeavors, continuously providing me their support and kind encouragement. Every small success of me is attributed to them and every compliment from them always adds to my strength for my aspirations.

Muhammad Ilyas

# **EFFECTS OF WATER TO BINDER RATIO AND SLAG FINENESS ON THE PROPERTIES OF SLAG MORTAR**

## **INTRODUCTION**

The dominant role of Portland cement is slowly decreasing in the favor of additives and composite cements. The future lies in the combinations of different binders into more durable and controllable systems thereby trying to making concrete less expensive.

The first recorded production of Portland blast-furnace slag cement dates back to 1892 in Germany and in 1896 in the US. Since its introduction in 1982, the production and marketing of granulated blast furnace slag (GBFS) has grown multifold in the United States. In Pakistan also since 1987, granulated blast furnace slag (GBFS) has been used as a supplementary cementitious material (SCM) in cement concrete (Hussain 1987). Presently there are quite a few cement producers in Karachi who are also producing ASTM Type I plus blast furnace slag (BFSC), alongside other types of cements.

Blast-furnace slag is produced when iron ore is reduced by coke at 1350-1550 °C in a blast-furnace. Main product of blast-furnace is molten iron, which is formed from iron ore, whereas the other components form a liquid slag. Liquid slag flowing on its way to the bottom of the furnace forms a layer above the molten iron, which is then separated and put for cooling by air or by water. 65 % of all the steel manufactured worldwide comes from the blast furnaces/LD converter while the remaining 35 % is produced by the electric furnace process. From three main categories of blast-furnace slag viz., granulated, pelletized and air-cooled, ground GBFS is the most valuable one due to its cementitious properties when mixed with lime, alkalis or Portland cement.

ASTM C 219-94 provides the following definition: ‘the glassy granular material formed when molten blast-furnace slag is rapidly chilled, as by immersion in water—with the following items under the heading of Discussion: Granulation may be achieved by quenching blast-furnace slag from its original molten state or by

quenching air-cooled blast-furnace slag after smelting. Also small percentage of silica and alumina may be added whilst the slag is molten to enhance desired characteristics.’

ASTM C989 provides the specification for granulated blast furnace slag wherein it specifies three grades as specified by their strength: grade 120, grade 100 and grade 80. Grade 120 provides the highest strength among these. ASTM C595 provides specification for the use of granulated blast furnace slag in blended cements either by intergrinding with Portland cement clinker or by blending Portland cement with granulated blast furnace slag (GBFS), or a combination of blending and intergrinding. The American Association of State Highway and Transportation Officials equivalent specification of the same name as ASTM is AASHTO M302, and ASTM C595 equivalent is AASHTO M240.

Granulated blast furnace slag (GBFS) typically replaces 25-70% Portland cement in concrete as per ASTM standards. Table 1 shows the replacement levels for various concrete applications suggested by the Slag Cement Association. The percentages basically show the replacement level of Portland cement by mass and are based on the historical performance. This means that a 50% replacement of each ton of Portland cement would result into a reduction of nearly 0.5 million tons of CO<sub>2</sub>.

**Table 1** Suggested slag cement replacement level.

Concrete Application	Slag Cement
Concrete Paving	25-50%
Exterior flatwork not exposed to deicer salts	25-50%
Exterior flatwork exposed to deicer salts with $w/cm \leq 0.45$	25-50%
Interior flatwork	25-50%
Basement floors	25-50%
Footings	30-65%
Walls and columns	25-50%

**Table 1 (Continued)**

Concrete Application	Slag Cement
Tilt-up panels	25-50%
Prestressed concrete	20-50%
Precast concrete	20-50%
Concrete blocks	20-50%
Concrete pavers	20-50%
High strength concrete	25-50%
Alkali-silica reaction mitigation	25-70%
Sulfate resistance	
Type II Equivalence	25-50%
Type V Equivalence	50-65%
Lower permeability	25-65%
Marine exposure	25-70%
Mass concrete (heat mitigation)	50-80%

**Source:** Slag Cement Association (2002)

Ample research has been conducted which concludes that blast furnace slag can be used as a replacement for cement in concrete and mortar. Research conducted shows that up to 65% (by weight) of cement can be replaced by granulated blast furnace slag; thereby the construction industry can further benefit from its utility on a commercial scale in developing countries.

Blast furnace slag comprises of silicates, the alumina silicate of lime, a minor percentage of ferric and manganese oxide and sulfur. In terms of chemical composition, slag has the same oxides as Portland cement such as lime, silica and alumina but with different proportions. The typical percentage of blast furnace slag is as follows:

1. Calcium Oxide	36 - 40%
2. Silica	36 - 39%
3. Alumina	14 - 16%
4. Magnesium Oxide	9% max
5. Manganese Oxide	1.3% max
6. Sulfur	1.5% max

These days the cement along with other construction materials are becoming more and more expensive, out of the buying power of poor and middle-class citizens in Pakistan, and elsewhere in the world. As cement is the main expensive component of concrete and mortar generally, its partial replacement with pozzolan becomes reasonable for the low-cost housing schemes in the developing countries.

Prusinski *et al.* (2004) reported as part of a study that comparing the energy utilized in the production of a ton of Portland cement with a ton of slag cement (at least 70 % GBFS as replacement) showed 86 % reduction in energy when slag cement is to be produced. Similarly, 98 % reduction in CO<sub>2</sub> emissions and 93 % reduction in the utilization of virgin materials were reported. Table 2 shows the achievable percentage reductions on usage of 35 and 50% slag cement in all kinds of concrete from 3000 psi to 7500 psi strength, with virgin material reduced up to 15 %, energy up to 37 %, and CO<sub>2</sub> emissions up to 46 %.

From the environmental sustainability point of view, cement manufacturing is the next largest industrial producer of CO<sub>2</sub> after vehicle and utility emissions, and 50% of all industrial CO<sub>2</sub> emissions. In fact, 7.7 billion metric tonnes per year i.e., 88% of the carbon emissions come from fossil-fuels and cement industry combined. For every ton of cement manufactured in the industry, 1 to 1.25 tons of CO<sub>2</sub> are produced through the cement manufacturing. One of the solutions for minimizing the environmental effects of cement production is to use a supplementary cementitious material (SCM) in concrete.

**Table 2** Reductions in embodied energy, CO<sub>2</sub> emissions, and virgin material use in concrete using slag cement.

Item	3000 psi ready mixed concrete		5000 psi ready mixed concrete		7500 psi ready mixed concrete		Concrete Block	
	35 %	50 %	35 %	50 %	35 %	50 %	35 %	50 %
	Slag	Slag	Slag	Slag	Slag	Slag	Slag	Slag
Virgin material	4.80	6.80	6.80	9.80	10.30	14.60	4.30	6.30
Energy	21.10	30.20	23.50	33.70	25.70	36.50	19.90	28.60
CO <sub>2</sub> emissions	30.10	42.90	31.20	44.70	32.30	46.10	29.20	42.00

The calcinations process has the following reaction:

### Statement of Problem

Roy et al. (1986), Binici et al. (2007) and Oner et al. (2007) have reported that the early-age compressive strength values of GBFS-blended concrete mixes are lower than the control mixes, but the long-term compressive strength of GBFS-blended cement concretes is higher than the control mixes. Slag cement is being used in private and state-owned massive construction projects across Pakistan like in the canals of Ghazi Barotha Hydropower Project, mainly due to its low heat of hydration property. However, in recent times its production has slowed down almost to a halt due to its lack of durability in aggressive environment (Khan, 2009). Therefore, the long-term strength parameter needs to be studied to check the ASTM C 989 criteria for strength activity index.

Temperature is a significant factor during a curing regime which enormously effects the strength development of mortar. In precast construction, sometimes the acceleration of strength development is intentionally desired so that the structural elements gain ample strength in order to sustain their self weight. Consequently formwork can be shifted to another location thereby improving the construction management. One of the ways of making this possible is by raising the temperature of the curing regime (Neville, 1997).

## OBJECTIVES

The objectives of this study are as follows:

1. To determine the effect of grinding of GBFS on the strength and porosity of mortar.
2. To determine the effect of water-binder ratio on GBFS mortar for fixed workability.
3. To investigate the effect of partial replacement of cement with GBFS (20, 40, 60%) on the compressive strength of cubes with time.
4. To correlate between accelerated strength and strength gained at later age from conventional curing method.
5. To investigate the porosity parameters of pastes with and without GBFS using Mercury Intrusion Porosimetry (MIP).
6. To study the phase composition of the GBFS-blended cement mortar, and compare with control mix using the X-ray Diffraction (XRD) analysis.

### Scope

Variables for fineness of GBFS were two i.e., two different fineness of GBFS achieved through grinding and measuring by ASTM C204 “Standard Test Method for Fineness of Hydraulic Cement by Air-Permeability Apparatus”, to study their individual effect on parameters of mortar. The workability of GBFS mortar was fixed as per ASTM C1437 “Standard Test Method for Flow of Hydraulic Cement Mortar” and ASTM C109/C 109M “Test Method for Compressive Strength of Hydraulic Cement Mortars (Using 2-in or [50-mm] Cube Specimens)” and the variable were water content. A relationship was made between flow value and water content to achieve the required workability. The number of mortar cubes was 135 in to two groups of curing method. The accelerated temperature curing and the conventional curing were applied to mortar cubes. Variables for the compressive strength is the partial replacement of GBFS and the cubes were tested for compressive strength on 3-

, 7-, 28- and 90-days. The porosity of pastes was studied using mercury intrusion porosimetry (MIP) method. A relationship was also developed between porosity and strength parameters showing the correlation of porosity with the strength of mortar with and without GBFS. X-ray diffraction method is used to study the phase composition of control mix and GBFS-blended mixes.

## LITERATURE REVIEW

### 1. Hydration of Portland cement and slag

The chemical reactions of pure cement compounds have been mentioned clearly before by researchers (Odler *et al.*, 1981). Hydration of tricalcium silicate ( $C_3S$ ) and dicalcium silicate ( $C_2S$ ) produces calcium silicate hydrates, calcium hydroxide (CH) and heat:

Calcium silicate hydrate gel, the main hydration product, does not have a well-defined composition. The formula  $C_3S_2H_3$  is denoted as C-S-H (C=CaO, A=Al<sub>2</sub>O<sub>3</sub>, S=Si<sub>2</sub>O<sub>3</sub>, H=H<sub>2</sub>O). Tricalcium aluminate reacts with gypsum (CaSO<sub>4</sub>·2H<sub>2</sub>O; CSH<sub>2</sub>) in the presence of water to produce ettringite (AFt; C<sub>3</sub>A·3CaSO<sub>4</sub>·32H<sub>2</sub>O; C<sub>6</sub>AS<sub>3</sub>H<sub>32</sub>) and heat.

Ettringite (AFt) and monosulfate (AFm) are two groups of minerals that occur in cement. Ettringite crystallizes into hexagonal shape, as slender needles with a length up to 10 μm and 0.25 μm in diameter (Stutzman *et al.*, 2001). Once all the gypsum is consumed in reaction (2.3), the ettringite becomes unstable and reacts with the remaining tricalcium aluminate to form monosulfate aluminate hydrate.

Monosulfate crystals are stable only in sulfate-deficient solution.

Ferrite reacts in two different reactions with gypsum. Firstly, ferrite reacts with gypsum and water to form ettringite, lime and alumina hydroxides.

Secondly, ferrite reacts with ettringite to form garnets.

The GBFS when blended with ordinary Portland cement, after ground to the fineness comparable to Portland cement, the two ingredients hydrate at different rates. When water is added, Portland cement in the blended cement hydrates immediately, whereas a small amount of GBFS reacts may be due to gypsum in cement. The hydration of slag is greatly activated by alkalis and later by the Portlandite (CH) released by the hydration of Portland cement. Generally, GBFS hydration is far too low than clinker. After one year, the clinker hydrates about 90-100% whereas the GBFS has hydrated around only 45-75%. Reasons for GBFS's low reactivity are related to hydraulic modulus and fineness (Lumley *et al.*, 1996).

**Table 3** Chemical composition of mineral phases in Portland cement clinker.

<i>Formula</i>	<i>Mass fraction (%)</i>	<i>Name</i>
C <sub>3</sub> S	50-70	Alite
C <sub>2</sub> S	15-30	Belite
C <sub>3</sub> A	5-10	Aluminate
C <sub>4</sub> AF	5-15	Ferrite

**Source:** Taylor (1997)

The main hydration products of pure slags consist of CSH, hydrotalcite (M<sub>5</sub>AH<sub>13</sub>; M=MgO), an iron-containing hydrogarnet, ettringite and some AFm phases. The composition of hydrotalcite is that of natural mineral M<sub>6</sub>ACH<sub>12</sub>. Pure hydrotalcite is difficult to distinguish in hardened cement paste as it is attached to CSH. AFm phases comprises of tetracalcium aluminate hydrate (C<sub>4</sub>AH<sub>13</sub>) and stratlingite (C<sub>2</sub>ASH<sub>8</sub>). If the aluminum content in slag is relatively low or the magnesium content is high, the AFm phases are not formed.

Hydration of GBFS-blended cement is much more complex than ordinary Portland cement due to the fact that two components hydrate simultaneously and interfere with each other. GBFS is activated by the alkalis and CH produced by the hydration of ordinary Portland cement and consumes a large amount of CH as well. The main hydration products of GBFS-blended cement consists of CSH, CH, hydrotalcite, ettringite, and tetracalcium aluminate hydrate.

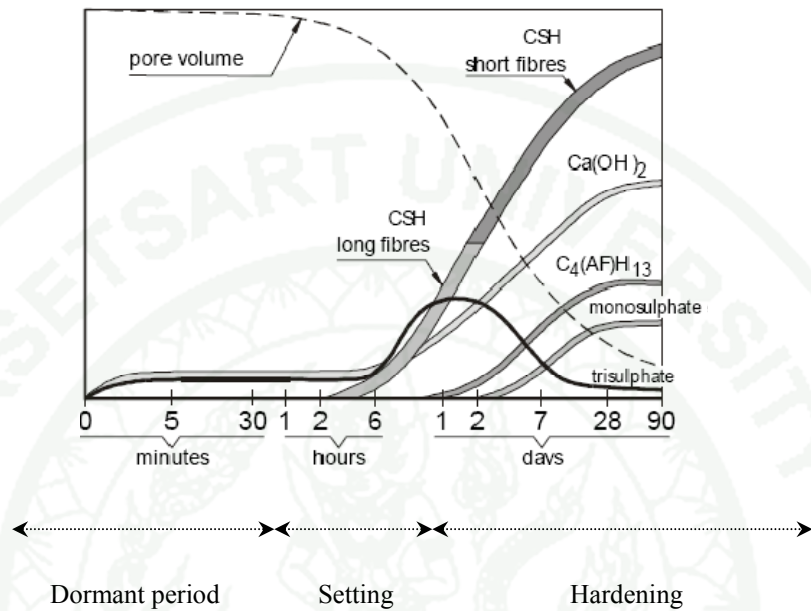

**Figure 1** Stages of ettringite formation (a) First stage: thin layer of ettringite is formed on  $C_3A$  grain, (b) second stage: Ettringite is directly formed on  $C_3A$  grain, (c) third stage: bursting of ettringite layer caused by pressure of crystallization, (d) fourth stage: bursting section is sealed by newly formed ettringite, (e) fifth stage: insufficient sulfate ions to allow formation of ettringite; on further hydration of the  $C_3A$ , ettringite converts to monosulfate.

**Source:** Soroka (1979).

CSH is the most plentiful hydration product whereas CH comes from the hydration of clinker and works together with GBFS hydration to increase the C/S ratio in CSH. The quantity of CH participating in GBFS hydration depends upon the blending proportions of GBFS in the cement. Increasing the GBFS proportions in the cement increases the proportions of CSH in the hydration products (Chen *et al.*, 2006).

**Source:** Soroka (1979).

**Figure 3** Morphology of plate-like CH and fine bundles of type I CSH, type II CSH, and ettringite needles.

**Source:** Stutzman (2001).

## 2. Chemical Analysis

The composition of slag for a wider range of steel-producing countries is: Silica ( $\text{SiO}_2$ ), 27-42%; alumina ( $\text{Al}_2\text{O}_3$ ), 5-33%; CaO, 30-50%; MgO, 0-21%.  $\text{SiO}_2$  and  $\text{Al}_2\text{O}_3$  in GBFS are associated with the ore or present in ash from the coke. The effect of  $\text{Al}_2\text{O}_3$  content was reported to be very complex (Taylor 1997), and so from the analysis of western European GBFSs (Smolczyk 1978), showed that  $\text{Al}_2\text{O}_3$  content above 13% has increased early-strength-effect but lower late strengths. MgO content up to 11% was quantitatively equivalent to CaO. The research from Wang et al. (2004) concluded that 15 % of  $\text{Al}_2\text{O}_3$  content has a positive effect on the reactivity of GBFS, but should not be lower than 10.5% and CaO content at the same time should not be lower than 40% by mass. BS 6699 states a term ‘chemical modulus’ or ‘reactivity index’  $(\text{CaO}+\text{MgO})/\text{SiO}_2$  should be greater than 1.0, which is also reported by Pal et al. (2003) at a maximum of 1.4. Chojnacki *et al.*, (1981) performed tests in Ontario, Canada which showed that low-alumina (7-8%) GBFS with 50:50 combination by mass with ASTM Type I Portland cement is equivalent in sulfate resistance to the ASTM Type V cement.

Loss on Ignition, or LOI, is the percentage of weight that is lost when cementitious material is heated at 950 °C. The main sources of LOI in cement are water from gypsum ( $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ), and  $\text{CO}_2$  from limestone ( $\text{CaCO}_3$ ). LOI for ordinary Portland cement (ASTM Type I) is set at a maximum of 3%.

## 3. Grinding

GBFS varies widely in its grindability but usually it's harder to grind than Portland cement clinker. Ehrenberg (2003) investigated the grinding resistance of GBFS and compared with Portland cement clinker. The study comprises of various factors affecting the grindability of GBFS and reported the variability over a wide range, resulting into effects from the microstructure, the chemical composition and the storage and testing conditions. The factors that partly influence are melt history and the granulation conditions of the blast-furnace slag. GBFS is usually considered

to be hard during grinding procedure thereby utilizes more resources than other cements. Some consider the possibility of intergrinding the clinker with slag which produces cement which has coarser slag and finer clinker. Therefore separate grinding can be a better option over intergrinding. It is said by Swamy *et al.*, (1998) that grinding the GBFS in concrete two to three times finer than ordinary Portland cement would benefit in preserving the engineering properties such as bleeding, setting-time, heat evolution, high strength and excellent durability.

#### 4. Compressive strength

The standard specification details shown in Table 4 describes the composition of all cement produced in Pakistan.

**Table 4** Summary of Standard specifications for cements produced in Pakistan.

Description		Composition			Performance requirement	
Type	Symbol	Clinker + calcium sulfate	Slag %	Fly ash %	Vicat set, minutes	
					IST	FST
Ordinary Portland	P	100			45	600
High strength Portland	HSP	100			45	600
Rapid hardening	RHP	100			45	600
Sulfate resistant	SR-P (A)	100			45	600
	SR-P (B)	100			45	600
White cement	WC	100			45	600
Blast furnace slag	PBLF	≥35	≤65		45	600

**Source:** Young *et al.*, (2004).

The compressive strength of GGBFS initially was slow at 3-days but after 28-days curing, the strength increased and higher long-term strength was obtained as compared to normal PC concrete (Roy *et al.*, 1986). 20% finely granulated blast furnace slag can significantly increase the compressive strength of concrete after 3 days. Whereas combination of 10% finely ground fly ash and 10% finely granulated blast furnace slag can increase the compressive strength of concrete at all ages (Tan *et al.*, 1998).

The compressive strength of all mixes decrease with an increase in water-to-binder ratio at all ages. The mix with 30% GBFS achieve higher strength than the Portland cement concrete and 70% GBFS mix at all ages. The reason is that sufficient quantities of alkalis rapidly hydrated the relatively small quantity of the GBFS (Olorunsogo *et al.*, 1998).

The strength development of mortars incorporating GGBFS and Portland cement has variables such as replacement level of GGBFS in binder, water-binder ratio and curing temperature. The early age strength development of mortars containing GGBFS is highly dependent on curing temperature. Therefore GGBFS mortars usually gain strength more slowly than Portland cement mortars. But at higher temperatures, the gain in strength is much more rapid and significant (Barnett *et al.*, 2006).

It was observed that by increasing the GGBFS content, the water-binder ratio decreases for the same workability, thus GBFS has positive effects on workability. Also the early strength of GGBFS concretes is lower than the control concretes with the same binder content. But if the curing time is extended, the strength increase for the GGBFS concretes compared to control concretes was higher. The reason explained is the pozzolanic reaction is slow and the formation of calcium hydroxide requires time. The compressive strength of GGBFS concrete increases with increase in the GGBFS content up to an optimum level of 55-59 % (Oner *et al.*, 2007). The finer ground blended cements yield superior compressive strength and sulfate resistance than other cement types. The rate of increase of compressive strength of

blended cement is lower than Portland cement in the early ages but increases to higher level at later ages (Binici *et al.*, 2007).

## 5. Accelerated curing

The rise in the curing temperature accelerates the hydration process of concrete and increases the early strength without any adverse effects on its later strength. However, very high temperature may increase the early strength but introduces adverse effects on the later age strength (Neville, 1997).

The rate of increase of strength of concrete under the normal conditions are lethargic and slow therefore to avoid the production rate of concrete plants, it is beneficial to accelerate the hardening process using various methods available at hand. Accelerated curing by temperature has adverse effects on the chloride penetration resistance of concrete; therefore these negative effects can be mitigated using supplementary cementitious materials (SCM) in concrete (Hooton *et al.*, 2004).

Heat treatment cycle is a process of accelerated curing (steam curing) through temperature rise up to a benchmark temperature ( $60 \pm 5$  °C) and then cooled down. The total duration of a usual heat cycle is 12-13 hours. The cycle starts with pretreatment of 2h at around room temperature (23 °C), which is called as the *delay period*, the aim of it is to allow the concrete to achieve the maximum early age strength. It is the time from the casting of concrete to its exposure to steam. After delay period, there is a gradual rise of temperature for 2h. Heating rate of this steam curing stage was 20 °C/h. Then there is a constant temperature zone which is named as treatment with duration of 8h. Afterwards cooling phase follows with one hour duration completing the heat cycle procedure. The relative humidity of the steam-curing box is above 90 % (Lui *et al.*, 2005). Another method of steam curing was adopted by Yazici *et al.*, (2009) for the investigation of mechanical properties of reactive powder concrete containing supplementary cementitious materials such as class-C fly ash and GGBFS. The heating rate for steam curing was 11 °C/h until reached to a maximum temperature of 100 °C for total duration of 3 days. Steam-curing does not affect the physical and chemical properties of the hydration products

of concrete. But some physical causes such as the coefficient of thermal expansion do affect the later-age strength of concrete causing micro-cracking in the paste and at the aggregate-paste interface. Therefore it is said that supplementary wet-curing can avoid these deficiencies and would enhance the later-age strength (Soroka *et al.*, 1978).

Comparison between OPC concrete and Portland BFS cement manufactured in the US shows the values for early-age and 28-days compressive strength in Table 5. Strength values from accelerated curing are similar to that of OPC for concrete w/c ratio of 0.42.

**Table 5** Effect of steam curing on strength of US Portland BFS cement and OPC.

Curing	Cement	Compressive strength (MPa)		
		1 day	3 day	28 day
4h at 23 °C 16 h in steam at 71 °C, then at 23 °C	Portland BFS Cement	27.6	30.7	42.7
	OPC	25.5	27.9	39.3
23 °C	Portland BFS Cement	9.0	18.6	44.8
	OPC	10.0	23.1	44.8

## 6. Porosity

Different parameters are used to characterize the pore structure of a cementitious material, of which some are elaborated below:

- Porosity
- Hydraulic radius

- Specific surface area
- Threshold diameter
- Pore size distribution (PSD).

Porosity is also a major component of microstructure study. Porosity is further subdivided into two classes: total porosity, and effective porosity as shown in figure 4. Total porosity is the ratio between the volume of pores and bulk volume of the material expressed as percentage.

$$\varepsilon = \frac{V_p}{V_b} \times 100$$

Where  $\varepsilon$  is the total porosity (%),  $V_p$  is the total volume of pores,  $V_b$  is the bulk volume of the material. For the case of MIP method, mercury density ( $\rho_{Hg}$ ) and helium density ( $\rho_{He}$ ) values are used to find porosity of a material.

$$\varepsilon = \left[ 1 - \frac{\rho_{Hg}}{\rho_{He}} \right] \times 100$$

In finer materials such as powders, interparticle porosity and intraparticle porosity constitute to the total porosity which can be as follows (Quantachrome 2009):

$$\text{Interparticle porosity (\%)} = \frac{V_v}{V_b} \times 100$$

$$\text{Intraparticle porosity (\%)} = \frac{V_t - V_v}{V_b} \times 100$$

$$\text{Total (mercury intrusion) porosity (\%)} = \frac{V_t}{V_b} \times 100$$

Where  $V_v$  is the volume of the mercury intruded up to the Interparticle Filling Limit,  $V_t$  is the volume of mercury intruded up to the maximum experimental pressure and  $V_b$  is the volume of the bulk sample.

Effective porosity is the fraction of pores with respect to the bulk volume of the material constituted only by open and interconnecting pores. Ye *et al.*, (2003) defined effective porosity as the volume of the mercury removed during the extrusion

process. If the mercury is pressurized second time after the extrusion, effective porosity can be obtained from the second intrusion curve of the pore size distribution. Effective porosity is always going to be less than or equal to the total porosity.

Porosity parameters by Mercury Intrusion Porosimetry (MIP):

Washburn equation (Washburn, 1921) is responsible for the elaboration of the relationship between pressure  $p$  (MPa) and the pore diameter  $d$  ( $\mu\text{m}$ ) based on the assumption of cylindrical pores,

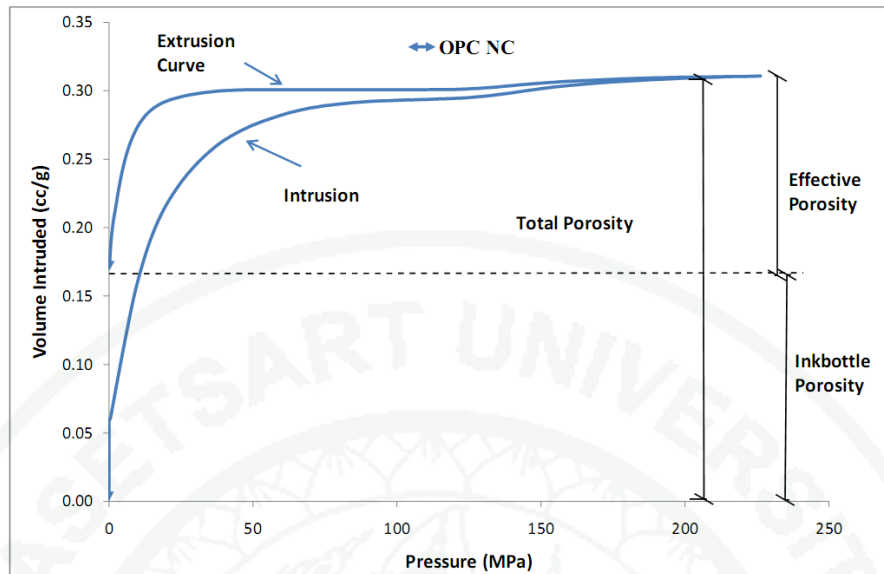

$$p = -\frac{4\gamma \times \cos \theta}{d}$$

Where  $\gamma$  is the surface tension of the mercury (mN/m) and  $\theta$  (-) is the contact angle between the mercury and the pore surface of the cement. For cementitious material, Cook (1991) proposed the contact angle of  $139^\circ$  and the surface tension of 480 (N/m) for mercury for the intrusion process. These values were used in this study like many other studies.

The pore size distribution differential curve is obtained by taking the slope of the pore size distribution curve  $dV/d\log d$  against  $\log d$  as shown in the Figure 5. For cement paste, several peaks can be found from this curve, where these peaks represent the pore diameters corresponding to the higher rate of mercury intrusion per change in pressure.

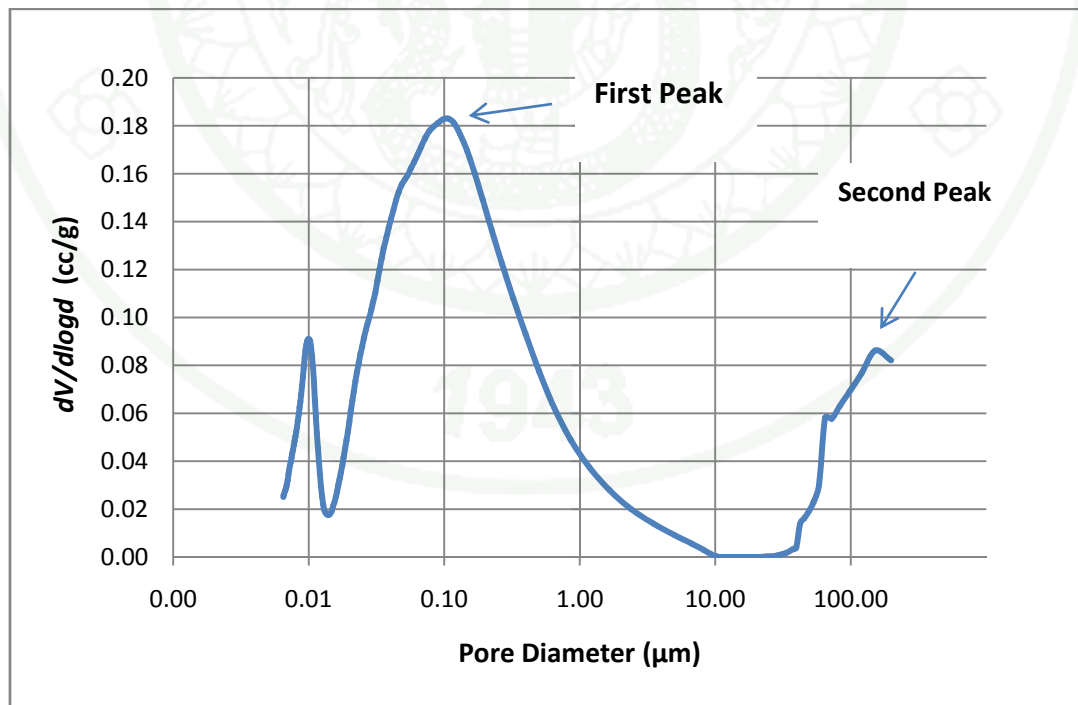

Mode radius or mode diameter is the value where the greatest volume intruded/extruded occurred (Quantachrome operating manual 2009).

Cook et al. refers to these peaks as ‘threshold’, ‘critical’ or ‘percolation’ pore diameters. In cement pastes, the first peak corresponds to capillary porosity,  $0.01 \mu\text{m}$  to  $10 \mu\text{m}$ , whereas the second peak corresponds to the gel pore,  $0.001 \mu\text{m}$  to  $0.01 \mu\text{m}$ . These parameters are considered to be important and essential for the transport properties, such as permeability properties of the cement pastes.

**Figure 4** Mercury intrusion and extrusion hysteresis for OPC paste for moist curing.

Source: Ye (2003).

**Figure 5** Pore size distribution differential curve.

Source: Ye (2003).

Generally it is accepted that capillary pores are the pores with diameter larger than  $0.01\ \mu\text{m}$ , and gel pores are the one with diameter smaller than  $0.01\ \mu\text{m}$ . As a matter of fact, in the early hydration stage, the capillary pores are well-connected and they are larger in diameter than the CSH gel pores.

With the advent of hydration, the capillary pores decrease in size and become partially connected. The second peak corresponds to the gel pores within the hydration products. With the increase in curing age, the hydration products blocks the capillary pores, therefore the mercury now has to flow through gel pores to reach the capillary pores. Threshold pore diameter was also explained by Winslow *et al.*, (1970) which said that threshold pore diameter is minimum diameter of channels that are continuous through the paste at a specific age.

**Table 6** Categorization of pores in hardened Portland cement paste.

Categories	Sizes	Name	Role of water	Effect on concrete
Capillary pores	50nm – 10 $\mu\text{m}$	Macropores	Behaves as bulk water	Permeability, diffusivity
	10 – 50 nm	Large mesopores	Small surface tension generated	Permeability in the absence of macropores, shrinkage above 80% RH
Gel pores	2.5 – 10 nm	Small mesopores	Large surface tension generated	Shrinkage between 80% RH and 50% RH
	0.5 – 2.5 nm	Micropores	Strongly adsorbed water	Shrinkage at all RH, creep
	Smaller than 0.5 nm	Interlayer spaces		

**Source:** Mindess *et al.*, (2003).

After the completion of hydration process in cement concrete, this “stone-like”, solid and porous material contains different aforementioned phases which are intermixed having structure to a micro-level (or nano-level) scale. This structure is generally called microstructure, and the time-dependent variation in microstructure due to continuous cement hydration is called microstructure development. The microstructure of cement paste develops when hydration products are formed, which is the solid phase, and pore structure is distributed as network, which is the pore phase.

C<sub>3</sub>A is the most active phase during the first stage of hydration of cement paste. The volume of the pore phase decreases with the increase in the volume of the solid phase. The pore phase is classified in to two categories according to their sizes: gel pores and capillary pores. Table 6 shows the classification of pores as given by Mindess *et al.*, (2003) which lays down the vast ranges for different categories of pores.

This categorization is used in concrete technology but for a more general classification of pores in solids, International Union of Pure and Applied Chemistry (IUPAC) is officially referred which classifies as follows:

- Macropore have size larger than 50 nm
- Mesopore has size ranging from 2 to 50 nm
- Micropore has size less than 2 nm.

From the proposed terminologies and size ranges in various literatures, apparently there is no distinct terminology applied to the different sizes of the pores in cement paste. Furthermore, the division of sizes between capillary pores and gel pores are arbitrary due to the spectrum of pore sizes in cement paste is continues. Normally, it is assumed that the capillary pores are those remaining water-filled pores in saturated paste between the cement particles. Gel pores are those still existing in the hydration product CSH, thereby gel porosity being the part of CSH gel itself.

The interconnectivity of pores in cementitious material paste is important due to the fact that they contribute to the transport properties. Capillary pores are

classified by Ye *et al.*, (2003) into a continuous pore, continuous pore with inkbottle, dead-end pore with inkbottle or an isolated pore as shown in the Figure 6.

Isolated pores do not contribute to the transport properties and cannot be detected by mercury intrusion porosimetry. There are certain limitations to MIP measurements which can eventually affect the data interpretation, therefore needs caution. Pore shape which was said to be cylindrical are actually irregular, thereby pore volume becomes an important factor. Ink-bottle effect is that mercury must pass through the narrowest pores connecting the pore network.

**Figure 6** Types of capillary pores (a) Continuous pore, (b) continuous pore with inkbottle, (c) dead-end pore with ink-bottle, and (d) isolated pore.

**Source:** Ye (2003).

This irregular pore shape pattern causes an overestimation of pore volume due to different mercury intrusion pressure. Figure 7 shows the hysteresis for the whole MIP testing procedure, including first intrusion, extrusion and the second intrusion. Ye *et al.*, (2003) has reported that continuous pores and the inkbottle pores can be detected from the first intrusion curve and extrusion curve. Water must be removed from the samples before mercury pressure is applied during the MIP testing. The

reason for this is that water being present in the pores during mercury intrusion would provide inaccurate results on the porosity parameters. Prior to the MIP testing, the samples are treated with various drying procedures to remove water from the pores.

**Figure 7** Mercury intrusion and extrusion hysteresis.

**Source:** (Ye, 2003).

One of the methods is oven-drying, in which the samples are oven-dried at 105 °C for 2-3 days. It is reported that a total porosity of 21% increase has been found by oven-drying, compared to vacuum-drying and freeze-drying for a cement paste with water cement ratio of 0.40 at a curing age of 28 days (Ye 2003). For freeze-drying, the samples are immersed in liquid nitrogen for 5 minutes at -195 °C. The low freezing process produces small ice microcrystals and prevents the growth of large ice microcrystals. After freezing, the samples are introduced in freeze-dryer in which the temperature is -40 °C and vacuum pressure is  $10^{-1}$  Pa (Gale 2001).

Li *et al.*, (2006) performed a study on the relationship between porosity of cement paste with mineral additives and compressive strength of mortar based on this paste. It was accomplished that mineral additives delayed the process that the

micropore structure of the OPC paste developed. The porosity of OPC paste with GGBFS decreased after 28-days whereas the strength increased.

Pandey *et al.*, (2000) investigated the influence of mineral additives on the strength and porosity of Ordinary Portland Cement mortars. It was accomplished that the addition of GGBFS in OPC increased the total porosity of mortars during the early hydration period. The strength of mortars containing GGBFS decreased with the increase in porosity. At the age of 7 days, the pore size greater than 2000 A seems to affect the strength of mortars with fly ash and slag. Whereas 28- and 90-days strength depended on pores greater than 1000 A and 500 A, respectively. The total volume of pores smaller than 200 A at 90-days of hydration increased, indicating improvement in the hydration and strength of mortars incorporating GGBFS.

## MATERIALS AND METHODS

### Materials

#### 1. Granulated Blast Furnace Slag

Granular Blast Furnace Slag (GBFS) was procured from Pakistan Steel Mills Corporation (PVT) LTD., Karachi, Pakistan which is the sole manufacturer of steel products in the country. Pakistan Steel comes under the Ministry of Industries and Production. It is located at 40 kilometers south east of Karachi and spreads over 75 square kilometers of main plant, township for employees and water reservoirs. It is Pakistan's largest industrial complex of the country with component units of more than 20. Pakistan Steel' production capacity is 1.10 million tonnes of steel expandable up to 3.0 million tonnes per year.

#### 2. Preparation of GBFS

Grinding was done by using Los Angeles abrasion machine as per ASTM C131 – 03 “Standard Test Method for Resistance to Degradation of Small-Size Coarse Aggregate by Abrasion and Impact in the Los Angeles Machine” rotated at 35 rpm to get two different fineness of blast furnace slag, as fineness being a parameter in terms of cycles. Zain *et al.*, (2011) experimented with two types of rods (10 and 20-mm) for grinding burnt rice husk ash in Los Angeles machine. 5.0 kg specimen was placed in the drum of Los Angeles machine along with mild steel rods type D as shown in Table 7.

#### 3. Chemical properties

Table 8 shows the chemical properties of ordinary Portland cement type-I and GBFS.

#### 4. Fine Aggregate

Natural river sand (Malir Sand) was procured from the local market, washed, cleaned from the impurities, sieved for sieve analysis (ASTM C136) and used as fine aggregate for the mortar. The specific gravity of sand was 2.60; its fineness modulus

was 1.98, unit weight of 1511.98 kg/m<sup>3</sup> and water absorption of 1.01%. Table 9 and Figure 8 shows that the sand that was about to be used for mortar was finer than the upper limit of the ASTM C33. Therefore graded sand complying with the limits of ASTM C778 “Standard Specification for Standard Sand” was used in mortar.

## 5. Portland cement

Ordinary Portland cement (ASTM Type 1) was used throughout this study. The cement was manufactured by the Lucky Cement Company conforming to ASTM C150 – 04 “Standard Specification for Portland Cement”, and available in the local market.

## 6. Water

Water for the mixing and curing purpose was obtained from ordinary tap which was usually used for drinking and domestic purpose, free from the organic matters and acidic matter.

**Table 7** Types of MS rods used in grinding GBFS.

	Types of rod used			
	A	B	C	D
Number	5	5	5	
Diameter (mm)	12	16	25	Combination of A, B and C.
Length (mm)	500	500	500

## Methods

### Experimental Procedures

An experimental investigation was carried out to study the effects of several parameters on the strength and porosity of GBFS-blended mortars and pastes. The main parameters were fineness, water-binder ratio, percentage replacements of GBFS and curing methods. GBFS was used to partially replace with 30%, 40%, 50% and 60% by weight of cementitious materials. The replacement was achieved by blending GBFS together with ordinary Portland cement while mixing. All compressive strength tests were conducted as per ASTM C109/C 109M “Test Method for Compressive Strength of Hydraulic Cement Mortars (Using 2-in or [50-mm] Cube Specimens)”. All specimens consisted of 1 part cementitious material and 2.75 parts of graded sand proportioned by weight. Water content for the mixes was varied to achieve constant flow ability at  $110 \pm 5\%$ . Trial mixes were made with varying dosage of water until the specified flow was achieved. The details of mix proportions are shown in Table 10.

**Table 10** Mix proportioning of fresh mortar.

Symbol	Water (liters)	Cement (g)	GBFS (g)	Sand (g)	S/B (%)	W/B (%)
OPC	120	248	0	691	2.75	0.484
GS-30/1	155	174	74	691	2.75	0.625
GS-40/1	170	149	99	691	2.75	0.685
GS-50/1	170	124	124	691	2.75	0.685
GS-60/1	188	99	149	691	2.75	0.758
GS-30/2	146	174	74	691	2.75	0.589
GS-40/2	151	149	99	691	2.75	0.609
GS-50/2	153	124	124	691	2.75	0.617
GS-60/2	156	99	149	691	2.75	0.629

Two-inch or 50-mm specimen cubes were compacted by tamping in two layers and were casted for 24 hours, after which they were subjected to curing methods.

Determinations of the few physical and chemical requirements of GBFS were conducted in material laboratories of NED University of Engineering and Technology, Karachi, Pakistan. These included Blaine's fineness for GBFS. X-ray fluorescence spectrometry (XRF) for the chemical analysis of GBFS was conducted at the Pakistan Council for Scientific and Industrial Research (PCSIR) Laboratories Complex, Karachi. Physical requirement tests were conducted in accordance with ASTM C989-04 "Standard Specification for Ground Granulated Blast-Furnace Slag for Use in Concrete and Mortars". The X-ray diffraction (XRD) analysis and mercury intrusion porosimetry (MIP) for GBFS and pure cement pastes were conducted at the Thailand Institute of Scientific and Technological Research (TISTR), Bangkok, Thailand.

#### 1. Flow Table

Water content of mortar containing granulated blast furnace slag was adjusted to give a flow of  $110 \pm 5\%$  determined by using flow table test as recommended in ASTM C230 "Specification for Flow Table for Use in Tests of

Hydraulic Cement”. The flow of  $110\pm 5\%$  is recommended in ASTM C109/C 109M “Test Method for Compressive Strength of Hydraulic Cement Mortars (Using 2-in or [50-mm] Cube Specimens)” for cements other than Portland or air-entraining Portland cements. Sand-binder ratio was fixed at 1:2.75 by weight. First the table was wiped clean and flow mold was placed at center. Then a layer of 1 inch mortar was placed in mold and tamped 20 times. Similarly successive layers were placed till mold was full and then the mold top was flushed with a trowel. The table was then dropped 25 times in 15 seconds and afterwards the diameter of mortar spread was measured from four scribed lines to record the flow value. The flowability of the mortar was expressed as a flow percentage of the spread diameter over the original bottom diameter of the sample.

## 2. Compressive Strength Tests

For compressive strength tests of mortars, Universal Testing Machine was used. GBFS was used to replace 30%, 40%, 50% and 60% by weight of the total cementitious materials. Mortars of size 50x50x50 mm molds were cast and covered with polyurethane sheet and damped cloth in  $23 \pm 2$  °C chamber for 24 hours. Two curing conditions were used i.e., conventional moist curing (NC) and accelerated curing (AC - steam curing) with delay period of seven hours and three regimes i.e., initial curing with increasing temperature, constant regime and decreasing temperature. The compressive strength tests (ASTM C 109) were conducted at the age of 3-, 7-, 28- and 90-days for conventional moist-curing, whereas for accelerated curing, the compressive strength test was performed after the specified period for accelerated curing.

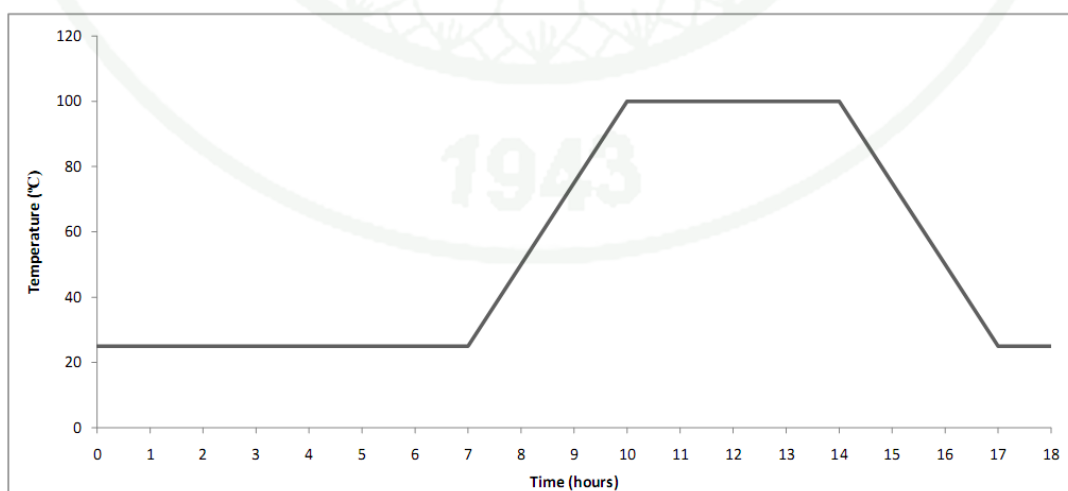

## 3. Accelerated Curing/Steam Curing

Specimens were exposed to accelerated curing conditions to develop a significant portion of their ultimate strength. The delay period of seven (07) hours was applied before the specimens were de-molded from their molds. Time period for initial curing with gradual increasing temperature for 3 hours (25 °C/h); to a maximum 100 °C temperature was kept constant for 4 hours; then there was gradual

decrease in temperature to 23 °C temperature within 3 hours (Figure 9). Relative humidity was held constant at 100% throughout the procedure.

**Table 11** Detail of Testing Program for the Compressive Strength of Mortars.

Type	Blaine's fineness (m <sup>2</sup> /kg)	Replacement level (%)	Number of 50 mm cube specimens				Steam Cured at 100 °C
			Normal Curing Conditions				
			23 °C

		50	3	3	3	3	3
		60	3	3	3	3	3

**Figure 9** Steam-curing regimes under the atmospheric pressure.

**Source:** Soroka (1979).

#### 4. Mercury Intrusion Porosimetry (MIP)

The control and GBFS-blended pastes were prepared from the same water binder ratio as in the case of cementitious mortars for the compressive strength tests. For the measurement of pore size distribution (PSD) of paste, mercury intrusion porosimetry (MIP) was carried out with a low pressure range from 1.5 to 55 psi (for large pore size), and high pressure range from 55 to 33,000 psi (for small pore size), capable of measuring pore diameter down to 0.0065 micron. The contact angle of  $140^\circ$  and surface tension of 485 mN/m were assumed. The hardened pastes moist-cured up to 7 days were carefully broken with a clean hammer, taking representative sample of 5mm pieces from the middle of the specimen. The samples were dried at  $110^\circ\text{C}$  for 1 hour in the oven before being introduced into porosimeter. MIP study is expressed by Washburn equation (Washburn 1921).

The weight of the sample usually varies according to the machine, 60-90% of penetrometer stem volume is proposed by Ye (2003) whereas 50-80% of penetrometer stem volume is suggested in the Quantachrome PoreMaster-33 Operating Manual. The sample was introduced in to the chamber where the sample was surrounded by mercury, and the pressure was applied and increased gradually on the mercury. Mercury was forced to enter the pores of the sample as the pressure was increased, and if there were continuous pores, a pressure would be achieved at which the mercury can penetrate the whole pore-network of the sample. On the other hand, if there were inkbottle pores or isolated pores, mercury might penetrate through the pore walls of the sample volume.

#### 5. X-ray Diffraction

X-ray diffraction was performed on the cementitious pastes for the structural and phase composition studies. XRD analysis was also used to study the hydration of GBFS-blended cement mortar with two curing methods as described in the scope of the study. XRD analysis of the pastes were carried out with Shimadzu XRD-6000 for the investigation of hydration process in both control and GBFS-blended pastes. After the samples were prepared in the same manner as MIP

investigation, except after crushing, the samples were passed from sieve No. 50. XRD was performed on the pastes containing various partial replacement levels of GBFS at 7-days conventional curing and steam curing. The samples were broken from the paste with the help of clean hammer and their size was not exceeding 1 cm<sup>3</sup>.

## RESULTS AND DISCUSSIONS

The experimental results are organized and presented in the subsequent sections as follows. All the tests were conducted in accordance with the relevant ASTM standards as mentioned in the previous section.

### 1. Slag Activity Index

Few physical requirements of OPC and two types of GBFS are shown in the Table 12. Type-2 GBFS is finer than the OPC whereas the OPC is finer than the type-I GBFS. The coarser type-1 GBFS eventually shows more water requirement which caused the strength to reduce and porosity to increase. On the contrary, type 2 GBFS is finer which means the water requirement reduces and thus increases the strength. Slag Activity Indexes as:

$$\text{Slag activity index, \%} = \left( \frac{SP}{P} \right) \times 100$$

Where,

SP = average compressive strength of slag-reference cement mortar cubes at designated ages, MPa (psi),

P = average compressive strength of reference cement mortar cubes at designated age, MPa (psi).

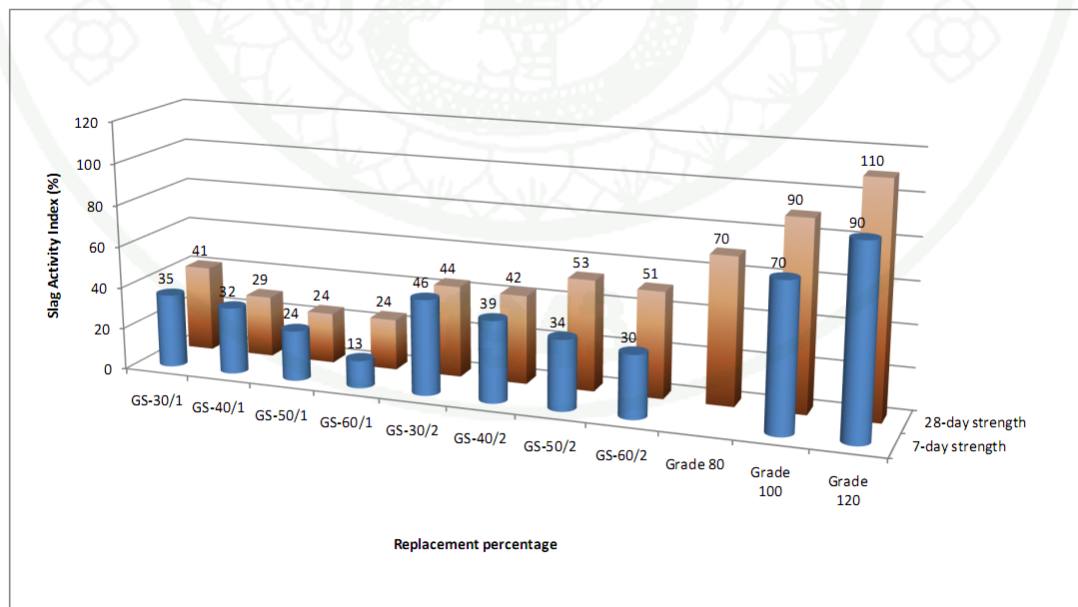

Slag activity indexes of both types of GBFS are tabulated in Figure 10 and Table 12, and compared with the limits of ASTM specification. The slag activity indexes of both GBFS were lower than the ASTM limits, and therefore failed to meet the requirements. The reference cement used to test slag activity has 28-day strength of 25 MPa which was lower than 35 MPa, the requirement of ASTM C 989 specification.

### 2. Workability

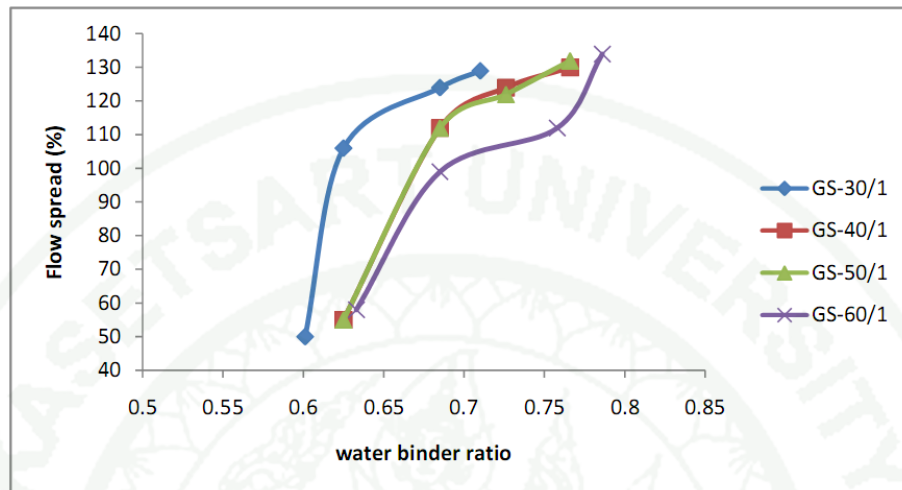

Figure 11 shows the relationship between flow spread (%) from the Flow Table Test against the water-binder ratio for the GBFS-blended mortars of type 1 fineness. Figure 11 and Figure 12 show that by increasing the water-binder ratio, the flow spread (%) increased.

**Table 12** Physical requirements of OPC and two types of GBFS as per ASTM C989.

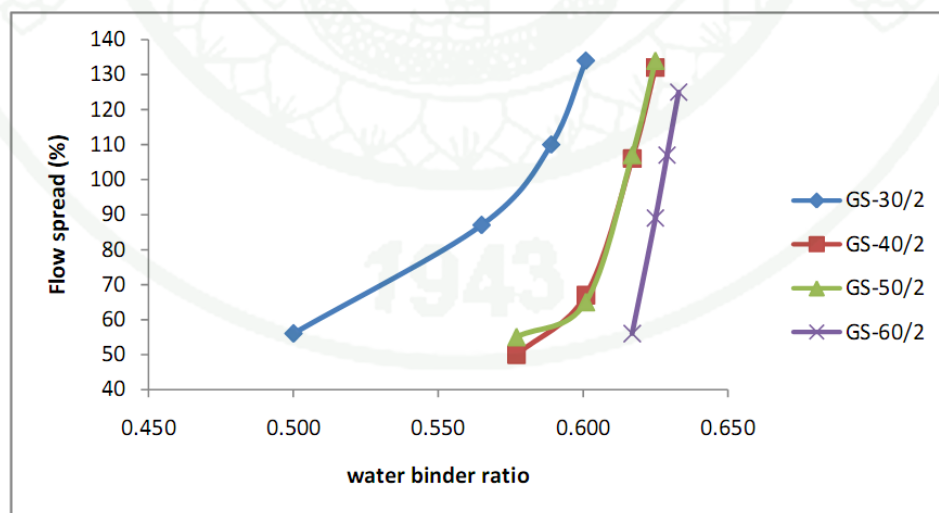

Physical Properties	Ordinary Portland Cement Type I	GBFS-1	GBFS-2	ASTM C 989
Blaine's Fineness (m <sup>2</sup> /kg)	304	217	386	--
Slag Activity Index with Portland Cement, at 7 days (%)	--	24	24	--
Grade 80	--			70
Grade 100				90
Grade 120				
At 28 days (%)	--	34	53	70
Grade 80	--			90
Grade 100				110
Grade 120				

**Figure 10** Relationship between Slag activity index and replacement percentage for both the finesses.

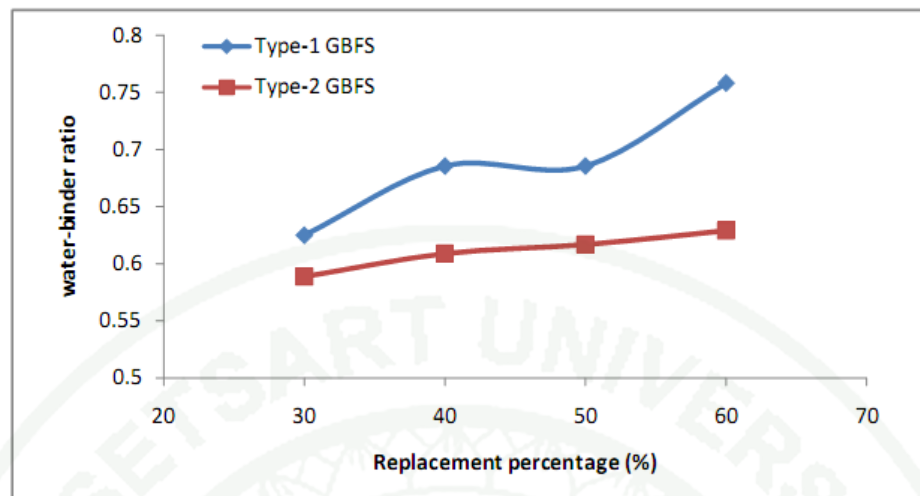

Also it was observed that on increasing the replacement level the water demand increased thereby consequently affected the strength and porosity parameters.

**Figure 11** Relationship between flow spread and. water-binder ratio of GBFS mortar for type 1 finenesses.

**Figure 12** Relationship between flow spread and. water-binder ratio of GBFS mortar for type 2 finenesses.

**Figure 13** Relationship between replacement percentage and water-binder ratio for both the finenesses.

### 3. Compressive Strength

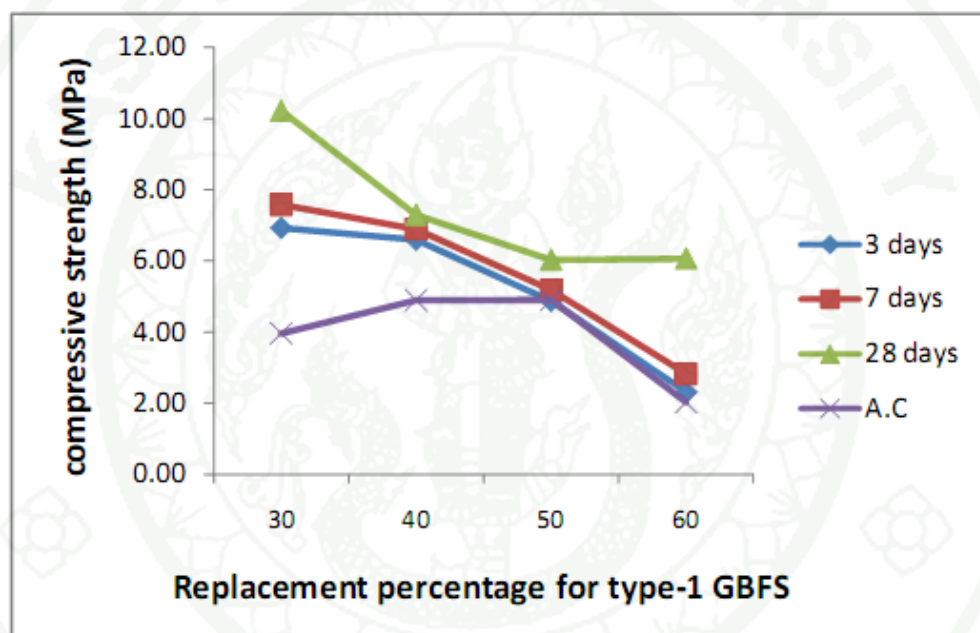

The results of the compressive strength tests of conventional curing and accelerated curing (steam curing) GBFS are presented in Table 13, Figure 14 and Figure 15. The unexpected increase in the 90-day strength of OPC specimen was observed. It was observed that the finer the cementitious material, the higher the compressive strength of mortars.

**Table 13** Results of compressive strength tests of control and GBFS-blended mortars.

		3 days	7 days	28 days	90 days	
GS-50/2	0.617	6.14	7.21	13.18	39.14	13.49
GS-60/2	0.629	5.73	6.47	12.62	41.58	13.90

**Figure 14** Relationship between compressive strength and % replacement of GBFS mortar cubes for type 1 finenesses.

As the replacement level was increased, the compressive strength gradually decreased for the conventional curing method. But in case of steam curing method for type 2 fineness, the compressive strength was shown to increase with the increase in replacement level.

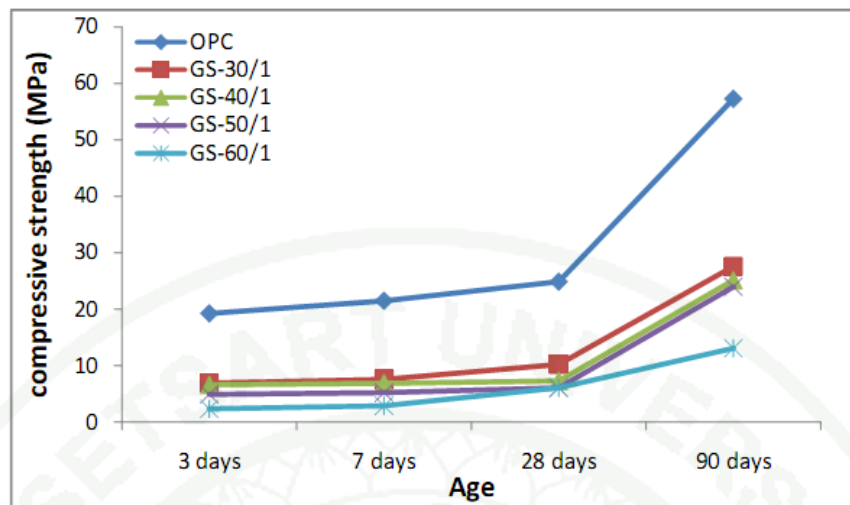

It was reported by Neville et al. (1995) that steam curing of concrete containing GBFS could be used at higher temperature to avoid the harmful effects of long-term strength and permeability. Steam curing was also useful where early

strength gain in concrete was essential or in cold weather where additional heat was required to achieve the hydration process. Figure 15 indicated that the steam curing in the case of finer GBFS (386 m<sup>2</sup>/kg) accelerated the hydration process and helped in the completion of hydration reaction and gain in early strength.

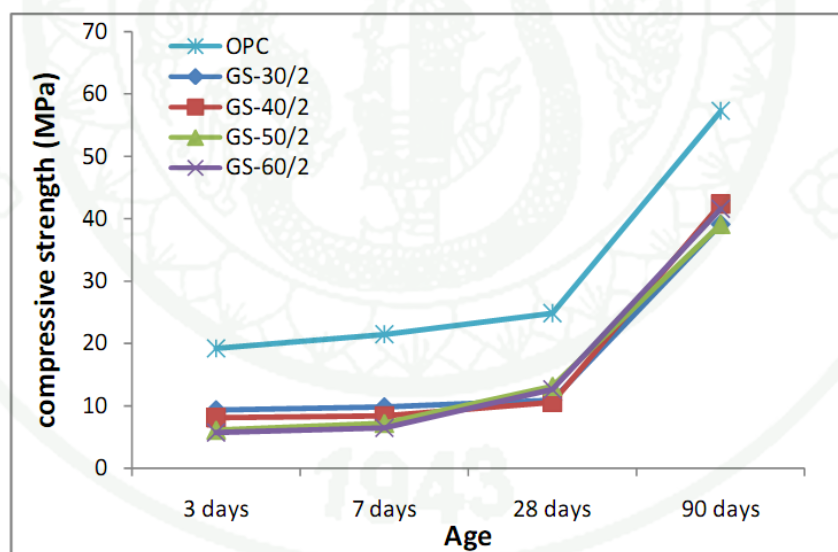

**Figure 15** Relationship between compressive strength and % replacement of GBFS mortar cubes for type 2 fineness.

In Figure 16 and 17 the relationships between compressive strength and age of the control and GBFS-blended mortar were shown. The compressive strength of control mix at 28-day was 25 MPa which should be a minimum of 35 MPa as per ASTM C989, whereas the compressive strength of various GBFS-blended mortars at 28-day varied from 6.03 MPa for GS-50/1 being a minimum to a maximum of 13.18 MPa for GS-50/2. Similarly, in the case of 90-days compressive strength, the values had increased substantially but the compressive strength of control mix was still much higher than any of the GBFS-blended mortar, which was unexpected. For 90-day strength, the maximum value was 27.58 MPa for GS-30/1 for type 1 fineness and 42.38 MPa for type 2 fineness.

**Figure 16** Compressive strength vs. Age of GBFS mortar cubes for type 1 fineness.

**Figure 17** Compressive strength vs. Age of GBFS mortar cubes for type 2 fineness.

For control mix, the compressive strength value was 57.28 MPa which showed the unexpected result of long-term strength for OPC being higher than the GBFS-blended mortars even after increased fineness in excess to the fineness of cement (Lea 2003, Neville 1995)

#### 4. Mercury Intrusion Porosimetry (MIP)

There are several terminologies that are used to explain the pore structure of a material, like capillary pores, gel pores, total porosity, effective porosity and threshold pore diameter as explained extensively in the Literature Review section. Effective porosity is a very important parameter when used for water permeability. Inkbottle porosity can be measured by subtracting effective porosity from total porosity.

##### 4.1 Total Porosity and Effective Porosity

Table 14, 15 and 16 showed some of the parameters of pore structure or microstructure using MIP measurements. The first peak and second peak were the threshold pore diameters for the control and GBFS-blended pastes for the conventional curing and steam curing methods. In the same table, threshold pore diameters of first peak showed the capillary porosity, and second peak showed the gel porosity.

Aligizaki (2009) classified capillary pores into two categories of small and large capillary pores due to the influence of mineral admixtures on the microstructure of cement paste. Large amount of pores in the range between 2 to 50 nm were formed by the addition of mineral admixture with cement paste. First peak for GS-30/1 is 143.20 nm which was the maximum value of among the three samples. This showed that GS-30/1 had most capillary pores than others and OPC had the least capillary pores for the conventional curing method. When comparing the conventional curing with steam curing, the reduction in the values of total porosity was due to the gel pores changed into inkbottle pores or isolated pores during the hydration process (Ye *et al.*, 2003). The second threshold pore diameters, in the Table 16, had the sizes between 7-13 nm in all samples regardless of the w/b ratio, which classified them in gel pores.

4.2 Effect of replacement level and curing methods on pore size distribution of pastes.

**Table 14** Porosity parameters for OPC and GBFS-blended pastes for 7-days.

Symbol	W/B (%)	Conventional Curing (23 °C) at 7-day			Steam Curing (100 °C)		
		Total Porosity (%)	Eff. Porosity (%)	Eff./total (%)	Total Porosity (%)	Eff. Porosity (%)	Eff./total (%)
OPC	0.485	44.37	24.08	0.54	37.26	18.05	0.48
GS-30/1	0.625	48.64	20.55	0.42	44.20	15.47	0.35
GS-50/2	0.617	43.24	20.29	0.47	36.19	19.91	0.55

**Table 15** Results of MIP parameters of OPC and GBFS-blended pastes .

Symb ol	Conventional Curing (23 °C) at 7-day			Steam Curing (100 °C)		
	Total Porosity (%)	Interparticle porosity (%)	Intraparticle porosity (%)	Total Porosity (%)	Interparticle porosity (%)	Intraparticle porosity (%)
OPC	44.36	8.53	35.83	37.26	1.69	35.57
GS-30/1	48.63	0.17	48.46	44.20	1.29	42.90
GS-50/2	43.24	1.14	42.09	36.18	0.67	35.15

Relationship between pore diameter and incremental pore volume of OPC and GS-30 pastes moist-cured at 7-day were shown in the Figure 18. The peaks of capillary pores (mode pore diameter) of OPC and GS-30 were at 0.1071 micron and 0.1163 micron respectively; with incremental pore volume of 0.183 cc/g and

0.1726 cc/g, respectively. This result suggested that the replacement of OPC with GBFS increased the porosity. Similarly Figure 23 also showed the same behavior pore diameter and incremental pore volume of OPC and GS-50/2 pastes in moist curing condition at 7-day. The increase in porosity was due to the higher water binder ratio when cement was partially replaced.

In Figure 19, the peaks of capillary pores (mode pore diameter) of OPC and GS-30 were at 0.07484 micron and 0.0672 micron respectively; with incremental pore volume of the two were 0.1972 cc/g and 0.1889 cc/g, respectively. This result suggested that accelerated curing reduced the pore size and consequently porosity. These results also suggested that inclusion of finer GBFS reduced the capillary pores which were also reported elsewhere with fly ash as a partial replacement (Chindapasirt *et al.*, 2007). Similarly Figure 20 also showed the same behavior pore diameter and incremental pore volume of OPC and GS-50/2 pastes in steam curing condition at 7-day.

**Table 16** Data of OPC and GBFS-blended pastes with w/b ratio and curing methods.

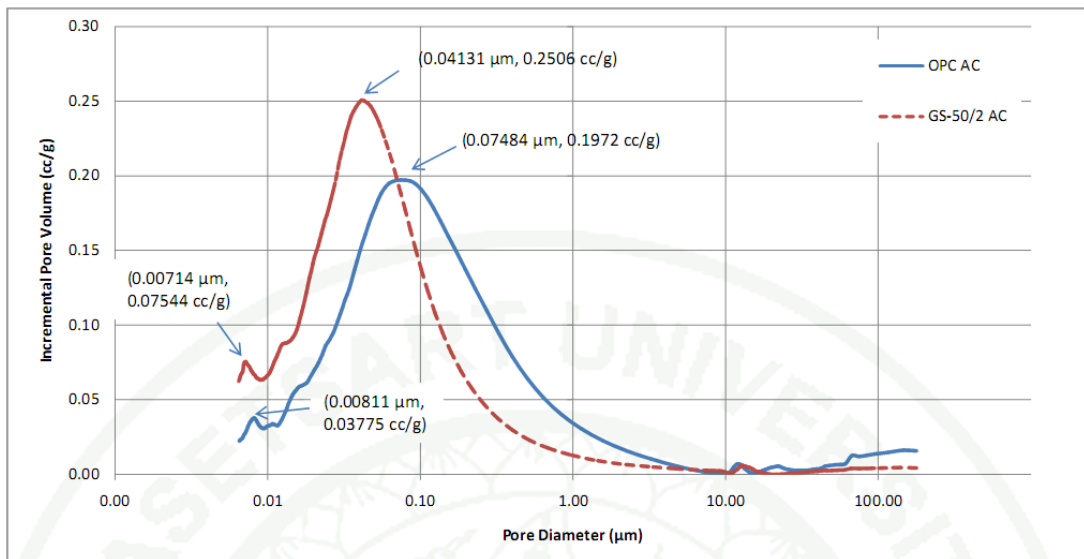

Symbol	W/B ratio (%)	Conventional Curing (23 °C) on 7-day					Steam Curing at 100 °C				
		Total Porosity (%)	threshold pore diameter (nm)		Mode pore diameter (nm)	Bulk density (cc/g)	Total Porosity (%)	threshold pore diameter (nm)		Mode pore diameter (nm)	Bulk density (cc/g)
			1 <sup>st</sup> Peak	2 <sup>nd</sup> Peak				1 <sup>st</sup> Peak	2 <sup>nd</sup> Peak		
OPC	0.485	44.37	107.1	9.92	107.10	1.427	37.26	74.84	8.11	74.84	1.465

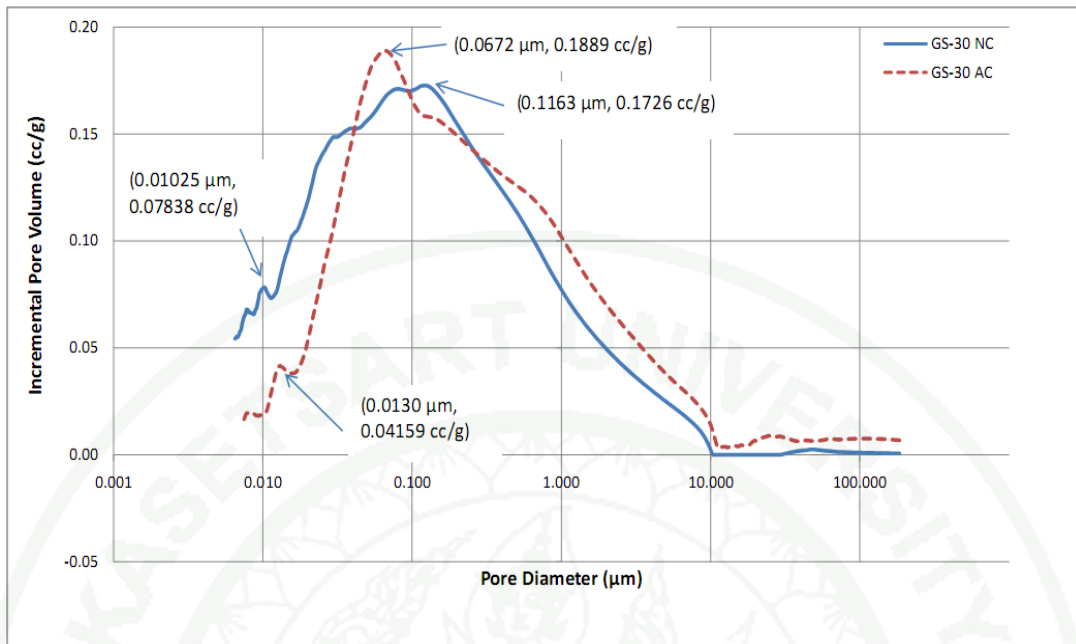

**Figure 19** Relationship between pore diameter and incremental pore volume of OPC & GS-30 pastes in steam curing

**Figure 20** Relationship between pore diameter and incremental pore volume of OPC & GS-50/2 pastes in steam curing

**Figure 21** Relationship between pore diameter and incremental pore volume of GS-50/2 pastes in steam curing and normal curing.

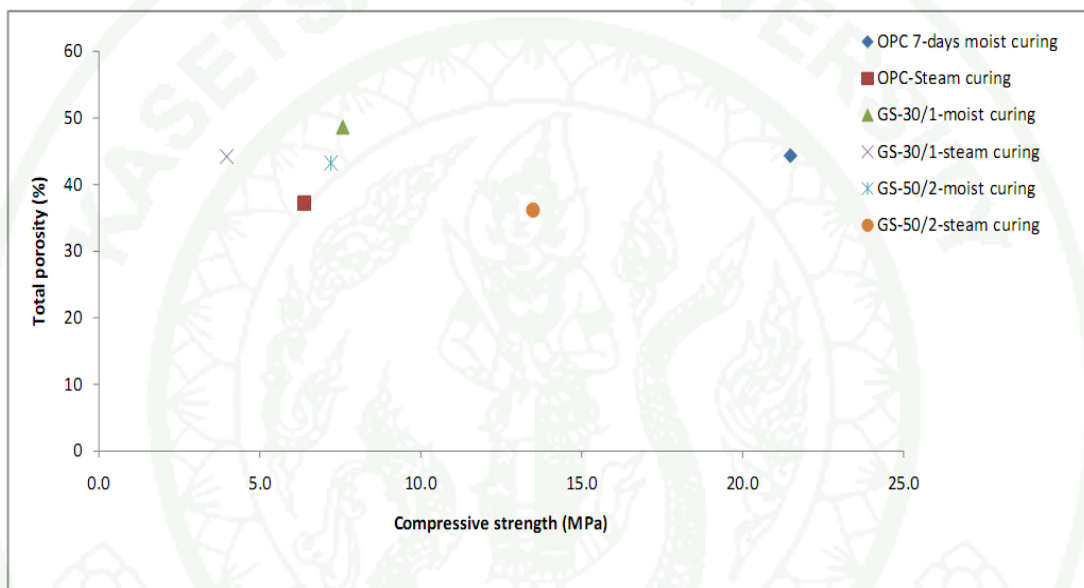

**Figure 22** Relationship between pore diameter and incremental pore volume of GS-30/1 pastes in steam curing and normal curing.

**Figure 23** Relationship between pore diameter and incremental pore volume of OPC & GS-50/2 pastes in conventional moist curing.

Figure 24 shows the relationship between compressive strength and total porosity of OPC, GS-30/1, and GS-50/2 with comparison on their curing methods respectively. The maximum compressive strength of 21.48 MPa was of OPC with 7-day moist curing and total porosity of 44 %. Then GS-50/2 with steam curing had the next highest compressive strength of 13.49 MPa and total porosity of 36 %.

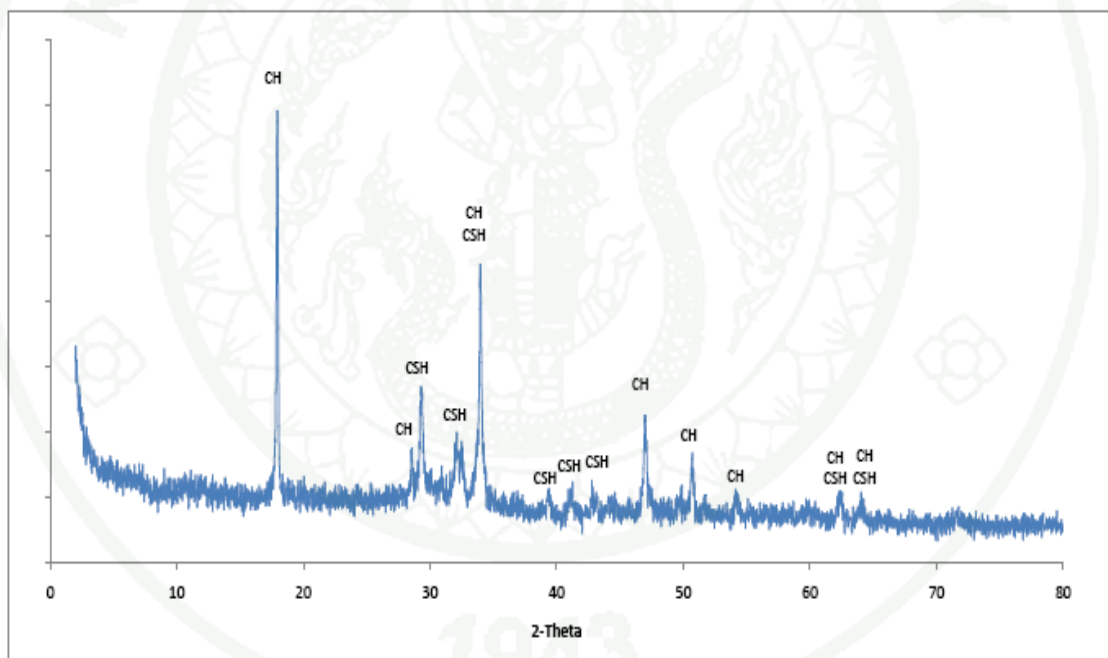

**Figure 24** Relationship between compressive strength and total porosity of all pastes.

## 5. XRD analysis

When hydration of GBFS-blended cement paste takes place, both Portland cement and GBFS hydrations comprise of the hydration products, except the CH phase formed by the Portland cement is influenced by the GBFS hydration. The hydration of GBFS is very slow in pure water. Figure 25 and 26 shows the XRD patterns of OPC pastes both in normal curing at 7 days and accelerated curing, and bore close similarity i.e., accelerated curing had little effect on OPC. Steam curing had unremarkable effect on the hydration of Portland cement paste. Figure 27 to 30 shows that the hydration products of OPC when mixed with GBFS and water, yield

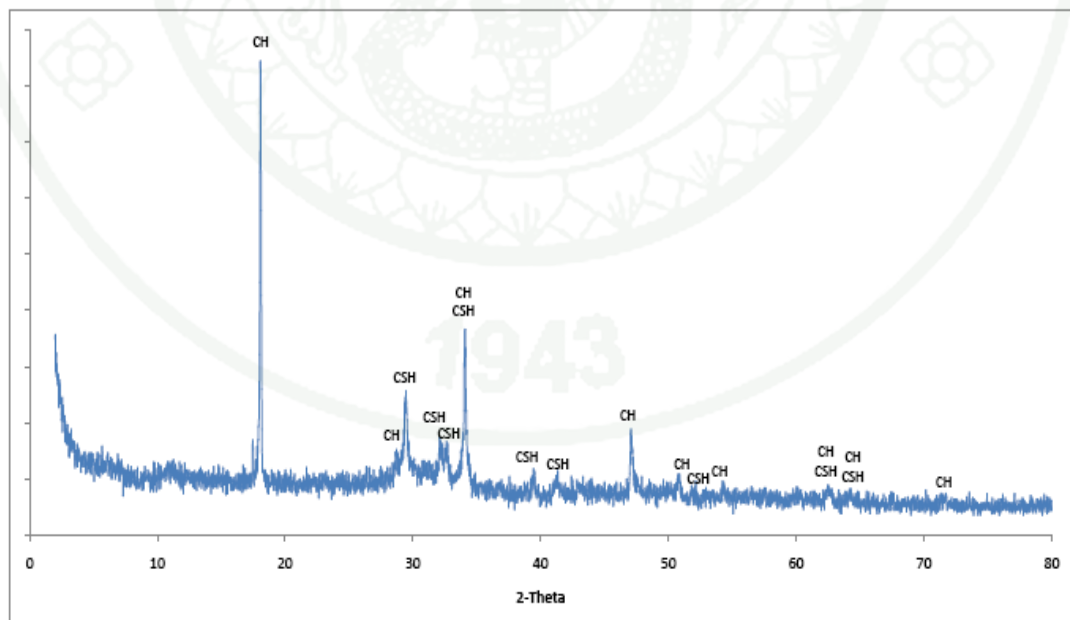

CSH and CH same as when OPC hydrate. When GBFS was replaced with OPC, peaks of CSH increased as compared to CH, which suggested that the hydration of GBFS consumed CH to produce more CSH as expected. In other words, CH encouraged the growth of CSH. Same results were reported elsewhere (Pal et al. 2003). The CH produced during the hydration of Portland cement acted as an activator or catalyst to the GBFS hydration. Figure 27 to 30 shows the XRD patterns of GS-30 and GS-50 with moist curing and steam curing. In these figures, on the increase of GBFS content, the sharp peaks decreased, indicating that with higher GBFS content resulted in an increase in hydration process of Portland cement.

## CONCLUSION AND RECOMMENDATIONS

### Conclusion

The following conclusions are drawn from the experimental study of the tests:

1. Increasing the fineness of GBFS reduced the water binder ratio for the required flowability.
2. Increase in the fineness of GBFS increased compressive strength and reduced total porosity.
3. Increase in the percentage replacement of GBFS increased water-to-binder ratio, thereby decreased the compressive strength, and increased the total porosity.
4. GBFS partial replacement caused initial low-strength as expected but showed trend towards increase in long-term strength. The long-term strength for GBFS-blended cement increased but did not go higher than the value of compressive strength of control mix.
5. The optimum percentage replacement of GBFS was 30% to 50%.
6. Accelerated curing (steam curing) significantly increased early compressive strength of GBSF mortar, and decreased pore size.
7. The hydration of Portland cement produced CH and CSH. GBFS decreased the pore sizes, and eventually decreased total porosity.

### Recommendations

- The use of grinding aid in grinding of GBFS can be investigated.
- The use of workability admixture can be investigated so as to reduce the water content in the mix thereby increasing the strength, and reducing the total porosity.
- The effect of  $\text{TiO}_2$  nanoparticles in GBFS on the abrasive resistance, strength and porosity of GBFS mortar can be investigated.
- Same materials used in this study can be investigated for aggressive environment in order to compare with the results of Khan et al (2009).
- For mercury intrusion porosimetry measurement, samples can also be dried by freezing method, consequently comparing the results with other methods.
- An extensive study is recommended in the engineering properties of the GBFS procured from Pakistan Steel.
