ACKNOWLEDGMENT

I would like to express my sincere gratitude and deep appreciation to my major-advisor, Prof. Dr. Reon Somana, for his kindness, guidance, supervision, suggestion, helpful criticisms and encouragement throughout the course of this training which have enabled me to carry out this study successfully. I am greatly indebted to Prof. Dr. Boonsirm Withyachumnarnkul, Dr. Wisuit Pradidarcheep, my co-advisors, for their valuable comments, suggestions and consultation. To Asst. Prof. Dr. Sirinush Sricharoenvej, my supervisory committee, Assoc. Prof. Wantanee Trakulrungsi and Assoc. Prof. Dr. Vijittra Leardkamolkarn, members of thesis proposal committee, for their valuable criticism, comments and suggestions. I would like to extend my gratefulness to Dr. Wichai Ekataksin from Department of Anatomy, School of Medicine, Tokyo Medical and Dental University, Japan for his valuable scientific advice and latest technical contributions to my study.

I wish to extend my sincere gratitude to Assoc. Prof. Ayudthya Samridthong, Dr. Somluk Asuvapongpatana, Mr. Sakporn Thongpila and Miss Sununta Chuncher for their advice and technical assistance. To Mr. Decha Boonranajitpilom, Mr. Koumkrit Pisetpaisan, Mr. Ittipon Phoungpetchara, Mr. Prasert Meeratana and all members of endocrine laboratory for their kindness and generous cooperation.

It is my great pleasure to thank Mr. Phon and Mrs. Vasana Phudphetkaew for their kindness and the financial support throughout the course of my study.

Finally, I wish to express my faith and deepest appreciation to all members of my family for their love, care, understand and endless support.

CHURAIRAT DUANGCHAN : MICROVASCULARIZATION OF THE MIDBRAIN IN COMMON TREE SHREW (*Tupaia glis*). THESIS ADVISORS : REON SOMANA, M.D., Ph.D., BOONSIRM WITHYACHUMNARNKUL, M.D., Ph.D., WISUIT PRADIDARCHEEP, Ph.D. 101 p. ISBN 974-664-139-5

The study of the midbrain in the common tree shrew (*Tupaia glis*) with vascular corrosion cast under a stereomicroscope and a scanning electron microscope (SEM) reveals that the midbrain is supplied by the branches of the vertebrobasilar system which are the basilar artery bifurcation, posterior cerebral, superior cerebellar, medial posterior choroidal and collicular arteries. They give off the penetrating arteries which radially course into the internal part of the midbrain and reach the cerebral aqueduct. This is the centripetal arrangement. The internal artery of the midbrain is divided into anteromedial, anterolateral, lateral and posterior groups according to the points of entry and territories that they supply. The penetrating arterioles terminate as capillary networks. The degree of capillary density in the midbrain is closely related the density of the nerve cells that accumulate in the areas of the midbrain nuclei. Less vascularity is obvious in the areas occupied by nerve fibers. The arterial anastomoses could be observed in the perimesencephalic or external part of the midbrain. The midbrain capillaries are without fenestrations. The venous drainage in the midbrain could be divided into three groups. The venous blood from the area ventral to the cerebral aqueduct drains into the tributaries of the veins of the anterior or petrosal group. The posterior group collects the venous blood from the collicular vein and the superficial vein of the quadrigeminal plate. The superior or galenic group receives the blood from the thalamocollicular, the lateral and dorsal aqueductal veins that empty the venous blood into the great cerebral vein of Galen, rectus sinus. Finally, the venous blood from both rectus and superior petrosal sinuses drain mainly into the external jugular vein and some into the internal jugular vein.

CHAPTER I

INTRODUCTION

The midbrain or mesencephalon is a part of brainstem situating between the diencephalon and pons. The caudal limit of the midbrain is represented by the decussation of superior cerebellar peduncles and trochlear nucleus, while the rostral part of the red nucleus, oculomotor nucleus and posterior commissure form the rostral limit (1). It consists of tectum, tegmentum and crus cerebri. The midbrain contains important nuclei, many ascending and descending fibers (2). Concerning the midbrain vascularity, it is nourished by branches from the circle of Willis. In submammals, the midbrain is supplied by only caudal division of internal carotid artery (3). In primitive and higher mammals, it receives the arterial blood from branches of the vertebrobasilar system, namely, basilar, posterior cerebral and superior cerebellar arteries (4). In human, the pattern of arterial supply in the internal portion of the midbrain could be divided into median and paramedian (antreomedial), anterolateral, lateral and posterior groups depending on their points of entry and areas that they supply (5, 6, 7). The midbrain blood supply has been reported in human (1, 5, 7), camel (8), cat (9), dog (10, 11, 12) and guinea pig (13, 14). It is quite similar among these species. The venous drainage is some what different and with minimal information.

So far, the knowledge concerning the midbrain vascularity has been focused on the main blood vessels. As the three-dimensional configuration of the midbrain vascular system is difficult to visualize by the histological study with light microscopy

(LM). The vascular corrosion cast technique using intravascular injection of casting medium in conjunction with scanning electron microscope (SEM) has been employed for detailed studies of the microangioarchitecture in various visceral organs in the field of anatomy (15). It is of interest to employ this technique to elucidate the midbrain microvascularization in common tree shrew (*Tupaia glis*), an animal regarded as a primitive primate (16, 17, 18, 19).

CHAPTER II

OBJECTIVES

As very little information concerning the detail vascularization of the midbrain has been reported, it is of interest to elucidate the gross anatomy, source of blood supply, ramification of the blood vessels within particular parts and microvascularization of the midbrain in commom tree shrew (*Tupaia glis*).

CHAPTER III

LITERATURE REVIEW

The midbrain consists of three major regions. They are tectum, tegmentum and crus cerebri. The tectum composes of four rounded prominences, the corpora quadrigemina. The upper two prominences are the superior colliculi or optic tectum in non-mammalians. The tectum is the laminated structure containing many layers of cells and fibers. The dendrites of many cells orientate in a radial fashion and the axons course in parallel to the surface. The colliculus lamination could be divided into superficial, intermediate (central) and periventricular zones (2). In human, the superior colliculus is subdivided into five strata. They are stratum zonale, stratum griseum, stratum opticum, stratum lemnisci and stratum profundum (20). The superior colliculus receives multiple inputs which terminate in the different zones and relating mainly to the head and eyes movements (2).

The two lower prominences are inferior or posterior colliculi or torus semicircularis in non-mammalians. It has three main divisions, namely, central nucleus, collicular cortex and peri-collicular tegmentum (21). The inferior colliculus is the site for the termination of auditory pathways, a center for correlation and control reflex in response to sound.

The second region of the midbrain called tegmentum situates ventrally to the tectum with the cerebral aqueduct being in between. It contains the rostral connection areas with the hindbrain, ascending and descending fibers, cranial nerve nuclei

(oculomotor, trochlear and mesencephalic trigeminal nuclei), red nucleus, interpeduncular nucleus, MLF and reticular formation. The midbrain tegmentum is the gateway for incoming and outgoing to and from the forebrain.

The third region is called crus cerebri. It is separated from the tegmentum by substantia nigra and made up principally of efferent fibers from the motor cortex, corticospinal and cortibulbar tracts (2). The right and left crus cerebri are separated by interpeduncular fossa (IF) (22). The substantia nigra (SN) is a layer of gray substance consisting of the melanin containing neurons and producing dopamine. It composes of zona compacta and zona reticulata being the important part of the extrapyramidal system (23).

Embryologically, the midbrain is derived from the mesencephalic vesicle during the fourth gestation week and undergoes less change than any other parts of the developing brain. The tectum is formed by the migration of the neuroblasts from alar plates. The neuroblasts from the basal plates give rise to groups of neurons in tegmentum. The substantia nigra may also be differentiated from the basal and alar plates. The crus cerebri becomes progressively more prominent as descending fiber groups pass through the developing midbrain (24). In addition, the embryonic development of the cerebral vascularization had been proposed by Kaplan (25). The constant relationship of the cerebral artery to the specific vesicles of the neural tube, the direction and position of arteries are governed by the anatomic location of the cellular masses (25). The arterial development of the midbrain is limited by branches of the vertebrobasilar system (26).

The arterial supply the human midbrain is very complex because it is significantly contributed by posterior cerebral artery (PCA) in addition to basilar artery (BA) and superior cerebellar artery (SCA) (1, 27). The rostral midbrain is supplied by branches of mesencephalic artery which is the distal division of BA. The branches of PCA and SCA nourish the caudal midbrain (25). The internal or penetrating artery of the midbrain has a relatively fixed pattern. The internal consistency was noted as early as 1873 by Duret (5) but lacking in the details of the exact point of entry, internal course and area of distribution. The internal arteries could be divided into several groups according to the points of entry and areas that they supply them (5, 6, 7). The internal or penetrating arteries could be concluded as following:

1. The paramedian group (anteromedial) is nourished by the perforating branches arising from the most distal BA that called mesencephalic artery (25), the proximal or P1-segment of PCA. (28, 29), the pars basalis (30), the basilar communicating artery (31) and the basilar bifurcation (32). The perforating arteries of this group are also branches of the initial portion of SCA (33). They run dorsally in the IF and penetrate near the midline (5). They are named median and paramedian branches (30), interpeduncular profunda (34), paramedian mesencephalic pedicle (35), paramedian peduncular artery (31, 36), posterior perforating of Gillilan (37) and mesencephalic perforating artery (29, 38). In addition, Percheron classified the paramedian artery as inferior paramedian mesencephalic artery (IPMA), superior paramedian mesencephalic artery (SPMA) and posterior thalamoperforating artery (PThA) (7, 33, 39). This group of arteries is well known

as "Paramedian thalamo-mesencephalic artery of Percheron" that commonly arises together as a single trunk and also supplies the thalamus (40).

2. The anterolateral group comprises the peduncular branches of collicular and accessory collicular arteries (28, 33, 41), posteromedial choroidal artery (PMChA) (7, 41), anterior choroidal artery (30), P-2 segment of PCA (42) and short circumferential artery (6). In addition, the arteries of this group may also arise from posterior communicating artery (PCoA), a lesser extent from SCA or even the BA (7). Branches of this group supply crus cerebri and adjacent parts of the midbrain (42) and the multiple small arteries terminate within the SN and supply lateral tegmentum (27).

3. The lateral group enters the midbrain from the lateral surface between crus cerebri and tectum in the ambient cistern (5). This group of artery is from branches of SCA, collicular artery and PMChA (7), ambient segment of SCA (43), short circumferential artery (6), lateral branch of collicular artery (44) and short circumferential from P-2 segment of PCA (1).

4. The posterior group consists of arteries that reach the quadrigeminal cistern and terminate or branch to penetrate the colliculus. They are long circumflex branch of PCA (28), quadrigeminal artery (5, 25), arteriae laminae tecti (45), accessory collicular artery of P-2 segment (7), quadrigeminal segment of SCA (43), tectal artery (25), collicular artery (41, 44, 46), medial superior cerebellar artery (7), posterior branch of SCA (47), and PMChA (7, 28). The branches of PCA supply superior colliculus, while those of SCA nourish inferior colliculus (28, 48). There are numerous anastomoses among branches of two arteries over the surface of colliculus (48, 49).

The blood supply of the midbrain of submammalian vertebrates (fishes, amphibians and birds) had been studied by gross dissection after injection with several media such as latex, gelatin, vinylite and Indian ink. It is shown that the arterial supply to the optic lobes is from only caudal branch of internal carotid artery (3). This is different from that of the primitive and higher mammals of which the blood supply to optic lobe is from the vertebrobasilar system (4). In camel, the anterior cerebellar artery and PCA give off mesencephalic branches to supply colliculi (8). In the dog and cat, the basilar bifurcation give off perforating branches supplying the medial zone of the midbrain while the tectal branches of the SCA join the tectal rami of PCA to form the collicular plexus (9). The arterial trunk of SCA gives off branches to supply crus cerebri and caudal colliculus but its distal branch supplies rostral colliculus (10). In addition, by injecting with Indian ink and 3% gelatin, the detailed vascularization in the dog mesencephalon includes tectum, tegmentum and crus cerebri, could be demonstrated (11, 12).

Recently, Majewska-Michalska (13) found that particular parts of the guinea pig midbrain is supplied by SCA, PCA, PCoA and choroid artery. In 1997, she focused on the angioarchitecture of the three parts of the midbrain by injecting with microfil silicone resin. The internal vessels divide into anterior, lateral and posterior groups according to the area supply. Among the three parts of the midbrain, the richest vascularization is observed in the tegmentum, which contains many nuclei. The degree of blood supply is proportional to the accumulation of nerve cells (14).

Although a lot of studies have been carried out in human and various animals, the report regarding to the midbrain venous drainage is very limited. By using a radio-

anatomical study in human, a separate drainage between tegmentum and crus cerebri had been demonstrated. The tegmental veins use the superior or Galenic's pathway but the vein of the base of midbrain have an anterior course draining inferiorly into superior petrosal sinus and/or superiorly into the basal vein (50). The venous blood from the tectum is drained into the specific channel calls "quadrigeminal vein". Such vein could be divided into superior and inferior quadrigeminal veins (51). In the dog and guinea pig, the veins are variable and shorter than the corresponding arteries (11, 12, 14).

As the three dimensional configuration of the midbrain vascular system is difficult to visualize by using light microscopic examination of the serial sections after injection with various substances. The vascular corrosion cast technique using the intravascular injection of methyl methacrylate has been introduced (52) and was successfully studied with scanning electron microscope (SEM) (53). This technique has been employed for detailed studies of microangioarchitecture in various visceral organs in the field of anatomy including the brains of human (54, 55, 56), rat (15), black bear (57, 58) and various organs of the common tree shrew including olfactory bulb (59), pituitary gland (60), pineal gland (61), cerebral cortex (62), cerebellum (63), hypothalamus (64), and choroid plexus (65). However, this technique has not been used to study microvascularization of the midbrain of any animal and human, except in anuran (66). It is of interest to employ this technique in conjunction with SEM to elucidate the midbrain microvascularization in the common tree shrews (*Tupaia glis*), an animal regarded as a primitive primate. (16, 17, 18, 19). Many authors had used tree shrews as a model for the study of visual function since the

animal is with a highly organized visual system (67). On the basis of the morphology of visual system and other criteria, this animal has been considered as the most primitive living primates (67, 68).

CHAPTER IV

MATERIALS AND METHODS

Animal Preparation

Fifteen adult common tree shrews (*Tupaia glis*) of both sexes weighing about 127.93 ± 4.92 g were divided into three groups. The first group was used for gross and morphological observation of the midbrain and relative structures under naked eyes and stereomicroscope. The second group was for histological study of the midbrain under light microscope (LM). The last group was for the study of blood supply and microvascularization of the midbrain with vascular corrosion cast technique in conjunction with stereomicroscope and scanning electron microscope (SEM).

Each animal was anaesthetized with diethylether. The thoracic cavity was opened to expose the heart, injected with 0.05 ml of heparin (Leo 5,000 iu/ml) into left ventricle and let it circulate for one minute. Then, a blunt needle was inserted into ascending aorta through left ventricle and clamped, the right atrium was cut to serve as the efferent port of the blood and injected fluid. Through this blunt needle, gentle perfusion with 200 to 250 ml of 0.9% NaCl solution was made to rinse the blood from the circulation until the efferent solution was clear.

Group I. Gross and Morphological Observation

Immediately after 0.9% NaCl perfusion, 200 ml of Bouin's solution was injected manually through the blunt needle to preserve the tissue. The head was removed and immersed in the same fixative overnight. Then, the head was corroded in

10 % formic acid for 2 to 3 days to remove the inorganic component of the cranial bone. The decalcification bone of the cranial halves was carefully removed to expose the whole brain. The cerebral hemisphere and cerebellum, then, were dissected to show the midbrain and relative structures and viewed with naked eyes, examined and photographed under stereomicroscope.

Group II. Routine Histological Preparation of the Midbrain

The fixative common tree shrew heads were rinsed several times in 70% alcohol until the yellowish solution was lighten. The skulls were decalcified in 10% formic acid for 2 to 3 days. The whole brain was removed, rinsed with tap water. The brains were sliced in sagittal and coronal planes at 2 to 3 mm thick with a sharp blade. Each sliced brain was dehydrated in a graded series of ethanol, cleared with xylene, infiltrated and embedded in paraffin. The embedded tissues were sectioned at 10 μm thick and stained with cresyl violet to evaluate the various areas of the midbrain. The stained sections were viewed and photographed under light microscope (LM).

Group III. Preparation for Studying the Midbrain Vasculature by Using Vascular Corrosion Casts Technique

After perfusing with 0.9% NaCl solution, the modified Batson's # 17 plastic mixture was prepared according to method described by Chunhabundit and Somana (69). Approximately 23 ml of plastic mixture was injected manually into ascending aorta via the same blunt needle at the rate of 8-10 ml/min (70). Most of the blood

vessels were completely filled with the plastic mixture as it was flowed out from the right atrium. The great vessels at the root of the heart were clamped to prevent the leakage of the plastic mixture. The animal was left at room temperature for 1 to 2 hours to let the plastic mixture hardening and complete polymerization of the plastic casts.

The heads of the common tree shrews were cut at the level of first cervical spine, removed skin and tissues and placed into 10% formic acid for 2 to 3 days to decalcify the bone. The brains were removed and divided into three groups. The cerebral hemispheres and cerebellum of the first group were removed to expose the brainstem. The second group was cross sectioned through the midbrain into three levels such as rostral, intermediate and caudal midbrain at 2 to 3 mm thick. The last group was cut into midsagittal and parasagittal sections at the same thickness. All of the three groups were placed in 40% KOH at room temperature for 5 days with daily changing of solution. Then, the corroded specimens were rinsed in tap water and gentle washed with distilled water to remove the remaining tissues. The vascular casts were frozen at -70°C and placed into the lyophilizer overnight. The dried vascular casts were examined under stereomicroscope to select the suitable areas for further investigation with SEM. The specimens were mounted on the metal stub, coated with gold/ palladium. The vascular casts were examined and photographed under SEM at accelerating voltage of 15 kV for study the microvascularization of the midbrain.

CHAPTER IV

RESULTS

In the common tree shrew, midbrain is the largest part of the brainstem. It is covered mostly by the occipital pole of the cerebral hemispheres and partially by the rostral portion of the cerebellum. It lies among the diencephalon anteriorly, cerebellum posteriorly and pons inferiorly (Figs. 1, 3). When cerebral hemisphere and cerebellum have been removed, the dorsal aspect of the midbrain is seen as a prominence with approximately 8 mm long, 5 mm wide and 6 mm high (Fig. 1). The superior colliculus is ovoid and relatively large while the inferior colliculus appears as a small strip situating under the caudal end of superior colliculus (Figs. 1, 3). The small portion of the crus cerebri is seen from the ventral aspect of the brainstem (Fig. 2). There is a furrow between the two crura cerebri and the oculomotor nerves emerge through it. The upper border of the midbrain is limited inferiorly by the optic tract and the mammillary bodies. Its lower end is marked by the pontomesencephalic sulcus.

The LM studies of the coronal sections stained with cresyl violet reveal that the midbrain nuclei are dark and the fibers are relatively lighter. The internal structure of the midbrain could be divided into three important regions as tectum, tegmentum and crus cerebri (Fig. 4). The tectum composes of superior and inferior colliculi which are the mounds of gray matter. The superior colliculus could be divided into superficial, intermediate (central) and periventricular gray zones. It is seen as

laminated structure with six strata due to the arrangement of nerve cells and fibers. As seen in Figure 5, the superficial zone is subdivided into stratum zonale (SZ), stratum griseum superficiale (SGS) and stratum opticum (SO). The intermediate zone consists of stratum griseum intermediale (SGI) and stratum album intermediale (SAI), while the deep or periventricular zone comprises only the stratum griseum profundum (SGP) that adjacent to the central gray. Within the various tectal layers, multipolar cells are present. The optic fibers are seen as a small band entering the ventrolateral side of the superior colliculus (Fig. 5). The inferior colliculus consists of the pericentral, external and the central nucleus of small sized-multipolar cells surrounded by a capsule of white fibers from lateral lemniscus (Fig. 6).

The tegmentum situates ventrally to the cerebral aqueduct containing gray columns and tracts. It situates between the pons and thalamus. The major groups of neurons in the tegmentum are oculomotor nuclear complex, nucleus of trochlear nerve, Edinger-Westphal nucleus, interpeduncular nucleus, mesencephalic nucleus of trigeminal nerve and red nucleus. In the cross section, the oculomotor nuclear complex appears as the interval between V-shape of MLF (Fig. 8). It lies rostrally to nucleus of trochlear nerve and extends to the rostral part of the superior colliculus. The fascicles of the oculomotor nerve course ventrally through the medial side of red nucleus and emerge from the medial part of the crus cerebri and lateral to interpeduncular nucleus. The nucleus of trochlear nerve is seen at the transitional level of the superior and inferior colliculus (Fig. 9). It situates caudally to the oculomotor nucleus and indents the dorsal surface of the MLF. The Edinger-Westphal nucleus is a small collection of neurons seen in the plane of rostral midbrain. It lies close to the

midline and dorsal to the ventral part of oculomotor nucleus at the diencephalon-mesencephalon junction. The mesencephalic nucleus of trigeminal nerve is a scattered strand of small neurons seen in the lateral part of central gray (Fig. 8). The interpeduncular nucleus is a group of cells lying between the two crura cerebri. The red nucleus is a large group of neurons occupying the major part of the tegmentum (Fig. 7). It is a round rod of gray matter and extends from the subthalamic regions at the level of mammillary bodies to the caudal end of superior colliculus which is marked by the decussation of superior cerebellar preduncles. The red nucleus could be divided into pars magnocellularis and pars parvicellularis. The important fiber tracts that could be observed in the tegmentum are MLF, medial lemniscus, lateral lemniscus and decussation of superior cerebellar peduncles.

The substantia nigra (SN) is a curve plate of gray matter situating between the tegmentum and crus cerebri (Fig. 7). It could be subdivided into pars compacta, pars reticulata and pars lateralis. The last part of the midbrain is the crus cerebri that is a small band of white matter under SN. It contains many descending fibers of motor tract from the cerebral cortex (Fig. 4).

The study with vascular corrosion cast technique reveals that the arterial supply of the common tree shrew brain is from internal carotid and vertebrobasilar systems (Fig. 10). Two vertebral arteries (VA) join one another to form a single basilar artery (BA) at the level of the pontomedullary junction. The BA ascends on the ventral surface of pons in the midline and divides into superior cerebellar (SCA) and posterior cerebral (PCA) arteries at the pontomesencephalic sulcus. The internal carotid artery (ICA) gives off anterior cerebral (ACA) and middle cerebral (MCA)

arteries. The anterior communicating artery (ACoA) connects between two ACA. Moreover, the posterior communicating artery (PCoA) communicates between PCA and ICA. Thus, the complete arterial circle of Willis at the base of the brain in the tree shrew is evident (Fig. 10). It is obvious that the blood supply of the midbrain in common tree shrew is from the branches of the vertebrobasilar system, namely the BA, SCA and PCA (Fig. 13). However, the branches from the PCA are the major sources (Figs. 15, 16). The PCA has three types of branches as cortical, central and ventricular branches. The cortical branches mainly supply the cerebral cortex. The central branches convey the blood to the midbrain and other parts of the brainstem. The ventricular branches become the choroid plexuses of the third and lateral ventricles and extend some branches to supply the midbrain. After branching from BA, the PCA could be divided into P_1 to P_4 segments. The P_1 segment is proximal to the stem of the PCoA. It gives off direct perforating branches and peduncular branches to supply the ventromedial and ventrolateral parts of the midbrain. The P_2 segment extends from PCoA in the ambient cistern. It subdivides into anterior (P_2A) and posterior (P_2P) halves (Fig. 17). The P_2A is next to PCoA and runs in parallel to basal vein (BV). It gives off the lateral posterior choroidal artery (LPChA) that enters the choroid plexus of lateral ventricles and also supplies the metathalamus. The P_2A also sends branches to supply the cerebral cortex. The P_2P courses in parallel to the P_2A, inferior to BV and inferolateral to medial geniculate body (MGB). It could be subdivided into collicular and medial posterior choroidal (MPChA) arteries at the inferior pole the MGB (Fig. 17). The collicular artery gives off three to four branches distributing in tree-like pattern to reach the quadrigeminal plate of the midbrain

(Fig. 18). The MPChA extends from P2P and encircles the midbrain at the junction between upper end of superior colliculus and lower part of the thalamus. It sends branches to supply the superior colliculus and the choroid plexus of third and lateral ventricles. The MPChA and collicular arteries in the quadrigeminal cistern seem to be the P3 segment and the terminal branches to the cerebral cortex are the P4 segment. The superior cerebellar artery (SCA) is a branch of BA that emerges under the origin of PCA (Figs. 14, 17). It is separated from the PCA by the third cranial nerve. It then runs in parallel to the vein of the pontomesencephalic sulcus. The SCA is the main branch supplying the pons and the cerebellum. It also sends collicular branch to nourish the caudal pole of the inferior colliculus. The BA also gives off perforating branches at the basilar bifurcation to supply the midline portion of the midbrain and thalamus through the interpeduncular fossa (IF).

As seen in the cross sections of the vascular corrosion cast, the internal part of the midbrain receives the blood from the penetrating branches of the parent arteries that encircle the midbrain (Figs. 13-18). These penetrating branches run in the radial pattern towards the cerebral aqueduct (Fig. 11). According to their points of entry and areas of distribution, these internal radial branches could be divided into anteromedial, anterolateral, lateral and posterior groups. In the anteromedial group, the paramedian arteries are the longest vessels but less in number (Fig. 12). They are usually four. The posterior group is the highest in number of penetrating vessels when compares among the three parts. It is noted that the characteristics of these penetrating branches are the centripetal direction.

The study of the midsagittal sections of the midbrain illustrates the paramedian branches as the direct perforating branches from the basilar bifurcation, SCA and from the P1 segment of PCA (Fig. 12). They enter the midbrain in the fan-like manner to supply the medial part of the midbrain. The paramedian thalamomesencephalic artery is the branch of basilar bifurcation or the P1 segment of PCA. It supplies the midbrain and the thalamus. The paramedian arteries distribute in the areas of interpeduncular fossa (IF), crus cerebri and tegmentum. Finally, they end at the ventral part of the cerebral aqueduct. The tectum which is the area dorsal to the cerebral aqueduct does not receive the blood from arteries of this group but they are from the posterior group.

In order to visualize the distribution of the blood vessels in the various areas of the midbrain, the cross sections of vascular corrosion cast are performed at rostral, intermediate and caudal ends of the midbrain (Figs. 20, 22, 24). The histological sections of the similar levels to the sections of the vascular corrosion cast are put for comparison (Figs. 19, 21, 23). Among the three parts of the midbrain, the tegmentum is the most vascularized area as it contains many nuclei or groups of neurons. The arteries of the anteromedial group that supply the area of the tegmentum are the branches of the basilar bifurcation, SCA and of the initial portion of PCA. They give off direct perforating branches to supply the medial portion of the midbrain (Fig. 22). The oculomotor nuclear complex is supplied by the paramedian thalamomesencephalic branches (Figs. 22, 25 ,26). The right and left paramedian branches run in the IF and penetrate the midbrain at right angle near the midline. They run in parallel to each other in the dorsal direction to reach the floor of the

cerebral aqueduct and also run in curves, arcuate and pass laterally before entering the oculomotor nerve nuclear complex. They embrace the area corresponding to the medial side of the red nucleus and also supply nucleus of trochlear nerve, MLF and decussation of superior cerebellar peduncles. The collateral circulation among the arteriolar branches of the right and left paramedian arteries have not been observed. The anterolateral group consists of the penetrating branches of P1 and SCA (Fig. 25). The peduncular branches of P1 segment supply the crus cerebri and some of them pass through the crus cerebri to supply the SN, lateral side of red nucleus and of CN III and CN IV nuclei. It is noted that the arteries of this group do not reach the cerebral aqueduct. The lateral group is the penetrating branches of the initial portion of the collicular and MPChA arteries that supply the lateral part of the crus cerebri, lateral lemniscus and lateral part of the tegmentum. The branches forming the posterior group come from the collicular artery of P2P, SCA and MPChA. They give off branches to penetrate the colliculus (tectum). Many small arteries are seen to pierce the surface of the colliculus and end at various levels that relate to the arrangement of the layers of superior colliculus (Fig. 25). The dense vascularization is seen in the stratum griseum superficialis, stratum griseum intermedialis and central gray. At the level of inferior colliculus, the vascular density in the central nucleus of inferior colliculus is much higher than that in the superior colliculus.

When examining the midbrain vascular corrosion cast in the cross section at higher magnification (Figs. 27, 28), it is seen that the penetrating arteries give off arterioles and capillary beds inside the midbrain. The dark area indicates the high density of the capillary networks. The high density of the capillaries correspond to the

midbrain nuclei in the tectum and tegmentum. They are superior colliculus, inferior colliculus, oculomotor nuclear complex, trochlear nucleus, interpeduncular nucleus, interstitial nucleus of MLF, red nucleus and SN. It is noted that within the SN, the pars compacta has the most vascular density. The scantly capillary plexuses are usually found in the areas which contain nerve fibers. They are the areas of the crus cerebri, decussation of superior cerebellar peduncles, medial and lateral lemniscus. It is evident that medial part of the crus cerebri has the richest blood supply in comparison with lateral and central part.

When observing the vascular corrosion cast under SEM, it could also reveal that the common tree shrew midbrain receives the arterial supply from many sources (Fig. 29). They are BA, SCA and PCA (Fig. 29). The basilar artery bifurcation gives off the perforating branches to supply the midline region through IF. The PCA gives off some peduncular branches which anastomose on the outer surface of the crus cerebri. In the lateral aspect of the midbrain, the branches of P2A and P2P are shown (Fig. 30). The dorsal surface of the midbrain (quadrigeminal plate) is supplied by the collicular branches of P2P (Figs. 31, 35). There are a lot of arterial anastomoses on this collicular surface. The initial course of small arteries is in parallel to the collicular surface. They penetrate perpendicularly into the internal part the colliculus (Figs 32, 33). The small arteries usually cross over the superficial collicular veins.

After originating from the parent arteries on the surface of the midbrain, the arterial branches could be divided into two sets of the penetrating arteries. The superficial set breaks into arterioles and capillary networks in the superficial layer of the superior colliculus. The set of longer arteries goes deeper and ramifies into

capillary networks in the deep and central gray layers. It is evident that three microvascularization layers could be observed (Fig. 31). The superficial layer is the densest capillary networks. The vascular connections among branches of the penetrating arteries have not been observed. It is noted that the arterial sphincter are often seen at the branching site of small artery (Figs. 41, 42). After branching from the parent artery at the surface of the midbrain, the penetrating arteries rapidly reduce in diameter (Figs. 41). Occasionally, the smooth muscle cells are seen wrapping around the arteries (Fig.43). It is obvious that the capillary networks in the areas of midbrain nuclei are higher density than in the areas of nerve fibers when examine under SEM (Figs. 39, 40). When the surface of capillary casts is observed at high magnification, it appears very smooth indicating that the capillaries in the midbrain is without fenestrations (Fig. 45).

The venous blood from the capillary networks is collected into small venules (Figs. 44) and further into the tributaries of veins before being emptied into the larger veins at the surface of the midbrain. The capillaries in the central part of the midbrain around the central gray and the oculomotor nuclear complex collect the venous blood upward and dorsally into the lateral and dorsal aqueductal vein (Figs. 25, 26, 38). This joins with the thalamocollicular vein that lies in the edge between the superior colliculus and the thalamus (Figs. 18, 34). In some cases, lateral and dorsal aqueductal veins connect directly to the great vein of Galen. The venous blood from the tegmentum and crus cerebri (ventral part to cerebral aqueduct) are drained into the collecting veins which have the larger diameter than that of the accompanying arteries (Fig. 34). These collecting veins empty the blood into the posterior communicating

vein that lies in transverse direction in the IF and connects between the peduncular vein and BV (Figs. 36, 37). Some small veins drain the blood into the vein of pontomesencephalic sulcus that situates between the pons and the crus cerebri. The BV and vein of pontomesencephalic sulcus end at the junction between the superior petrosal sinus and transverse sinus (Fig. 24). The thalamocollicular vein originates from the BV which connects to superior petrosal sinus via lateral mesencephalic vein and then encircles the midbrain beneath the MPChA at the junction between the superior colliculus and the thalamus (Figs. 18, 34). It receives the venous blood from the both areas and drains into the great cerebral vein of Galen and rectus sinus, respectively. Some small veins at the dorsal surface of the caudal part of superior colliculus drain the venous blood directly into transverse sinus. At the junction between the superior and inferior colliculi there are two small veins running from each side and join one another at the midline before draining the blood into the dorsal aqueductal vein. After joining, it runs upward along the midline and connects with two or three veins of the colliculus at the caudal end of the quadrigeminal plate to form collicular vein (Figs. 24, 26). The collicular vein collects the venous blood from both colliculi into the rectus sinus. In some cases, it drains the blood into the confluence sinus and then to the transverse sinus and finally to the external jugular vein mostly and some into the internal jugular vein (Fig. 47).

Moreover, the venous drainage of the midbrain could be divided into three major groups according to the areas of drainage. The anterior or petrosal group is formed by the veins draining anteriorly into superior petrosal sinus. The second is the superior or galenic group that is the veins converging on the great vein of Galen and

the posterior group is the third group which drains into the transverse or rectus sinuses (Fig. 47). In common tree shrew, the veins at the ventral aspect of the midbrain are the posterior communicating, peduncular, anterior mesencephalic veins and the vein of pontomesencephalic sulcus. They drain the blood into the basal vein and then empty into the superior petrosal sinus that is the first group. The thalamocollicular vein that receives the venous blood from the internal part especially the dorsal part of cerebral aqueduct drains the venous blood into the great vein of Galen that is the second groups of venous drainage. The last group could be demonstrated in the caudal midbrain. The collicular or quadrigeminal vein empty directly into the transverse or rectus sinuses.

CHAPTER VI

DISCUSSION

The Anatomy of the Midbrain

In common tree shrew, the midbrain or mesencephalon is relatively very large when compares to the whole brainstem. It is covered by the expanded occipital pole, so that it is not visible from the dorsal aspect. This feature is common in all mammalian members of Orders Marsupialia, Rodentia, Lagomorpha and Primates (71). The internal structure of the common tree shrew midbrain could be divided into tectum, tegmentum and basis as in other mammals (72) and man (20, 22, 23, 24). The tectum or roof consists of superior and inferior colliculi. The superior colliculus in the tree shrew is remarkably large and well developed with distinctively differentiated layers (73, 74, 75). The laminated organization of the superior colliculus in *Tupaia glis* has been studied by many authors basing on the cytoarchitecture, afferent connection (73, 74, 75, 76) and receptive field properties (77, 78, 79). Various authors subdivided the superior colliculus into seven to nine layers by modifying from the pattern of six layers appearing in other vertebrates. The lamination of superior colliculus is formed during embryonic development. The cells migrate toward periphery from the periventricular mass and the successive layers are occurring (80). In *Tupaia glis*, there is the superficial gray layer as in mammals but not in nonmammalian vertebrates (2, 80). Among mammals, the best developed with very distinct layers could be observed in common tree shrew as well as in gray squirrels

(81), rat (82) and cat (83). However, the layers in tree shrew are more clearly depicted. The extremely large superior colliculus in the tree shrew could associate with compensative function for a poor-developed cerebellum. In addition, this well-developed organ could very well relate with effective visual system in order to achieve its arboreal habitat (18). The relative size and differentiation of the superior colliculus is not certain among mammalian Orders. It is very large in flying lemur, squirrel and tree shrew. These animals have common rapid locomotive behavior and with arboreal niche. In prosimian and insectivore, the superior colliculus is relatively small and less differentiated. Eventhough, the superior colliculus of the lemur is smaller than in tree shrew, this animal is with highly visual activity (75). The size of the superior colliculus among the closely related species has been supported to be correlated with different ecological requirements (74).

Unlike in nonmammalian vertebrates, the torus semicircularis (inferior colliculus) lies ventrally to the optic tectum (superior colliculus) because of the lateral expansion of the optic tectum with the tectal ventricle formation. The subdivisions of the inferior colliculus in *Tupaia glis* are quite similar to those in the cat (84, 85) and man (21) being the central, pericentral and external nuclei (84).

It is quite interesting that the tegmental nuclei of the common tree shrew concerning with the visual function are well developed. These nuclei are the oculomotor, trochlear and the Edinger-Westphal nuclei. The red nucleus in the tree shrew is an egg-shaped structure as seen in other mammals (72, 86, 87). The interpeduncular nucleus situates in the midline above the interpeduncular fossa (IF). This nucleus extends from the caudal pole of the mammillary body to the beginning of

the pontine gray. This feature is also exhibited in rodent (88), shrew, bat (89), dog and cat (90). In monkey and man, the whole mass is relatively small (72). The substantia nigra (SN) in the tree shrew could also be divided in zona or pars compacta, recticulata and lateralis as observed in other mammals (72, 88, 89, 90, 91, 92, 93, 94, 95, 96). The melanin pigment is seen in the nigral cells as in other mammalian Orders. However, there is less number of pigmented cells with minimal number of pigmented granules in each cell of the tree shrew substantia nigra. In Primates, the intensity of pigmentation increases when the animals are genetically close to man (97). The crus cerebri in *Tupaia glis* is less developed and relatively small when compare with other parts of the midbrain.

It is obvious that the mainly histological features of the midbrain in common tree shrew are quite similar to those of other mammals, especially primates. However, the large size of the superior colliculus indicates that the tree shrew brain has some primitive features when compare with other primates (18).

The Midbrain Vascularization

In general, the organization of the major cerebral arteries of the brain in common tree shrew is similar to that in man (64). These branches are from the internal carotid (ICA) and the vertebrobasilar systems that form complete circle of Willis. There is anterior communicating artery in the common tree shrew as in man (98, 99) but not in rat (98), opossum, armadillo (4), baboon and vervet monkey (100). It is obvious that the arterial circle of Willis in common tree shrew is quite similar to that of man than these in the rat and other primates. The main sources of the arterial supply

to the midbrain in common tree shrew are from the branches of the vertebrobasilar system. They are basilar bifurcation, posterior cerebral, superior cerebellar, medial posterior choroidal and collicular arteries. These are principally similar to those of man (1, 5, 7, 26), guinea pig (13, 14) and dog (11, 12). As the midbrain receives the blood from many sources and the midbrain in common tree shrew is very large, the organization of the blood vessels in this organ is very complex and quite different from other animals. The area distribution could correspond to the sources of the arterial supply. In the submammalian vertebrates as in fishes, amphibians, reptiles and bird, their midbrains are supplied by branches from the caudal division of the internal carotid artery (ICA) (3). However, the crus cerebri of the midbrain in the guinea pig (14), dog (12) and some cases of human (7, 48, 101), but not in common tree shrew, receives the blood supply from the posterior communicating artery (PCoA). In anuran, the midbrain is supplied by the superior mesencephalic artery that arises from the posterior ramus of the ICA (66) as in the case of other submammalian vertebrates (3). In many higher mammals (3, 8, 10, 11, 12, 13, 14) and man (102, 103) as well as in tree shrew, the posterior cerebral artery (PCA) is the major source of blood supply to the midbrain. This artery in the rat (98) and man (5, 28, 30, 104) usually originates from the basilar artery (BA). It is noted that the symmetrical appearance of the PCA could be observed. In human embryo, the PCA arises as a branch of ICA (25, 26, 28). Stephens and Stilwell (5) proposed that the PCA would be a unique artery as it receives the blood from the basilar artery (BA) but originates from the ICA.

The PCA in common tree shrew could be divided into four segments as in man (28, 30, 42). However, there is some difference from the cases of man that the

collicular artery in the tree shrew does not come from the P1 segment (7, 28). In some cases, there is the accessory collicular artery branching from the P1 segment. The P1 segment of the PCA or basilar communicating artery or mesencephalic artery is the segment that situates between the proximal portion of the PCA extending from the basilar bifurcation to PCoA (5, 25, 26, 28, 30, 35, 39, 105). The term of mesencephalic artery could not be acceptable because of it gives the branches to supply both the midbrain and the thalamus. The infarction occurring in this territories generally results in the mesencephalothalamic syndrome (106, 107, 108).

Most of the arteries that supplying the midbrain in common tree shrew are the branches from the rostral part of the vertebrobasilar system. They give the direct perforating arteries in the interpeduncular fossa and supply the midline region. Then they send the short and long branches encircle the midbrain and give the smaller branches to penetrate the midbrain at right angle into the tissue and reach the cerebral aqueduct. The penetrating arteries exhibit the radial pattern as appears in man (5, 25, 36, 47), guinea pig (13, 14), dog (11, 12), anuran (66) and submammalian vertebrates (3). The general radial pattern of the internal vascularity as seen in the midbrain of the common tree shrew could be observed in all vertebrates including primates.

The pattern of vascular arrangement within the midbrain has been described in man (5, 7, 36, 109), dog (11, 12) and guinea pig (14) as same as in this studies, the arterial supply the common tree shrew midbrain could be divided into anteromedial, anterolateral, lateral and posterior groups according to their points of penetration and the territories that supply them. The origins of the arteries and the arterial vascular

territories in the midbrain and brainstem are the basic information leading to the understanding of various syndromes (6, 47, 109).

The anteromedial group consists of the direct perforating arteries branching from the tip of basilar artery, P1 segment of PCA and initial segment of SCA. They are the paramedian thalamomesencephalic arteries that originate from the parent arteries in the symmetrical fashion. This is different from man of which the main stems of the perforating artery are usually seen in the interpeduncular fossa (7, 29, 32, 33) but after penetrating into the internal part, a tendency to go to the right and left sides is rather symmetrical (110). The penetrating arteries in the anterolateral group do not reach the cerebral aqueduct. They extend as far as the lateral part of the red nucleus (41). The arteries of the posterior group supply large territories when compare with those of other groups. The internal arrangement of this group could be observed as capillary plexuses in many areas corresponding to the cytoarchitectonic strata of the superior colliculus. This is also evident in the cat (111), anuran (66) and man (5, 47). The superficial layer is with the highest vascular density of the capillary networks. The suggestion is made that a lot of numerous of neurons in this layer associates with the visual activities (73, 74, 77, 78, 112). It is evident that there is close relationship among cytoarchitecture , richness of the capillary networks and the neuronal activity.

As observed in the midbrain of man (7, 44) and the cat (113), the arterial anastomoses could be observed in the perimesencephalic part (pial or external part of the midbrain). Such the external arterial anastomoses could be well observed in the dorsal aspect especially in the area of tectum. This is also true in man (7, 44), cat (9), fish, bird and chicken (3), guinea pig (14) and anuran (66). Which could be the reason

why the infarction in this area is very rare (115). In the ventral aspect, as in the man (29, 47), the arterial anastomoses could be less frequently demonstrated among the direct perforating arteries in the interpeduncular fossa (IF). It is also noted that they are considerable amounts of arterial anastomoses on the surface of the cerebral cortex in the common tree shrew (62) and rarely seen in thalamus (115). It is reasonable as the surface area of cerebral cortex is relatively large while that of the thalamus is rather small but the thalamus receives blood supply from branches of both ICA and the vertebrobasilar systems. It should be noted that the arterial anastomoses in the internal part of the midbrain in the common tree shrew could not be observed. The penetrating arterioles terminate into capillary networks as observed in all mammals, especially, in the primates. In opossum and marsupial, however, the capillary networks are not present. Instead, the capillary loops are found (4, 116).

The smooth muscle cells wrapping around the artery including the arteriolar and precapillary sphincters are usually found in the midbrain as well as in the thalamus (115) and in the human cerebral cortex (55, 56). These features could be participated in the regulating of blood flow into the capillary networks. As in the most parts of the tree shrew brain, the capillaries in the midbrain are without the fenestrations. However, the fenestrated capillaries in the tree shrew brain had been observed in choroid plexus (65), pineal gland (61) and pituitary gland (60). This type of capillaries has also been reported in the early developed chicken optic tectum (117).

With the light microscopic study of the midbrain paraffin sections in parallel to that of the sections of the midbrain vascular corrosion cast, it is obvious that the midbrain nuclei locate in the tegmentum are with a lot of blood supply. This finding is

also true in the dog (11) and the guinea pig (14). The dense vascularity could also be seen in the oculomotor nuclear complex, red nucleus, trochlear and interpeduncular nuclei. In pars compacta of SN, the capillary networks are much denser than those in other parts. This is quite similar to what has been reported in man (118), cat, monkey (119, 120) and primates (121). As in the rat (122, 123, 124), the central nucleus of inferior colliculus is with the greatest capillary density in the midbrain. The less vascularized areas are the crus cerebri and lateral part of the midbrain. These areas contain nerve fibers predominantly. It is quite certain that the degree of vascularity depends on the density of nerve cells.

The venous drainage of the midbrain in common tree shrew is quite similar to that in man (5, 50, 125, 126, 127, 128) but somewhat different from the guinea pig (14) and dog (11, 129). In man and in the common tree shrew, the venous drainage in the midbrain could be divided into anterior or petrosal, superior or galenic and posterior groups (130, 131). It is noted that the basal vein in common tree shrew drains the venous blood into both petrosal and galenic groups but dominantly into the great cerebral vein of Galen as in man (125, 127, 130, 131). However, in the dog, this vein drains mainly into the superior petrosal sinus (129). The collicular or quadrigeminal vein in the tree shrew collects the venous blood into the rectus sinus. This is different from man that this vein flows into the great vein of Galen (51, 127).

So far, the tree shrew (Tupaiidae) has been classified as a member of the Order Insectivores (17, 133) or of Order Primates (16, 19, 134, 135, 136, 137) while many authors suggest that it is a transitional form of mammal when basing on the neuroanatomical data of the visual pathway (18, 67, 68, 138, 139). In this study, the

anatomy and histology of the midbrain in common tree shrew (*Tupaia glis*) can not be used as good criteria to classify this animal as Insectivores, Primates or in a separate Order as Order Scandentia (140). However, this study indicates that the midbrain microvascularization in the common tree shrew (*Tupaia glis*) is very similar to that of higher primates.

CHAPTER VII

CONCLUSIONS

The microvascularization of the midbrain in common tree shrew (*Tupaia glis*) has been studied by vascular corrosion cast technique with stereomicroscope and scanning electron microscope (SEM). The findings are:

I. The arterial supply the midbrain

1. The blood supply the midbrain comes from the vertebrobasilar system and its branches. They are the basilar artery bifurcation, superior cerebellar, posterior cerebral, medial posterior choroidal and collicular arteries.

2. These arteries give off branches penetrating into the internal part of the midbrain in the radial pattern. It is the centripetal arrangement directing toward the cerebral aqueduct.

3. The penetrating arteries of the midbrain could be divided into anteromedial, anterolateral, lateral and posterior groups according to the points of penetration and the corresponding territories that they supply.

4. The arterial anastomoses could be observed in the perimesencephalic or pial or external part but not in the deep part of the midbrain.

5. The midbrain capillaries are without the fenestration.

6. The degree of vascularity in the midbrain is closely related to the density of nerve cells. The vascular density is high in the areas occupied by the midbrain nuclei and the low in the areas containing nerve fibers.

II. The venous drainage of the midbrain

1. The venous drainage could be divided into the anterior or petrosal group, the superior or galenic group and the posterior group.

2. The venous blood from the area ventral to the cerebral aqueduct is collected into the posterior communicating, peduncular and anterior mesencephalic veins that empty into the basal vein. The basal vein and the vein of the pontomesencephalic sulcus drain into the anterior or petrosal group.

3. The superior or galenic group receives the venous blood from the thalamocollicular vein, the lateral and dorsal aqueductal veins that drain into the great vein of Galen, rectus sinus, transverse sinus and finally into the external jugular vein predominantly.

4. The posterior group drains the venous blood from the superficial vein of the quadrigeminal plate and collicular veins into the rectus and transverse sinuses.

APPENDIX I

The common Tree Shrew

Taxonomic Status

Kingdom: Animal

Subkingdom: Metazoa

Branch: Enterozoa

Division: Bilateria

Section: Eucoelomata

Phylum: Chordata

Group: Craniata

Subphylum: Gnathostomata (Jawed Vertebrates)

Superclass: Tetrapoda

Class: Mammalia

Subclass: Eutheria

Order: Primate or Insectivore or Scandentia

Suborder: 1. Prosimii

Infraorder: Lamuriformes

2. Menotyphla

Family: Tupaiidae

Subfamily: Tupaiinae

Genus: Tupaia

Species: glis

Subspecies: At least 13 subspecies

Synonyms

Serex glis (Diard, 1820)

Tupaia feruginea (Raffles,1821)

Tupaia müllendorffi (Matschie, 1898)

Tupaia sordida (Miller, 1900)

Tupaia chrysomalla (Miller,1900)

Tupaia phaeura (Miller,1902)

Tupaia castanea (Miller,1903)

Tupaia pulonis (Miller,1903)

Tupaia tephrura (Miller,1903)

Tupaia chrysogastra (Miller,1903)

Tupaia discolor (Lyon, 1906)

Tupaia siaca (Lyon, 1908)

Tupaia lacernata (Thomas& Wroughton, 1909)

Tupaia cuyonis ((Miller,1910)

Tupaia raviana (Lyon, 1911)

Tupaia pemangilis (Lyon, 1911)

Tupaia obscura (Kloss, 1911)

Tupaia riabus (Lyon, 1913)

Tupaia anabae (Lyon, 1913)

Vernacular Names

Common tree Shrew

Spitzhörnchen

Tupaia furrugineux

Painted tree shrew

Mill's tree shrew

Tupajas

Topaies

Tupayes

Tupaide's

Diagnosis

A large tree shrew with a bushy tail that is slightly less to a little more than body length.

Distribution

From Nepal and Sikkim east South China and throughout Southeast Asia to Indonesia but not in Philippine. In Thailand, the following are Thai subspecies that divided into mainland and island subspecies.

Mainland subspecies:

1. *Tupaia glis ferruginea*
2. *Tupaia glischinensia*
3. *Tupaia gliswilkensoni*

4. *Tupaia glis charissa*
5. *Tupaia glis belangeri*
6. *Tupaia glis laotum*
7. *Tupaia glis olivacea*
8. *Tupaia glis concolor*

Island subspecies:

1. *Tupaia glis larcernata*
2. *Tupaia glis cognata*
3. *Tupaia glisoperosa*
4. *Tupaia glis ultima*
5. *Tupaia glis sinus*

Characteristics of common tree shrew

Morphological characteristics

Size	Male	Female
Body length (mm):	161-240	175-240
Tail length (mm):	145-196	140-190
Weight average (g):	177	159

Color: The dorsal parts are red-dish, olive, shades of brown and gray to almost black

: The ventral part is whitish or buff to dark brown

Cranium: Primate-like, rounder, elongated muzzle and small brain case laterally directed orbits but show a part orbital bar

Brain: More complex than that insectivore, the olfactory center reduced, the visual apparatus enhanced, neocortex expanded

Nose: Elongated shrew-like nose terminating in a naked moist snout

Long whiskers: Absent

Eyes: Relatively large, located in the anterolateral side of head and completely encircled by bone

Ears: Quite human inform

Dental formula: Total teeth are 38

Incisor	Canine	Premolar	Molar
$\frac{2}{3}$	$\frac{1}{1}$	$\frac{3}{3}$	$\frac{3}{3}$

Limbs:

Forelimb: Highly mobility, bones of the forearm articulate to allow pronation and supination. Thumb can oppose to the other digits but limited extent

Hindlimb: Longer than forelimb, tibia and fibula are joined by ligaments that can not rotate. Ankle joint can perform lateral movement

Digits: Five fully formed digits on each hand and foot, all digits bear claws, not nails and fully opposable

Tail: Long and slender, but well haired, the longer hairs are confined to the dorsal surface but the ventral surface lacking long hairs

Chromosome: Diploid number =60

Reproductive system:

In female: Mammae: 1-3 pairs, Uterus: Bicornuate

In male: Testis: Scrotal testes, Penis: Pendulous penis

***Tupaia glis* is distinguished from other general of tree shrew by this feature:**

1. The lower lobe of the ear is smaller than the upper part.
2. The naked area on top of the nose is cut squarely across instead of being slightly prolonged backward in the midline.
3. The tail is covered by long hairs.

The main similarities between tree shrew and primates:

Skull: Snout relatively short, enlarged, forward-facing orbits, postorbital bar present, pattern of bones in medial orbital wall, enlarged braincase, advanced form of auditory ossicles

Dentition: Tooth comb present in front of lower jaw

Limbs: Highly mobile, ridged skin on palms and soles, five fully formed digits on each hand and foot, grasping hand characteristic

Brain and sense organ: Olfactory apparatus reduced, visual apparatus enhanced, avascular area of macula, neocortex expanded, calcarine sulcus present

Reproductive: Pendulous penis, scrotal testes, discoidal placenta and small number of feat

Miscellaneous: Caecum present

The main similarities between tree shrews and insectivore:

1. All digits bear claws and not nails
2. The vision is not fully stereoscopic
3. The auditory bulla is constituted from the entotympanic bones and not the petrosal or petrosal plus the ectotympanic

Ecology and Behavior

The common tree shrews actually spend much of their time on the ground foraging on the forest floor and generally omnivorous, eating anything they come across, including ants, termites, beetles, fruit, spiders, seeds, bugs and even lizards and small rodents. There is no evidence that they shovel through the forest litter as shrews do.

Tree shrews are nervous and aggressive animals. Males will not tolerate the presence of other males, through there seems to be little fighting between the sexes. They typically form pairs which are strongly territorial and follow the same pathways within their territory. They are very fond of water and often bath in water-filled hollows of tree.

There is no indication of a breeding season. Pregnancies have been observed to be associated with the period of low rainfall; June, July and August. Nests are built in hole in fallen trees, hallow bamboo or similar site. The gestation period is approximately 41-50 days. The numbers of young are 1-4 (usually 2). Newborn is pink, hairless and has closed eyes. Pigmentation appears on the fourth day. Hair begins to grow on the fifth day. Teeth begin to appear about the eleventh day and the

eyes open on the twenty-fifth day. At sixth months, they are sexually mature. Longevity is 2-3 years, with the maximum of 5.5 years in captivity.

APPENDIX II

Batson's # 17 Plastic Mixture for Vascular Casting

Plastic Mixture Preparation

Batson's # 17 Monomer base solution*	12.5 ml
Batson's # 17 Catalyst*	3.5 ml
Batson's # 17 Promoter*	0.5 ml
Acron Denture Base **	6.5 ml

Prepared in an ice bath, the solution are mixed thoroughly and used immediately.

* Batson's corrosion kit can be obtained from:

Polyscience, Inc.

Paul Valley Industrial Park

Warring, Pa. 18976 USA

** Acron Denture Base can be obtained from:

Yoawarach

Bangkok, Thailand

APPENDIX III

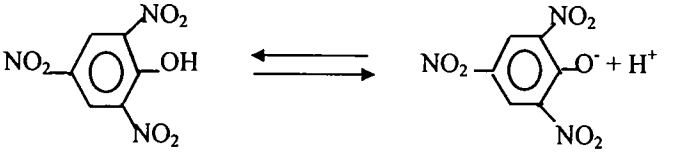
Bouin's Solution (Bouin, 1897)

Saturated aqueous picric acid	750 ml
40% Formaldehyde	250 ml
Glacial acetic acid	50 ml

Bouin's solution is not used in histochemistry but preserves morphological features, especially of connective tissue. This fixative is valuable for purely histological work because physical distortion of tissue is minimal. However, intracellular structures other than nuclei are poorly preserved. Specimens are usually fixed in Bouin's solution for 24 hours, but material stored in it for several months is sometimes still usable. Each of Bouin's solution composition is described following:

1. Picric acid [$C_6H_2(NO_2)_3OH$ or 2,4,6- trinitrophenol]

Picric acid is trinitrophenol. It is a much stronger acid than unsubstitited phenol aqueous solution owing to the electron-withdrawing effect of the three-nitro groups on the hydroxyl group:



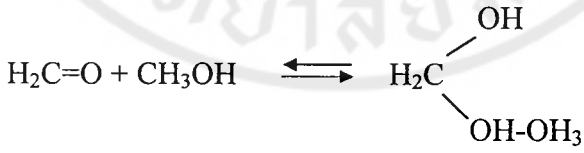
Trinitrophenol is a bright yellow solid. It is dangerously explosive when dry and is therefore stored under water. It is sparingly soluble in water (about 1% at room temperature) but more so in alcohol (nearly 5%) and benzene (10%).

2.Formaldehyde

formaldehyde is a gas (-21°C) with the structural formula 
It is solution in water to containing 37-40% by weight of the gas in water and sold under the name of 40% formaldehyde or formalin. In aqueous solution, formaldehyde is present as methylene hydrate or methylene glycol, the product of the reaction:

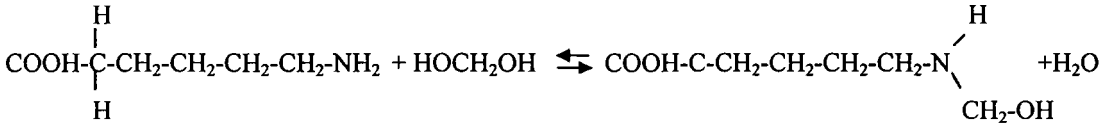
$$H_2C{=}O + H_2O \rightleftharpoons HOCH_2OH$$

Therefore, formalin also contains solution polymers of the form HO(CH2O)nH (n = 2-8), know as lower polyoxymethylene glycol. The polymers are hydrolyzed when formalin is diluted with on excess of water. Thus, trioxymethylene glycol ($HO(CH_2O)_3H$): $HO(CH_2O)_3H + 2H_2O \rightleftharpoons 3HOCH_2OH$. Formalin also contains methanol (commonly about 10% v/v) which is added a stabilizer to inhibit the polymerization. Methanol is formed by formaldehyde a hemiacetal (methylal), Which is more stable than methylene hydrate:



The content of formaldehyde in a fixative is best denoted by stating the percentage by weight of the gas rather than the amount of formalin used in preparing the mixture. Thus, 4% formaldehyde is referred to 10% formalin (for the same solution), though the latter designation is in common use.

Formaldehyde reacts with several parts of protein molecules. The methylene glycol molecule added to many functional groups to form hemiacetal and related adducts. For example, with primary amines (N-terminal amino acids and lysine side-chain):



This reaction are all readily reversible by washing in water or alcohol. However, the hemiacetal-like adducts all have free hydroxymethyl groups and there are capable of further reaction with functional groups of protein:

Thus, different protein molecules can be joined together by methylene bridges, which are chemically stable. Cross-linking of protein molecules by formaldehyde is much slower than the other fixative agents and requires 1-2 weeks for completion at room temperature. For non-histological methods especially for the nervous system, work better after complete fixation very long periods of storage in the formaldehyde solution results in excessive hardening, loss stain ability of nuclei.

Formaldehyde preserves most lipids. The chemical reactions of formaldehyde with lipid under ordinary conditions of fixation are 1). Addition to the amine groups of phosphatidyl ethanolamine which is probably reversible by washing in water 2). Prevention of the histochemical reactivity of plasmologens owing to oxidation, probably to a glycol, of the ethylenic linkage next to the other group.

Formaldehyde dose not react with carbohydrate. All common mucosubstances can be demonstrated after fixation with formaldehyde through appreciable quantities of glycogen are lost. Bouin's solution are preferable to formaldehyde because 1). It protects the tissue against damaging effects of embedding in wax, and 2). Staining with almost of dyes is brighter then after formaldehyde alone. In addition, formalin gives off an unpleasant vapor that causes irritable to the eyes, respiratory epithelium and unpleasant "formalin dermatitis" after immersion of hands in this solution.

3.Glacial acetic acid (CH_3COOH)

Pure acetic acid is called "glacial" because it solidifies at 17°C if water free. It does not fix protein, but it coagulates nucleic acids. The mechanism by which this change is brought about is obscure. Gracial acetic acid is included in fixative mixtures to preserve chromosomes, precipitate the chromatin of interphase nuclei and oppose the shirking actions of other agents such as ethanol and picric acid.

APPENDIX IV

Cresyl Fast Violet Stain Paraffin Section

Fixative: Bouin's solution

Section: Paraffin section at 10 μm

Preparation of stain:

Cresyl Fast Violet (Cresyl Violet Acetate)	1 g
Distilled Water	100 ml

Method:

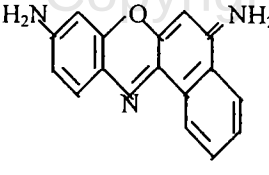
1. Dewax section and remove wax with xylene, rinse in second dish of xylene.
2. Rinse in absolute, 95%, 90%, 80%, 70% alcohol and bring to distilled water.
3. Cover with filtered cresyl fast violet, stain for 20-30 minutes.
4. Wash in distilled water and place in 70%, 80%, 90% alcohol.
5. Leave in 95% alcohol until excess stain has been removed.
6. Pass through absolute alcohol into three changes of xylene and mount in Canada balsam.

Results:

- Nissl substance — deep purple-dark blue
- Nuclei and some cytoplasmic process of neuron — purple-blue
- Background — colorless

Note:

1. Cresyl Violet Acetate (No C.I. number; M.W. 321)



Cresyl Violet Acetate is the modern equivalent of cresyl fast violet (cresyl echt violet). Both are often loosely formed "cresyl violet". They are useful as violet cationic dyes, soluble in water and alcohol. They are popular as "Nissl stains" for nervous tissue. Basing on the structures of the major chromopholic systems, cresyl violet acetate is synthetic oxazine dye which consists of the oxazine chromophore []. The oxazine chromophore has obvious similarity to those of the azine and thaizine dyes and exists in o-quinonoid form (with positive change attributed to the oxygen) and p-quinonoid form.

2. If only Nissl substance in required to be demonstrated the stain is acidified with 0.25 percentage acid.

APPENDIX V

Film Processing for SEM Photograph

Negative Film Processing

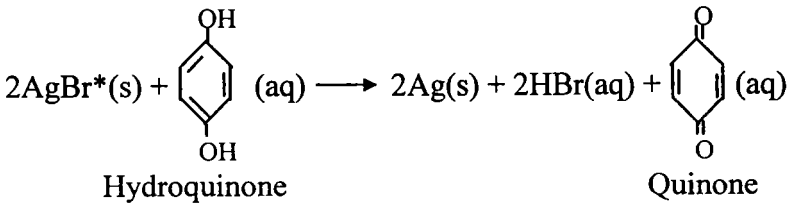
1. Load the exposed film into the film holder in the dark room.
2. Wash the film in the cool distilled water (20-21°C) for 1 minute to clear the excessive softening of the emulsion.
3. Develop with Microdol-X (22°C) with continuously stirred for 12.5 minutes to silver metallic under alkaline condition.
4. Wash in the distilled water for 1 minute.
5. Place in stop bath (acetic acid) for 1 minute to stop the reaction of the developer.
6. After washing in the distilled water for 1 minute, the film is immersed in a fixer to convert silver thiosulfate that is water-soluble. this step is under acidic condition which will neutralize excess alkaline developer that preventing film fog.
7. Wash in distilled water before placing in hypoclearing agent for 2 minutes.
8. The well developed film can be visualized under the room light. It is rinsed in the tap water for 10-15 minutes before dipping in the water-repellent fluid (photo flo) for 1-2 minutes to prevent water spots.
9. Finally, the film is dried in the film dryer or left in the opened air.

Note:

1. The process of film development involves a redox reaction. Black and white photographic film contains small grains of silver bromide, evenly over a thin gelatin coating on paper. Exposures of the film to light activates silver bromide as follow:

$$AgBr + Light \longrightarrow AgBr^{*} \text{ (AgBr affected by light)}$$

Next, the exposed film is treated with a developer, a solution containing a mild reducing agent such as hydroquinone as follows:



Hydroquinone Quinone

In this redox process, The Ag^+ ions in the activated AgBr are preferentially reduced to metallic (silver) while hydroquinone is oxidized to quinone. After placing in acetic acid ($HC_2H_3O_2$) to complete reaction with hydroquinone, the unreacted AgBr must be removed from the film by treated with a fixer. The fixer is a solution containing sodium thiosulfate ($Na_2S_2O_3$) to removed the silver ions:

$$AgBr(s) + 2S_2O_3^{2-}(aq) \longrightarrow Ag(S_2O_3)_2^{3-}(aq) + Br^-(aq)$$

Enlargement and Printing

The quality of the negative film should be evaluated prior enlarging. To classified the quality according to the contrast are three groups. The low contrast negative film requires high contrast papers (BH papers), while the medium to high contrast negative film should require the normal to low contrast papers (BN to BS papers). The process of enlargement and printing is done under the safe light as follows:

1. Place the negative film on the negative holder by emulsion down.
2. Turn on the light source of enlarger and open the aperture widely.
3. Adjust the enlarger by either raising up or lowing down for the appropriated size as need. The image is projected on the easel.
4. The sharp grains on the image, seeing with the image focuser, is adjusted by focusing knob.

5. Adjust the easel until the image fills on the paper.
6. Set the appropriate aperture.
7. Turn off the light of the enlarger and set the proper exposure time.
8. Place the photographic paper in the easel, turn on the light of the enlarger and allow exposing it for the desired time.
9. Take the exposed paper and submerged in developer (Dextol:water = 1:2).
10. Transfer the developed paper to stop bath for 20 to 30 second minutes.
11. Rinse in running tap water and dip in fixer for fixer for 15 minutes.
12. Wash the photograph in running tap water for 30 minutes to 1 hour.
13. Submerge in a dilute water-repellent agent (Photo flo) for 15 minutes.
14. Dry with the print dryer or air dry and the scanning electron micrograph is now ready for evaluation.

BIOGRAPHY

NAME Miss Churairat Duangchan

DATE OF BIRTH 28 July 1970

PLACE OF BIRTH Petchaburi, Thailand

INSTITUTIONS ATTENDED Prachomklao Nursing College, Petchaburi,1989-1993: Diploma in Nursing (Equivalent to Bachelor of Science in Nursing) Mahidol University, 1998-2000: Master of Science (Anatomy)

POSITION & OFFICE 1993-Present, Prachomklao Nursing college, Petchaburi, Thailand. Position : Instructor
