## ACKNOWLEDGMENT

I would like to express my sincere gratitude and deep appreciation to Dr. Pairash Saiviroonporn my major advisor for his guidance, invaluable advice, supervision and encouragement throughout. He was never lacking in kindness and support. I am equally grateful to Dr. Kitima Thammarak and Dr. Kamolwan Choegmeechoke my co-advisors for their constructive comments, supervision and encouragement. They were always nice and friendly.

I also express my appreciation to the examination committee, Dr. Vipha Boonkitticharoen and Associate Professor Manus Mongkolsuk. I would like to thank Ms. Somporn Krasaesub who taught me about SPSS program for window.

I wish to thank, SM1 Suwan Lagdang and SM1 Watanachai Julasak, the technicians of magnetic resonance imaging at Royal Thai Army hospital for their co-operation and generous assistance. I also thank Mr. Somrak Chaipipat, the MR engineer GE Medical System, who help me in MRI data.

I am particularly indebted to the school of Medical Physics for my academic knowledge and all staff members for their good collaboration.

Finally, I thank my family, my husband and son, for their encouragement throughout. Word can not describe all they have done for me.

Fast fluid-attenuated inversion recovery (FLAIR) pulse sequence, is a powerful method for detecting intracranial lesions especially those located near ventricles. This method generates a  $T_2$ -weighted image nulling the cerebrospinal fluid (CSF), thus creating a distinct image of the lesion. The purpose of this study was to determine the optimal TI values of fast FLAIR technique in order to suppress signal CSF so as to obtain a good periventricular image.

Seventeen patients (age 40-86 years), were sampled for this investigation on the basis of their periventricular lesions appearing as bright images by both fast FLAIR and  $T_2$ -weighted fast spin echo (FSE) imaging techniques. A total of 41 lesions were examined by the magnetic resonance imaging (MRI) unit for brain investigation (1.5 Tesla imager).  $T_2$ -weighted FSE image was the standard of reference. The patients were scanned by fast FLAIR pulse sequencing of varying TI (2000, 2100, 2200, 2300, and 2400 msec). Signal intensity (SI) values for CSF, white matter (WM) and the lesion were averaged from data acquired from 5 images and subsequently used for determining signal to noise ratio (SNR), contrast to noise ratio (CNR), and contrast ratio (CR).

The fast FLAIR with TI 2100 msec was found to yield minimal  $SNR_{CSF}$ , maximal  $CNR_{lesion,CSF}$  and maximal  $CR_{lesion,CSF}$ . Statistically, the  $CNR_{lesion,CSF}$  and  $CR_{lesion,CSF}$  were superior to those obtained from  $T_2$ -weighted FSE imaging ( $p$ -value < 0.0005). When the comparison was made between the lesion and WM,  $CNR_{lesion,WM}$  and  $CR_{lesion,WM}$  were at maximum TI of 2400 msec. However, the  $CNR_{lesion,WM}$  image was less distinct than those obtained by the standard approach ( $p$ -value < 0.005). In conclusion TI of 2100 msec is the optimal value for fast FLAIR imaging of the periventricular lesions.

พัชราภรณ์ แสงเรืองอ่อน : การศึกษาปัจจัยกำหนดการแยกความเปรียบต่างของขบวนการสร้างภาพคลื่นสนามแม่เหล็ก โดยวิธีให้ลำดับคลื่นวิทยุแบบ ฟลูอิด-แอทเทนนูเอเต็ด อินเวอร์ชันรีคัฟเวอรี ( CONTRAST OPTIMIZATION OF FLUID - ATTENUATED INVERSION RECOVERY (FLAIR) PULSE SEQUENCE IN MRI ) คณะกรรมการควบคุมวิทยานิพนธ์: ไพรัช สายวิรุณพร วศด., กิติมา ธรรมรักษ์ พบ., กมลวรรณ จึงมีโชค พบ., 146 หน้า ISBN 974-664-223-5

ปัจจุบันเราให้ความสนใจกับการสร้างภาพด้วยคลื่นสนามแม่เหล็ก โดยการให้ลำดับคลื่นวิทยุแบบ fast fluid-attenuated inversion recovery (FLAIR) pulse sequence ในการวินิจฉัยโรคทางสมองโดยเฉพาะเมื่อมีรอยโรคที่อยู่ใกล้หรือล้อมรอบน้ำหล่อเลี้ยงสมอง (CSF) ที่อยู่ในโพรงสมอง ในการให้ลำดับคลื่นวิทยุแบบนี้ จะให้ภาพเป็น  $T_2$ -weighted image ขณะเดียวกันสามารถทำให้สัญญาณที่ได้จาก CSF เป็นศูนย์ ทำให้เห็นขอบเขตของรอยโรคที่อยู่ใกล้หรือล้อมรอบน้ำหล่อเลี้ยงสมองที่อยู่ในโพรงสมองได้ดียิ่งขึ้น การศึกษานี้เพื่อหาค่า TI ที่เหมาะสม เพื่อสามารถแยกความเปรียบต่างระหว่างรอยโรคที่อยู่ล้อมรอบน้ำหล่อเลี้ยงสมองกับน้ำหล่อเลี้ยงสมองในโพรงสมองได้ดีที่สุด

กลุ่มตัวอย่างเป็นคนไข้ที่มาตรวจสมองด้วยคลื่นสนามแม่เหล็ก 1.5 เทสลา ที่ร.พ. พระมงกุฎเกล้าซึ่งมีรอยโรคปรากฏเป็นขาวทั้งใน fast FLAIR images และ  $T_2$ -weighted fast spin echo (FSE) images อยู่ล้อมรอบ CSF มีอายุตั้งแต่ 40-86 ปี จำนวน 17 ราย มีจำนวนรอยโรคทั้งหมด 41 รอยโรค ผู้ป่วยทุกรายได้รับการตรวจสมองด้วย fast FLAIR pulse sequence ที่ใช้ค่า TI ต่างกัน 5 ค่า (TI 2000, 2100, 2200, 2300 และ 2400 msec) และ  $T_2$ -weighted FSE pulse sequence เพื่อวัดค่าเฉลี่ยความเข้มของสัญญาณ (SI) ของ lesions, CSF, white matter (WM) ข้อมูลที่ได้นำมาหาค่า signal to noise ratio (SNR) ของทั้ง 3 เนื้อเยื่อ, contrast to noise ratio (CNR) และ contrast ratio (CR) ของ lesion กับ CSF และ WM ปรากฏว่า fast FLAIR pulse sequence ที่ TI 2100 msec ให้  $SNR_{CSF}$  ค่าที่ดีที่สุด ค่า TI นี้แตกต่างจากค่า TI ที่ประมาณได้ทางคณิตศาสตร์ เพื่อให้ได้ SI ของ CSF เป็นศูนย์ เท่ากับ 4.4%. โดย  $CNR_{lesion,CSF}$  และ  $CR_{lesion,CSF}$  ให้ค่าสูงสุดที่ TI 2100 msec ซึ่งค่าเหล่านี้สูงกว่าเมื่อเทียบกับ  $T_2$ -weighted FSE sequence (P-value < 0.0005).  $CNR_{lesion,WM}$  และ  $CR_{lesion,WM}$  ให้ค่าสูงสุดที่ TI 2400 msec โดย  $CNR_{lesion,WM}$  ของ fast FLAIR ที่ TI 2400 msec มีค่าน้อยกว่าเมื่อเทียบกับ  $T_2$ -weighted FSE pulse sequence (P-value < 0.005). ดังนั้น fast FLAIR pulse sequence ที่ TI 2100 msec ให้ contrast optimized ระหว่าง Periventricular lesion กับ CSF ดีที่สุด และดีกว่า เมื่อเทียบกับ  $T_2$ -weighted FSE pulse sequence.

T	Tesla
$T_1$	Longitudinal relaxation time
$T_2$	Transverse relaxation time
TI	Inversion time
TE	Echo time
TR	Repetition time
WM	White matter

## CHAPTER I

### INTRODUCTION

Previously, conventional  $T_2$  - weighted spin - echo (SE) magnetic resonance (MR) imaging has been a mainstay of evaluation many pathologic processes of the brain such as multiple sclerosis, infarct etc.(1). Most of these pathologic processes increase the  $T_2$  relaxation times of the affected tissue, causing the lesion to have signal intensities intermediate CSF and normal gray or white matter on  $T_2$  - weighted images (1,2). Therefore  $T_2$  - weighted images may be difficult to make diagnosis (3) when these lesions have side touching to the CSF border.

Recently, we are interested in fluid - attenuated inversion recovery (FLAIR) pulse sequence because the FLAIR sequence is a magnetic resonance imaging (MRI) sequence designed to produce a strongly  $T_2$  - weighted images while CSF signal is suppressed (2). We apply a  $180^\circ$  inversion - recovery pulse and chose an inversion time (TI) to allow the longitudinal magnetization of CSF to return to the null point before spin echo imaging(4). At this point, all other brain tissues have made almost complete recovery of longitudinal magnetization toward equilibrium. Also, the use of a long repetition time (TR) permits tissues with even very long  $T_1$  relaxation time to completely recover. This minimizes  $T_1$  differences of non-CSF tissues, thus producing heavy  $T_2$  -weighting given the relatively long echo time of the sequence. The CSF signal is completely suppressed, and pathologic lesions, with their typical  $T_2$

prolongation in the brain adjacent to CSF interfaces, become easily discerned in comparison with conventional  $T_2$ -weighted imaging (2).

The basis of the FLAIR method is to select the TI time so that the signal from CSF is nulled. It relies upon the known lengthy  $T_1$  relaxation time of CSF according to the equation (1) :

$$TI_{\text{null of CSF}} = T_{1 \text{ of CSF}} \{ \ln 2 - \ln ( 1 + e^{-(TR)/T_1} ) \} \quad (1)$$

Where,  $TI_{\text{null of CSF}}$  defined TI that make CSF is nulled.

TR is repetition time.

$T_{1 \text{ of CSF}}$  is the longitudinal relaxation time of CSF.

Using this equation,  $TI_{\text{null of CSF}}$  was calculated as a function of TR. from equation (1) that in the limit of infinite TR, the maximum  $TI_{\text{null of CSF}}$  is  $TI_{\text{null of CSF}} \times \ln 2$  (6). Thus  $TI_{\text{null of CSF}}$  required to known  $T_{1 \text{ of CSF}}$  to predicted contrast performance.

However, the major disadvantage of conventional FLAIR sequence is a very long acquisition time (7) caused by the long TI and TR that required both null CSF and adequate non - CSF tissues signal recovery before readout (1). One solution to improve the imaging efficiency of FLAIR is the use of the newer “FAST” or “TURBO” spin echo sequences based on the rapid acquisition with relaxation enhancement ( RARE ) technique (2),

This study measured  $T_{1 \text{ of CSF}}$  from 14 healthy volunteers with inversion - recovery ( IR ) technique, because this method is the most precise and accurate (8). The volunteers were performed with TR of 11,000 msec, and three different TI values

of 1500, 2000, 2600 msec. The SI of CSF was measured on each of three IR images. The acquired data from measurement is plotted between SI values with difference TI and determinate  $T_{1 \text{ of CSF}}$  by using the SPSS program for window. Then using  $T_{1 \text{ of CSF}}$  calculate interval of TI value to get the signal from CSF to be null in the equation (1).

Therefore we got the optimum TI values to performed fast FLAIR imaging from 17 periventricular lesion patients that these lesions show bright in both fast FLAIR images and  $T_2$ -weighted fast spin echo (FSE) images. Using fast FLAIR pulse sequence in different TI and  $T_2$ -weighted FSE pulse sequence scanned all the patients. Then we measured the mean SI of the lesions, CSF and WM. The data was calculated for SNR of individual type of tissues, CNR and CR of the lesion to CSF and normal adjacent WM. To evaluate optimum of TI value with fast FLAIR pulse sequence, to suppress CSF with good periventricular lesions to CSF contrast, and comparison with  $T_2$ -weighted FSE pulse sequence.

## CHAPTER II

### OBJECTIVES

#### Main objective

To determine the optimum TI value with fast FLAIR pulse sequence, to suppress CSF with good periventricular lesions to CSF contrast.

#### Sub-objective

1. To determine the values of  $T_1$  of CSF in lateral ventricles from healthy volunteers.
2. To compare fast FLAIR pulse sequence with optimum TI to suppress CSF with that of a  $T_2$ -weighted FSE pulse sequence in the evaluation of periventricular lesion that have side touching the CSF border of lateral ventricles.

## CHAPTER III

### THEORY

#### The cerebrospinal fluid spaces

Cerebrospinal fluid (CSF) in the cranial cavity appears within the ventricular system, cisternal spaces and the interstitium of the brain parenchyma. Function of CSF is an intermediary pathway between the neural tissue and vascular capillaries, providing nutrients and metabolites to the brain parenchyma. The choroid plexus in the ventricular cavity and the ventricular ependyma produces CSF. The largest volume of choroid plexus is located along the ependymal surfaces of the atrial walls of the lateral ventricles, while the rest is in the roof of the third ventricle, and along the posterior inferior surface of the fourth ventricle (Figure 1). CSF is produced continuously at rate of 25 ml/h (0.35-0.40 ml/min) (11). In the normal state, the total CSF volume at any time is 120 to 135 ml. Of this amount, 25 to 35 ml is within the ventricular space and the remaining is in the subarachnoid cisterns, with a small amount within the interstitial spaces of the brain parenchyma. CSF flows from the interstitial space to the ventricles and then to the subarachnoid cisterns by transmitted force from vascular pulsation (Figure 1). During its passage and turnover within the interstitial spaces, it allows the exchange of metabolites and nutrients.

CSF within the ventricles and the subarachnoid space has constant motion. On MRI, its signal characteristics depend on several factors.

1) The image acquisition time ( TR/TE ).

The longer acquisition time commonly causes loss of CSF signal. This is called CSF flow void sign therefore when evaluating long TR sequence MRI flow-related artifacts in the CSF spaces should be kept in mind.

2) Nature flow factor.

There is disturbance of CSF flow at narrow segments of CSF pathway such as the aqueduct of Sylvius, the foramen of Monro, these regions show varying CSF signal intensity depend on flow dynamics. The usual signal intensity of CSF is hypointense on  $T_1$  weighted image and hyperintense on  $T_2$  weighted image.

3) The relaxation time of the CSF and its constituents.

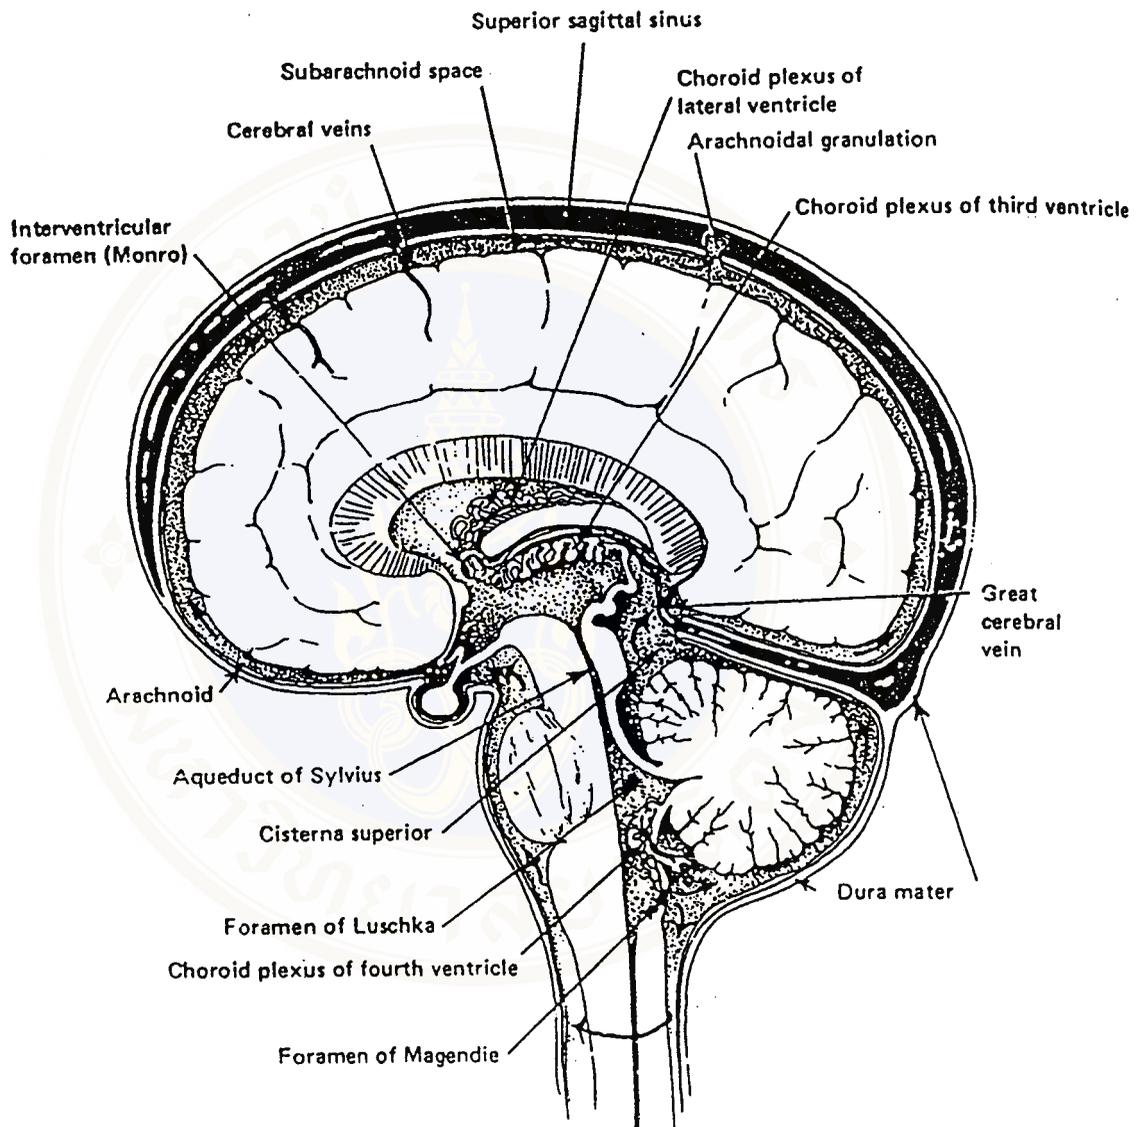

Figure 1. Midsagittal section of the brain demonstrating the choroid plexus of lateral ventricles; third ventricle and fourth ventricle including direction of CSF flow from the interstitium space to the ventricles and to the subarachnoid cisterns (10).

## Basic principle of magnetic resonance.

### 1. Atomic structure.

Atom composes of a core-nucleus and surrounding cloud of electrons. The nucleus consists of positive electrical charge called proton and neutral electrical charge called neutron (11). When a proton as charged sphere, spinning it represents a current flowing in a loop around the axis of rotation, thereby generating an electromagnetic field (12) ( Figure 2 ). We can think the proton as a “bar magnet”.

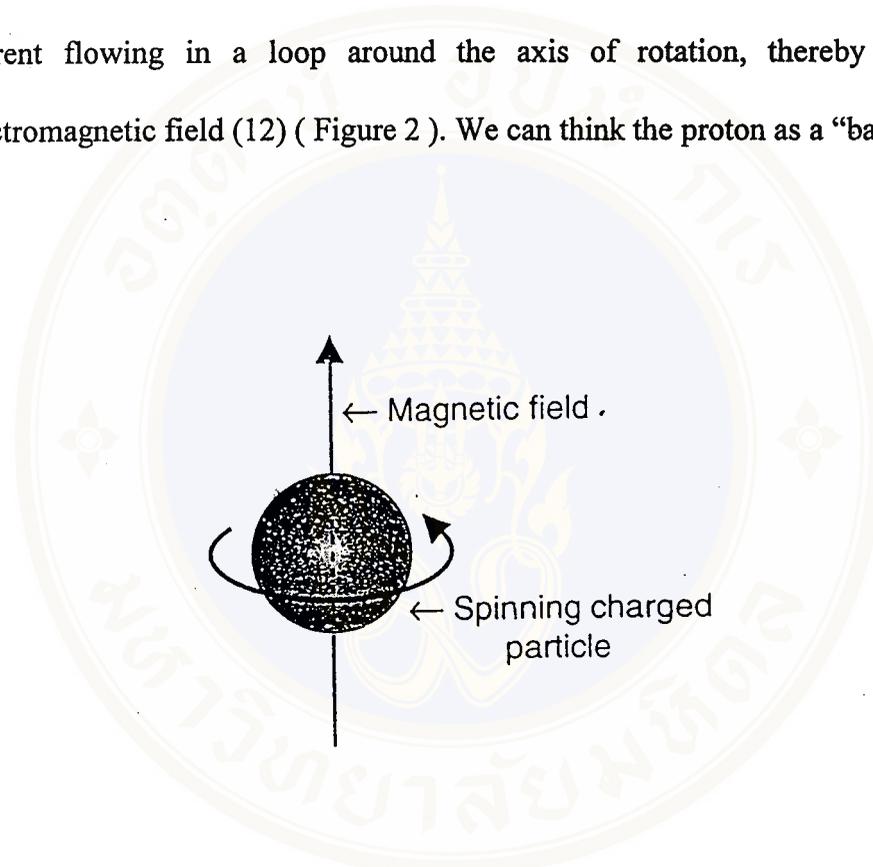

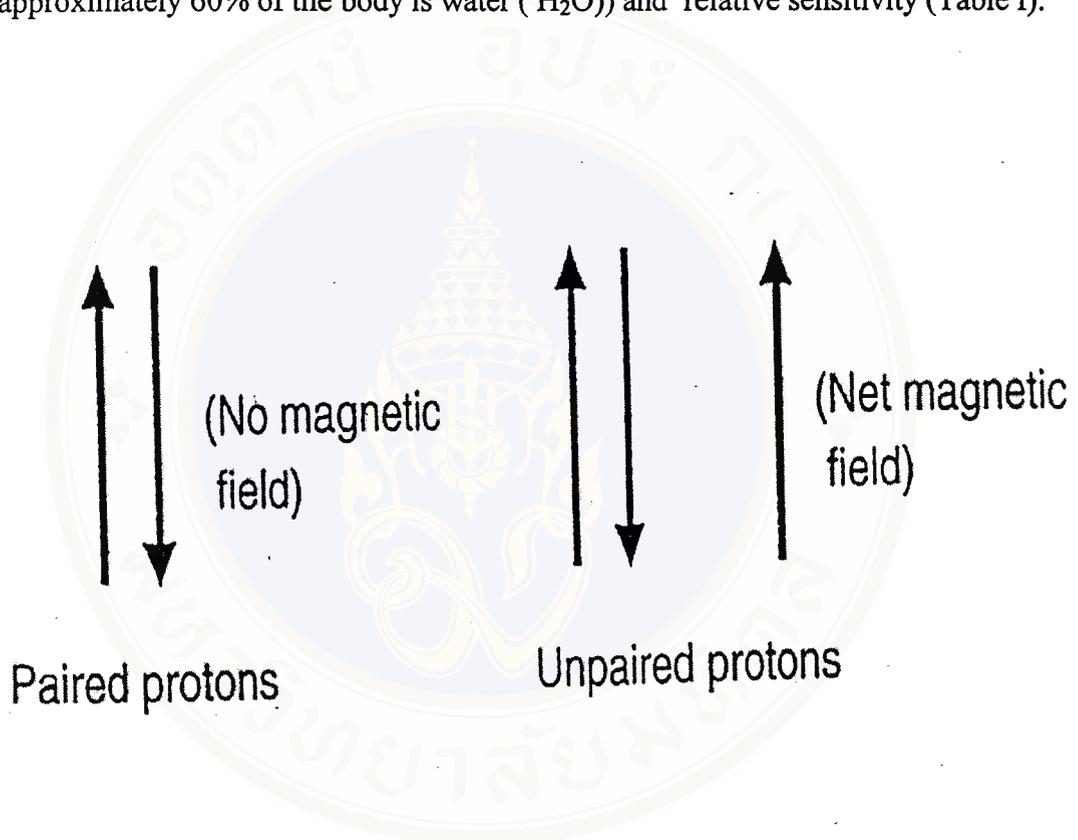

Figure 2. A spinning charged particle generates a magnetic field (13).

### 2. MR active nuclei.

MR active nuclei are nuclei that have odd number of protons or neutrons. That means there is one proton or neutron unpaired. The unpaired proton points either north or south and has a net magnetic field or “magnetic dipole moment”, its

symbol is  $\mu$  (Figure 3). But the nuclei that have even number of protons and neutrons, they will pair that means every spin with magnetic field pointing up, will have a paired spin with magnetic field pointing down. So the magnetic field of even nuclei will cancel and net magnetic field is zero. However in MRI, we are interested in hydrogen nucleus which has a single positive charged proton due to its natural abundance (approximately 60% of the body is water ( $\text{H}_2\text{O}$ )) and relative sensitivity (Table I).

**Figure 3.** A. The magnetic fields of paired protons with cancel each other out, giving no net magnetic field.

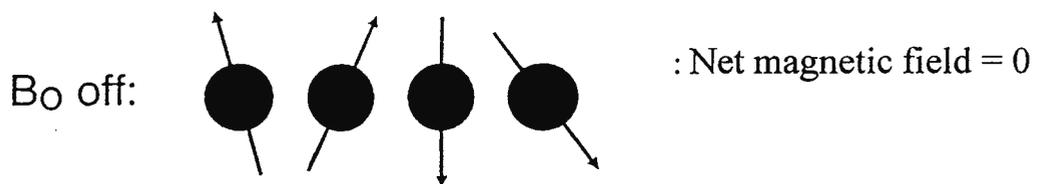

B. Show that unpaired proton gives a net magnetic field (13).

**Table I.** Show magnetic properties of medically important nuclei (14).

Nucleus	Spin Quantum Number (S)	Gyromagnetic Ratio (MHz/T)	Natural Abundance (%)	Relative Sensitivity
$^1\text{H}$	1/2	42.58	99.98	1
$^{13}\text{C}$	1/2	10.71	1.11	$1.7 \times 10^{-4}$
$^{19}\text{F}$	1/2	40.05	100	0.83
$^{23}\text{Na}$	3/2	11.26	100	$9.2 \times 10^{-2}$
$^{31}\text{P}$	1/2	17.23	100	$6.6 \times 10^{-2}$

### 3. MR active nuclei in the absence of an external field $B_0$ .

MR active nuclei in the absence of  $B_0$  will be randomly oriented, giving zero magnetization of the material (Figure 4).

**Figure 4.** In the absence of  $B_0$ , their net magnetic field will be zero (13).

#### 4. MR active nuclei in the presence of $B_0$ .

MR active nuclei in the presence of an external field  $B_0$  tends to align with the applied field, but they don't all align up in the same direction. Estimate half point north and half point south. Over time, more spins align with the applied field, generating net magnetization (Figure 5).

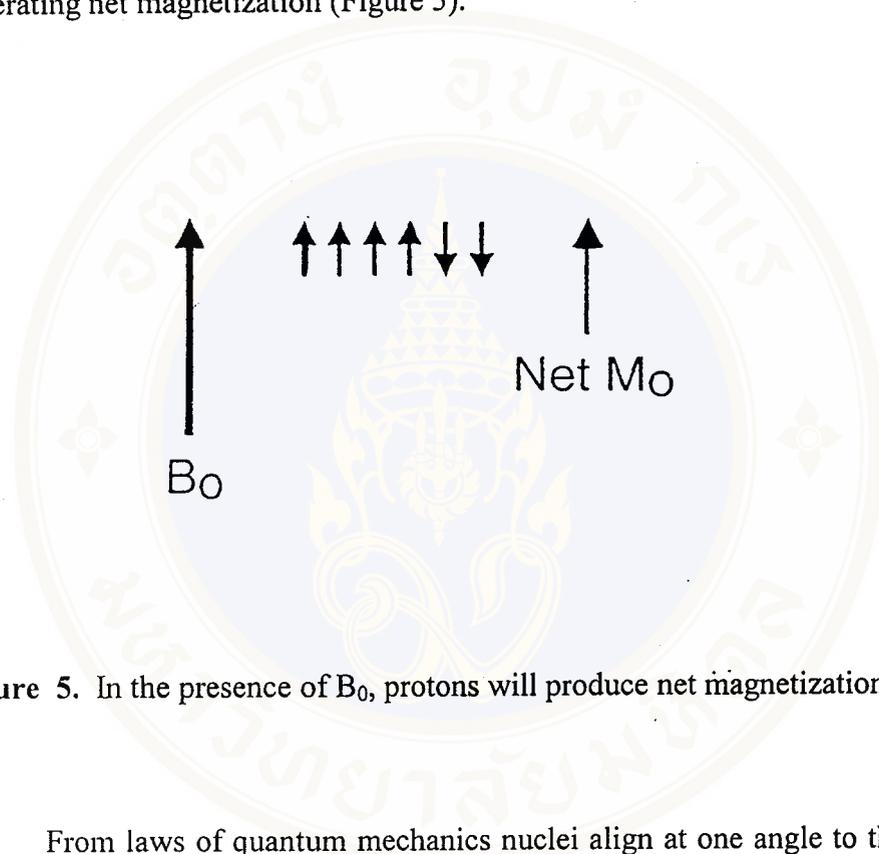

Figure 5. In the presence of  $B_0$ , protons will produce net magnetization (13).

From laws of quantum mechanics nuclei align at one angle to the direction of the field have specific energy levels related to property called “ spin quantum number  $S$  ”(13). The hydrogen nucleus has a spin quantum number  $S$  of  $1/2$  (Table I). The number of energy states of nucleus is determined by the equation: (13)

$$\text{number of energy states of nucleus} = 2S + 1 \quad (2)$$

$$\text{For a proton with a spin } S = 1/2$$

$$\text{So number of energy states of hydrogen nucleus} = 2(1/2) + 1 = 2$$

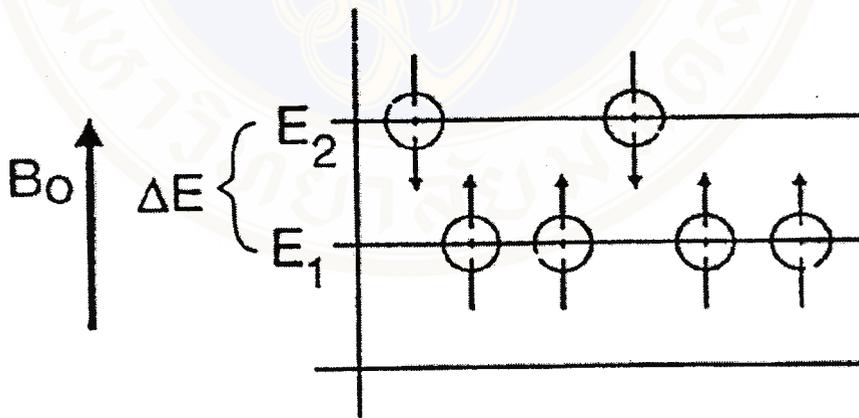

Therefore, a hydrogen proton has two energy states. The energy difference between these two states ( $\Delta E$ ) is calculated by:

$$\Delta E = E_2 - E_1 = (2\mu)(B_0) \quad (3)$$

where,  $\mu$  is the magnetic dipole moment.

$B_0$  is the external magnetic field.

At upper energy state ( $E_2$ ), the spin direction is antiparallel to the external magnetic field direction (spin down) while at the lower energy state ( $E_1$ ), the spin will parallel to the external magnetic field direction (spin up).

**Figure 6.** In a magnetic field  $B_0$ , protons are at two energy states; in the upper energy state they are antiparallel to  $B_0$ , but in the lower energy state they parallel to it (13).

### 5. Precession.

Precession is motion of proton that rotates around the axis of the apply external magnetic field  $B_0$  with constant angular precession frequency ( $\omega_0$ ) (Figure 7).

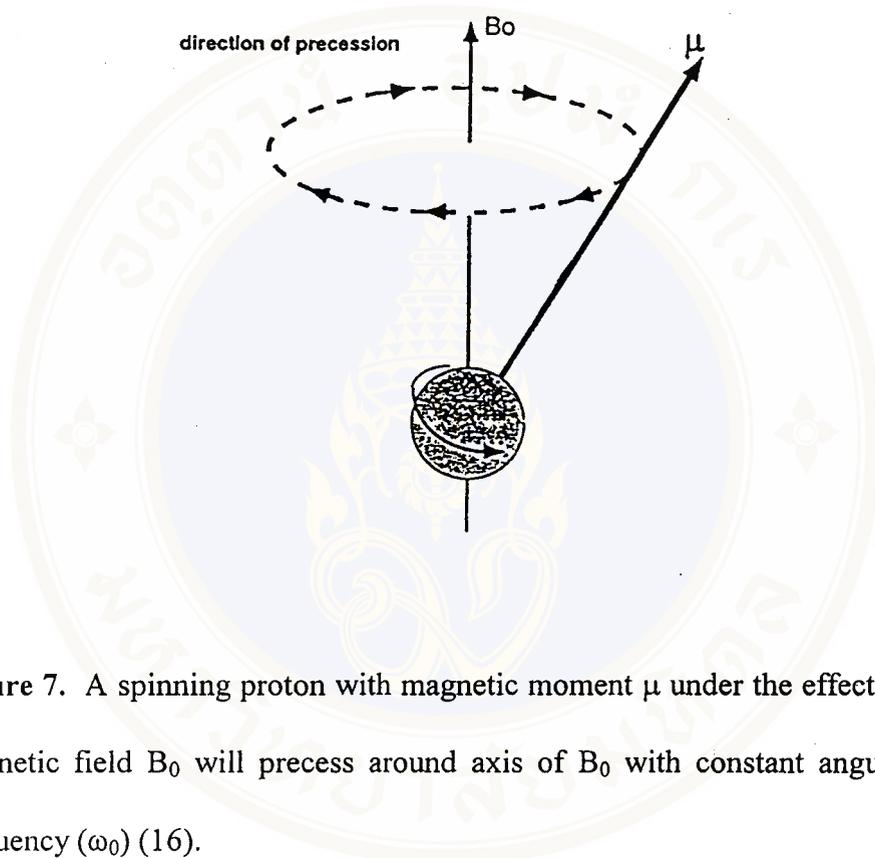

Figure 7. A spinning proton with magnetic moment  $\mu$  under the effect of an external magnetic field  $B_0$  will precess around axis of  $B_0$  with constant angular precession frequency ( $\omega_0$ ) (16).

### 6. Larmor equation.

Larmor equation is equation that represents the rate of the proton's, precession around an external magnetic field  $B_0$ , expressing as:

$$\omega_0 = \gamma B_0 \quad (4)$$

where,  $\omega_0$  is the angular precession frequency, called the Larmor precession frequency (in MHz or radians/second).

$\gamma$  is the gyromagnetic ratio which is specific for the nucleus (in MHz/Tesla) (Table I).

$B_0$  is the strength of external magnetic field (in Tesla).

### 7. Net magnetization and its component.

Net magnetization is a sum of the contributions of all the magnetic moments of the individual proton. Net magnetization composes of two components are the longitudinal and the transverse magnetization.

The longitudinal component is the projection of the net magnetization along the direction of the external magnetic field. The transverse component is the projection of the net magnetization onto the plane perpendicular to the direction of  $B_0$  (Figure 8).

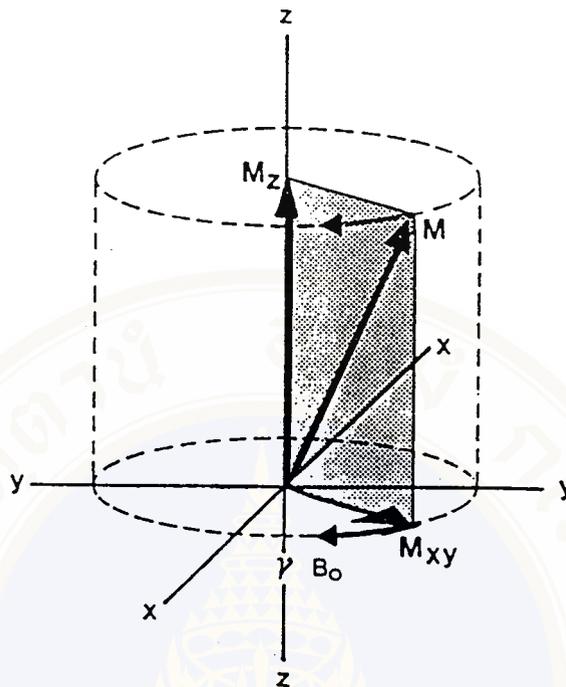

Figure 8. The net magnetization vector can be broken down into two components: longitudinal magnetization ( $M_z$ ), along the direction of the magnetic field, and transverse magnetization ( $M_{x-y}$ ), in the plane perpendicular to the field (17).

### 8. Radio frequency (RF) pulse.

Radio frequency (RF) pulse is in radio frequency range of the electromagnetic spectrum. When the patient is in the magnet, RF pulse is applied along the x axis perpendicular to the axis of  $B_0$  to flip the longitudinal magnetization  $90^\circ$  into the the x-y plane. If all of the vectors flip into the x-y plane, the magnitude of  $M_{xy}$  equals the magnitude of  $M_0$ . This is called a  $90^\circ$  flip, and the pulse that gives the  $90^\circ$  flip is called  $90^\circ$  RF pulse (Figure 9). When all vectors flip into the x-y plane, this transverse magnetization will precess in phase around the axis of  $B_0$  at the

Larmor frequency. Similarly, when we apply a  $180^\circ$  RF pulse, the longitudinal magnetization vector is inverted to  $-M_z$ .

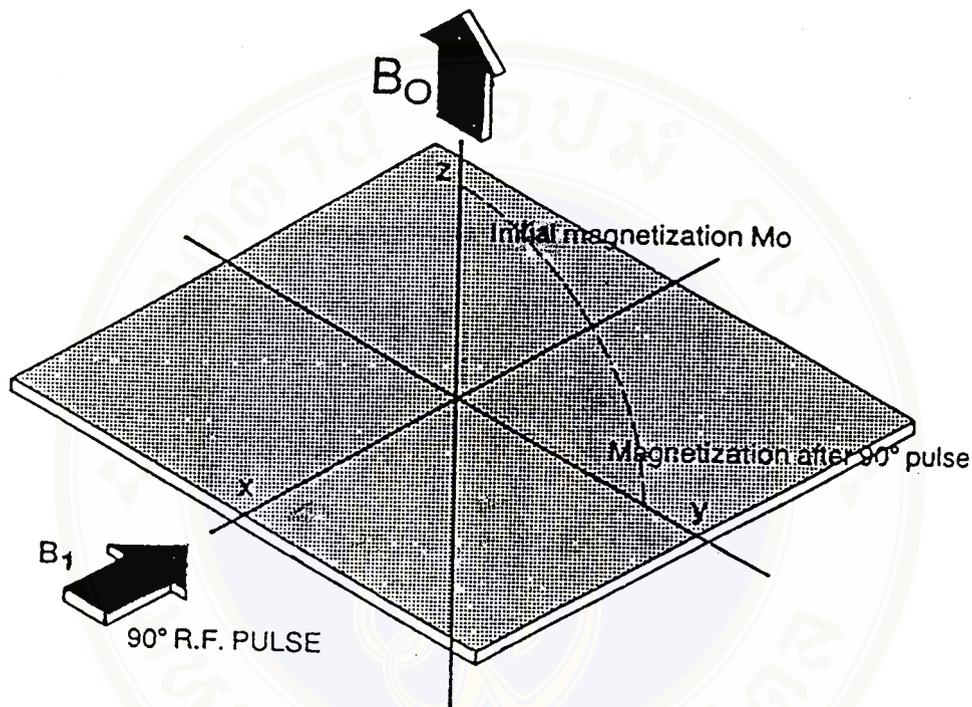

Figure 9. When the whole magnetization vector is flipped into the x-y plane, it is called a  $90^\circ$  flip (17).

### 9. Resonance.

Resonance is a phenomenon occurring when the frequency of the applied RF pulse matches the proton  $\omega_0$  allowing the proton to receive some energy from RF pulse. If the RF frequency does not match the  $\omega_0$  of the proton, the system won't resonate and can not receive energy from RF pulse.

When system resonates with  $90^\circ$  RF pulse, the protons flip into the x-y plane and are in phase because the protons don't point in random directions. This creates  $M_{xy}$ .

### 10. Relaxation of the magnetization.

Relaxation of the magnetization is the process that nuclei return to equilibrium state after the RF pulse is turned off, by emitting electromagnetic radiation that was received from RF pulse and transferring it to the surroundings (lattice) or between themselves.

Relaxation of longitudinal component is referred to as  $T_1$  relaxation time. It is measured by the time that the longitudinal component returns to 63 % of its original state ( $M_z$ ) after the RF pulse is turned off (17) (Figure 10). The  $M_z$  component will start to grow at a rate characterized by  $T_1$  relaxation time, and can be described mathematically as:

$$M_z(t) = M_0 (1 - e^{-t/T_1}) \quad (5)$$

Where  $M_z(t)$  is the longitudinal magnetization component at time (t).

$M_0$  is the equilibrium longitudinal magnetization.

t is the time after the RF pulse.

$T_1$  is the  $T_1$  relaxation time constant that is an exponential time constant that is related to the period required for longitudinal component to recover 63% of its equilibrium alignment ( 86 % after 2 X  $T_1$ , 95% after 3X  $T_1$ , and 98.5% after 4X  $T_1$ ).

$T_1$  relaxation time is commonly referred to as spin-lattice relaxation, because the emitting energy will be transferred to their environment (lattice).  $T_1$  relaxation time of proton is different in different tissues in the body, depend on the efficient transfer of energy to the surrounding lattice and strength of the external magnetic field.

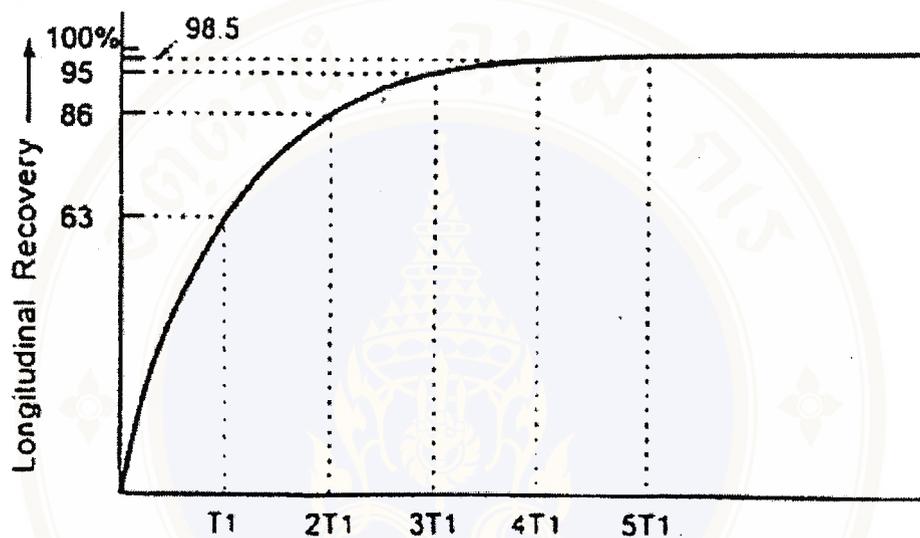

Figure 10. A typically  $T_1$  relaxation curves (16).

Efficient transfer of energy to the surrounding lattice depends on molecular motion and the presence of macromolecules. The most efficient energy transfer occurs when the natural motional frequencies (translation, rotation, and vibration) of the proton are at the Larmor frequency. Hydrogen protons in fat (medium-sized molecule) have natural motional frequencies that are almost equal to the Larmor frequencies for hydrogen. The efficiency of energy transfer from the protons to the lattice is increased, thus decreasing  $T_1$ . But Hydrogen proton in the small molecules and large molecules has natural motional frequencies that are difference from the Larmor

frequencies for hydrogen. So the efficiency of energy transfer from the protons to the lattice is decreasing, thus increasing  $T_1$  (Figure 11).

The presence of macromolecule, when water molecules is bound to a hydrophilic macromolecule such as a protein. These bound water molecules lose some of the freedom in their motion. As a result, the natural motional frequencies of the water molecules get closer to the Larmor frequency, thus yielding a more efficient energy transfer. The net result is shortening in the  $T_1$  relaxation time.

$T_1$  relaxation time also depends on the external magnetic field strength. It tends to increase at stronger field strength (Table II), because in the stronger magnetic field there will be more protons aligning with it. Thus these protons have more energy to give to the lattice, and take longer time in transferring energy to their environment, resulting in longer  $T_1$  relaxation time.

Relaxation time of the transverse component is referred to as  $T_2$  relaxation time.  $T_2$  relaxation time is a measure of the time that the transverse component has decayed to 37 % of its original value after the apply of the  $90^\circ$  RF pulse(Figure 12), and is commonly called spin-spin relaxation time. The transverse vector  $M_{x-y}$  decays at the rate characterized by  $T_2$  relaxation time: (13)

$$M_{x-y}(t) = M_0 e^{-t/T_2} \quad (6)$$

Where,  $M_{x-y}(t)$  is the transverse magnetization component at the time (t)

$M_0$  is the transverse magnetization component at the time  $t = 0$ , immediately after the RF pulse is turned off. It will be equal to the value of  $M_z$  just prior to the RF excitation pulse.

$t$  is the time after the RF pulse is turned off.

$T_2$  is the  $T_2$  relaxation time constant that is an exponential time constant of transverse component

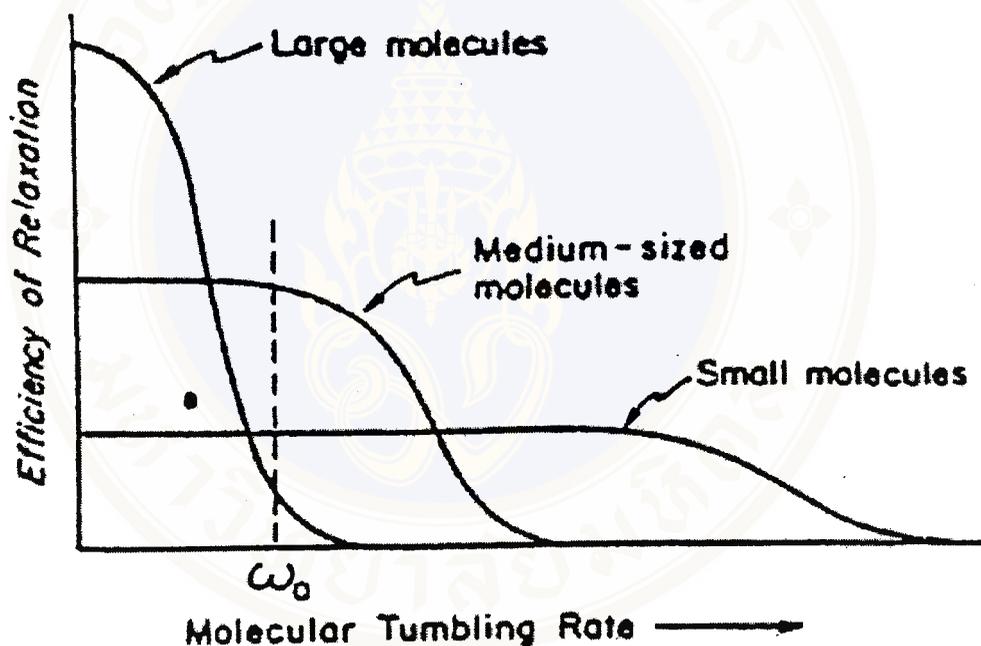

Figure 11. Show relaxation efficiency versus molecular size that spin-lattice relaxation efficiency is the best for substances with frequency of molecular nears larmor frequency  $\omega_0$  (17).

**Table II.** T<sub>1</sub> and T<sub>2</sub> values for human tissue (12).

TISSUES	T <sub>1</sub> at 1.5 Tesla (msec)	T <sub>1</sub> at 0.5 Tesla (msec)	T <sub>2</sub> (msec)
Fat	260	215	84
Liver	490	323	43
Kidney	650	449	58
Spleen	780	554	62
White matter	790	539	92
Lung	830	600	79
Skeletal muscle	870	666	47
Gray matter	920	656	101
Cerebrospinal fluid	>4000	>4000	>2000

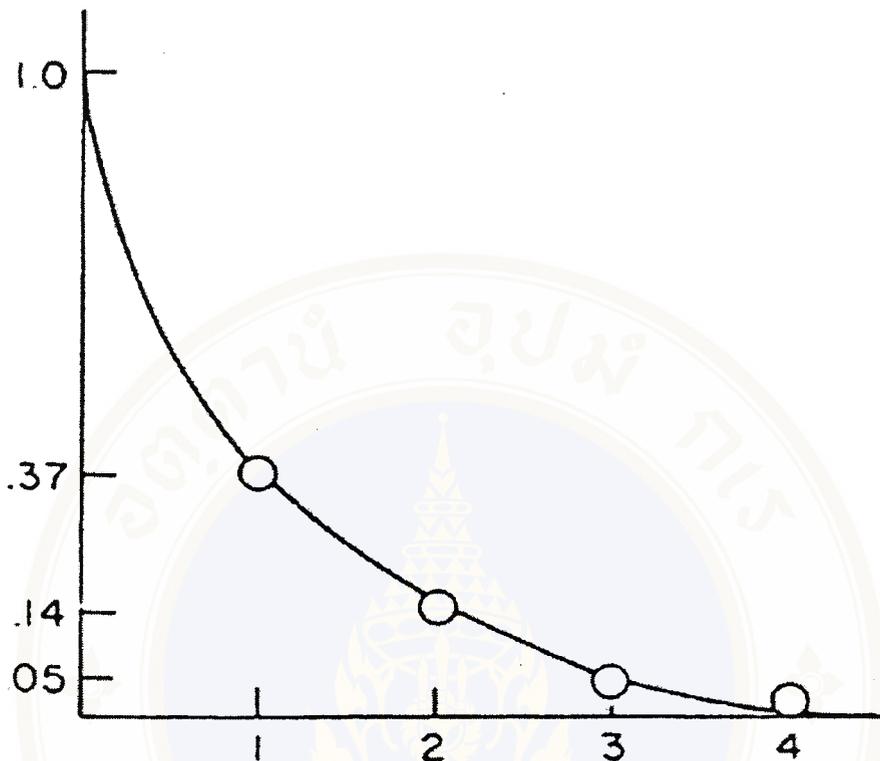

Figure 12. Curve showing decay of the transverse magnetization. At the time =  $T_2$  the magnetization has decayed to 37% of its initial value (17).

The mechanism that causes the decay of the transverse magnetization is the dephasing of the spin. Dephasing is the result of interaction between spins and external magnetic field inhomogeneities. An interaction between individual spins is called spin-spin interaction, which is inherent property of every tissue and is measured by  $T_2$  relaxation time. External magnetic field inhomogeneities cause protons in different positions to precess at different frequencies because each spin is exposed to a slightly different magnetic field strength.

### 11. Free induction decay

Free induction decay is decay of oscillating signal, that generated by oscillating spins of the net magnetization in transverse plane after turn off the RF pulse which it is induced by a current in a receiver coil. This decaying oscillating signal is described mathematically as:

$$M_{x-y}(t) = M_0 e^{-t/T_2^*} (\cos \omega_0 t) \quad (7)$$

Where,  $M_{x-y}(t)$  is the transverse magnetization component at the time (t).

$M_0$  is the transverse magnetization component at the time  $t = 0$ , immediately after the RF pulse is turned off.

$e^{-t/T_2^*}$  is the decay signal with the time constant of  $T_2^*$ .

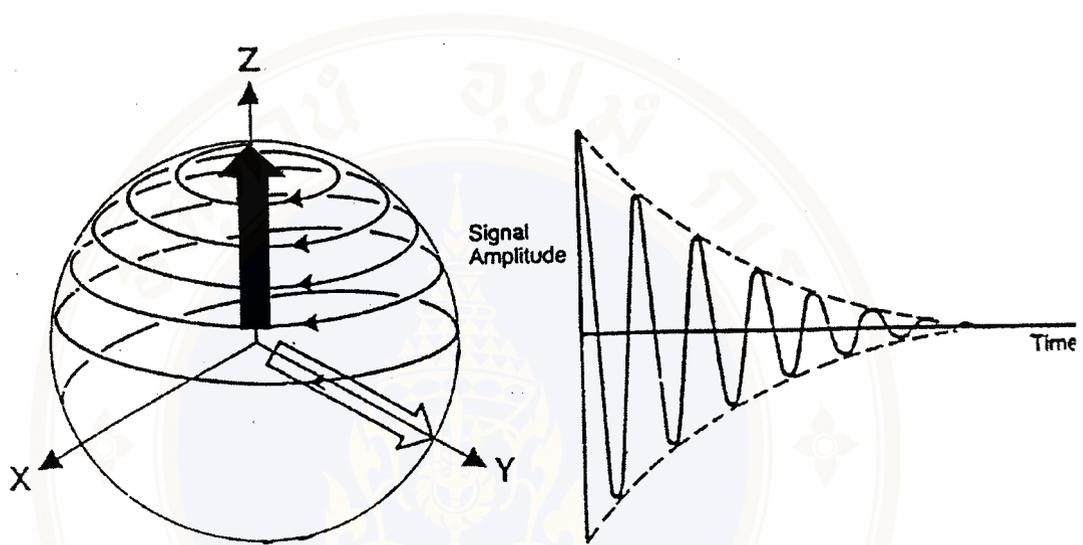

$\cos \omega_0 t$  is the formula for an oscillating wave, at a Larmor frequency of excited  $\omega_0$ .

Therefore, the general form of the signal come from an oscillating signal which varies as  $\cos \omega_0 t$  and a decaying signal which decays with time constant  $T_2^*$  as given by the exponential  $e^{-t/T_2^*}$  (Figure 13).

The free induction decay signal has the following characteristics:

- The free induction decay signal oscillates with component at the Larmor frequencies of the excitation.
- The free induction decay signal has an initial transverse magnitude related to the density of initial longitudinal magnitude before flipped into transverse plan.

- The free induction decay signal decreases in an amplitude with time, as a function of the transverse relaxation process.

**Figure 13.** Show Free induction decay after a  $90^\circ$  RF pulse. When the all vector flips into the x-y plane, this transverse magnetization will precess in phase around the axis of the external magnetic field ( $B_0$ ) at the Larmor frequency (17). Then when we turn off  $90^\circ$  RF pulse signal, this transverse magnetization will dephase with time at rate define as  $T_2^*$  (17).

### 12. Fourier transform.

Fourier transform is an analytical algorithm, which converts the received signal into one, which can be displayed on a monitor, having attributed frequency values to the amplitude variations. An image is formed because the computer is enabled to related values of signal strength (hydrogen density) to specific spatial locations.

### 13. Spin echo (SE) pulse sequence.

13.1 Spin echo (SE) pulse sequence consists of a  $90^\circ$  excitation pulse followed by  $180^\circ$  RF rephasing or refocusing pulse after time  $\tau$ , to eliminate the dephasing effects caused by external magnetic field inhomogeneities by maximizing spin rephasing at the time  $2\tau$ . We call  $2\tau$  "the echo time" (TE) at this time maximal SI will be obtained. The  $90^\circ$  excitation pulse and  $180^\circ$  RF rephasing pulse is repeated after an interval called repetition time (TR) (Figure 14).

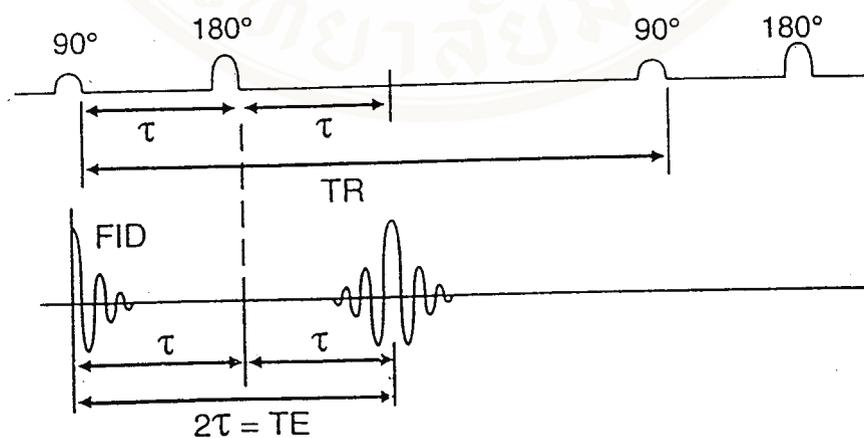

Figure 14. Show a diagram of a spin echo pulse sequence. A  $180^\circ$  rephasing pulse is applied after  $90^\circ$  excitation pulse at time  $\tau$  (13).

13.2 Tissue contrast in spin echo pulse sequence depends on TR and TE; there are three types of tissue contrast:

#### 13.2.1. Proton density weighted imaging.

Proton density weighted imaging represent a tissue contrast that is produced as a result of variations in the amount of mobile hydrogen nuclei. This can be done by using a long TR (1500-3000 msec) and short TE (10-40 msec). The long TR lets the tissue get full longitudinal magnetization. The short TE permits minimal loss of transverse signal due to  $T_2$  relaxation time. Therefore this sequence needs the long TR to reduce  $T_1$  effect and the short TE to reduce  $T_2$  effect.

#### 13.2.2. $T_1$ weighted imaging

$T_1$  weighted imaging represent tissue contrast that is produced by considering the variations in longitudinal relaxation rate. This is obtained by using a short TR (300-800 msec) and short TE (10-40 msec) (Figure 15). The short TR causes tissues with a short  $T_1$ , such as fat, to fully recover along the longitudinal direction and tissues with a long  $T_1$ , such as CSF, to only partially recover. The short TE reduces  $T_2$  effect and short TR increases  $T_1$  effect.

#### 13.2.3. $T_2$ weighted imaging

$T_2$  weighted imaging represents a tissue contrasts that is produced by considering the variations in transverse relaxation rate. This is done by using a long TR (1500-3000 msec) and long TE (50-100 msec) (18). The long TR causes all tissues to fully recover along the longitudinal direction and long TE controls loss of transverse signal due to  $T_2$  relaxation time. Long TR reduces  $T_1$  effect and long TE highlights  $T_2$  effect. It is very important to remember that many pathologies such

as tumor, infarction have long  $T_2$  but not equal to CSF.  $T_2$  weighted imaging is very good in producing very bright signal from these pathologies (Figure 16). But there may be some difficulties in differentiating pathologies from CSF especially when they are close to each other.

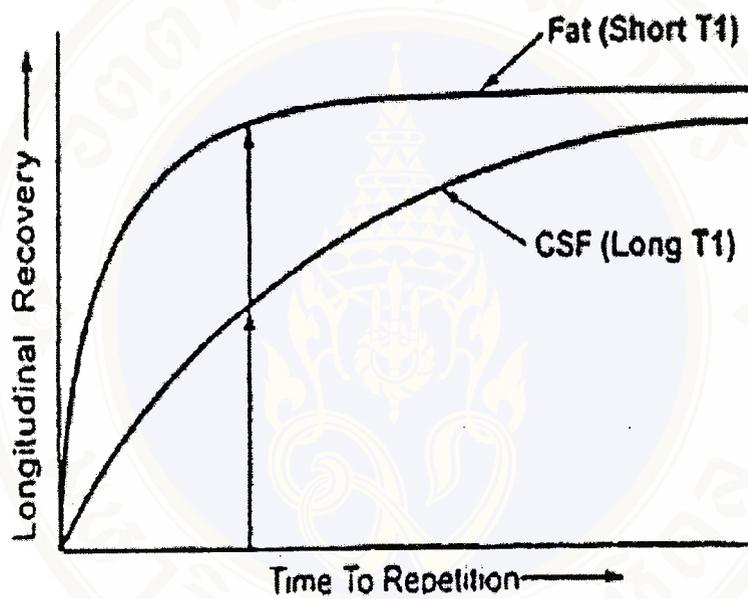

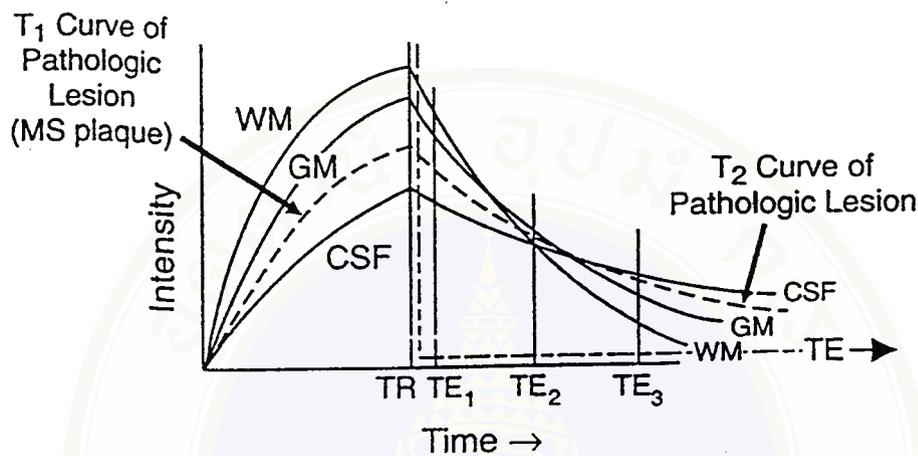

Figure 15. Show tissue contrast with short TR and short TE that short TR enhances the  $T_1$  contrast (16).

**Figure 16.** Show  $T_1$  and  $T_2$  curves of CSF, white matter, gray matter and lesion. The long TR allows tissues to reach full longitudinal magnetization that reduces  $T_1$  effects. The long TE allows controlled loss of transverse signal due to  $T_2$  relaxation and increases the signal intensity differences between these tissues (13).

### Inversion Recovery (IR) pulse sequence

Inversion Recovery (IR) pulse sequences consists of  $180^\circ$  inversion RF pulse, followed by the spin echo pulse sequence for signal detection. First, we apply  $180^\circ$  RF pulse to invert the longitudinal magnetization from the +Z direction to -Z direction (Figure 17) that allows tissue to relax over twice the dynamic range of spin echo technique. Then, when the  $180^\circ$  inversion RF pulse is removed, the magnetization returns toward its equilibrium state in the +Z direction. Because the

echo technique. Then, when the  $180^\circ$  inversion RF pulse is removed, the magnetization returns toward its equilibrium state in the  $+Z$  direction. Because the receiver's antennae (RF coil) can detect magnetization only in perpendicular plan to the main magnetic field, so after  $180^\circ$  inversion RF pulse we apply  $90^\circ$  RF pulse at a time called "inversion time" (Figure 18).

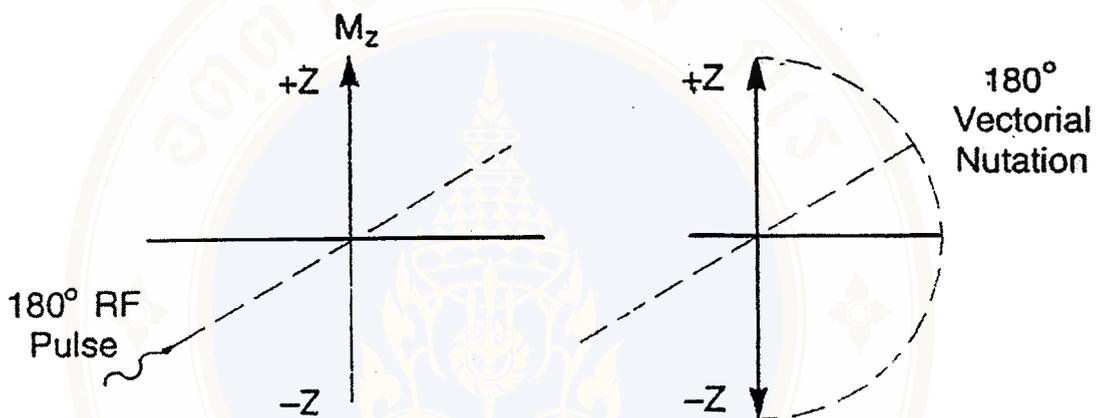

Figure 17. Show the effect of the  $180^\circ$  inversion RF pulse on longitudinal magnetization, that the magnetization is moved from the  $+Z$  into  $-Z$  direction (19).

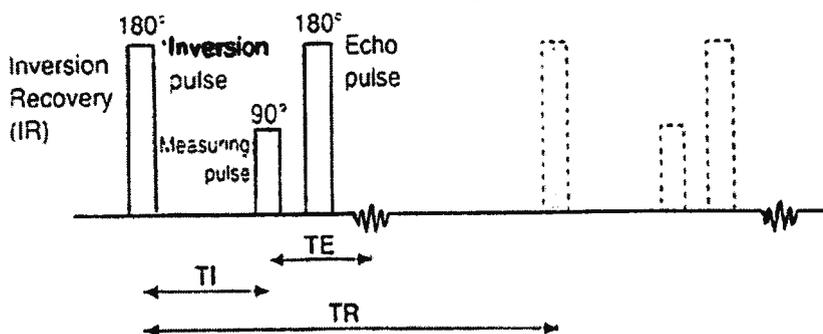

Figure 18. This figure shows diagram of inversion recovery pulse sequence. First, the magnetization is inverted with  $180^\circ$  inversion RF pulse. After interval  $T_I$ , a  $90^\circ$  RF

measurement pulses is applied to rotate the magnetization into the transverse plane, for detection (19).

This  $90^\circ$  RF pulses flips the partially recovered spins into the transverse plane, so that a signal may be detected. This signal amplitude (S) is given by:

$$S_{IR} = K\rho e^{-TE/T_2} (1 - 2e^{-TI/T_1} + 2e^{-(TR+TI)/T_1} - e^{-TR/T_1}) \quad (8)$$

Where K is the system-related scale factor.

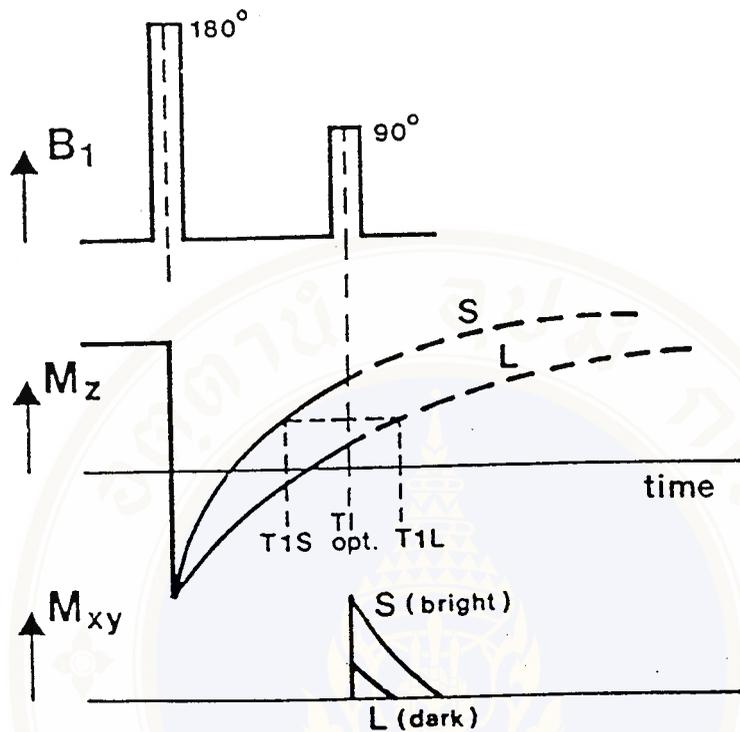

$\rho$  is the proton density.

However, TR is common very much larger than TI, to yield the simplified expression:

$$S_{IR} = K\rho e^{-TE/T_2} (1 - 2e^{-TI/T_1} + e^{-TR/T_1}) \quad (9)$$

#### **The advantages of inversion recovery (IR) pulse sequences:**

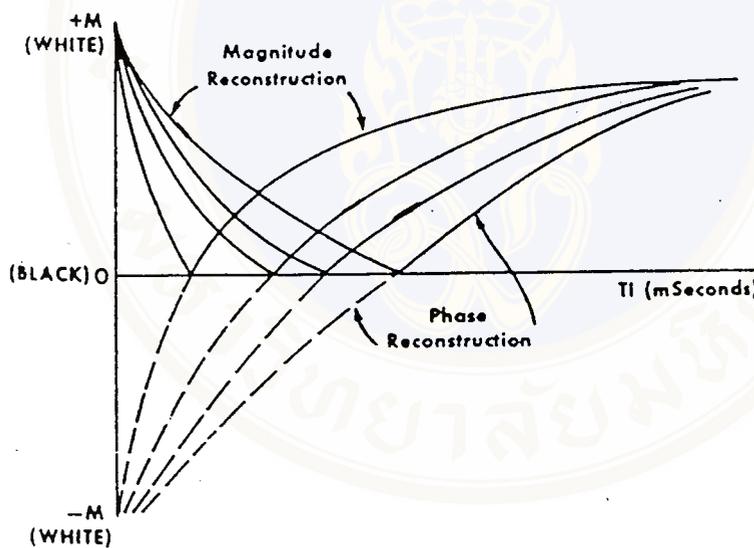

1. IR pulse sequence is a good method to demonstrate  $T_1$  difference between tissues. Although  $T_1$  difference is narrow, the contrast is high due to the effect of  $180^\circ$  inverting pulse, which allows tissue to relax twice the dynamic range of spin echo technique.  $T_1$  contrast can be varied by selection of the optimal value of TI. Figure 19 shows curves of the longitudinal magnetization recovery of tissues with a short  $T_1$  (curve S) and long  $T_1$  (curve L) after apply  $180^\circ$  inverting pulse. To produce maximum  $T_1$  enhancement of the image contrast, it is necessary to apply the  $90^\circ$  exciting pulse at time = optimum TI that is the maximum difference between the value of the recovered magnetization of one tissue and that of the other tissue.

**Figure 19.** The curves marked S and L represent the behavior of  $M_z$  after inversion in tissue with a short and a long  $T_1$  respectively. Ideally, the timing (TI) of the  $90^\circ$  RF pulses is set for maximum separation in the curves. The amplitude of the response signal is related to the value of  $M_{x-y}$  (17).

Therefore IR image need long TR for the longitudinal magnetization of each tissues recovered fully before to the next  $90^\circ$  exciting pulse. If the TR is short relative to  $T_1$ , the longitudinal magnetization will recovers partially before the next inversion pulse, so the contrast is less. However the level of  $T_1$  contrast obtained with IR images also depends on whether the images are sensitive to the phase of the MR

signal. Most MR systems generate IR images by using phase insensitive images (magnitude image). On these magnitude images, information about whether the longitudinal component of  $M_z$  is positive or negative is lost. As a result,  $M_z$  can vary between 0 to 1. Some system actually produces phase sensitive images, which can depict whether  $M_z$  is positive or negative. As a result,  $M_z$  can vary from -1 to 0 to 1; that is, the dynamic range for  $T_1$  contrast is doubled (Figure 20).

**Figure 20.** Show the magnitude and phase sensitive reconstruction of IR images. The magnitude reconstruction gives us only positive signals, so the curves are reflected above the zero line, this result may loss of contrast. But phase sensitive reconstruction retains sign of magnetization and may result in improved tissue contrast (17).

2. A second utility of IR sequences is suppression of some tissues that we need. When the inversion pulse is removed, the magnetization returns toward its equilibrium state in the +Z direction. At some point, the magnetization will pass from the -Z direction to the +Z direction. When this crossover occurs, there is no longitudinal magnetization. This point is referred to as the null point (Figure 21).

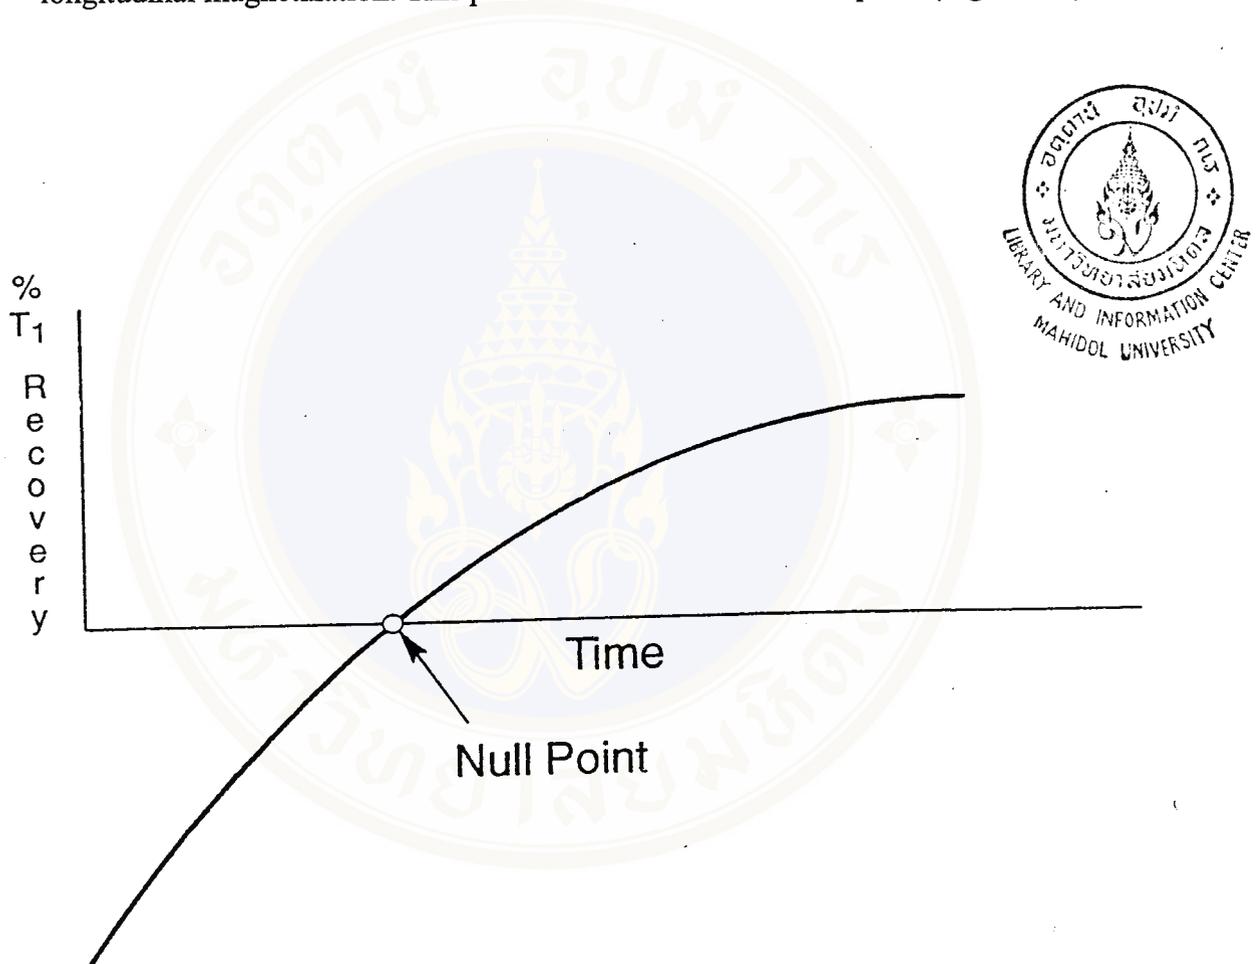

Figure 21. Show the null points which the signal crosses the zero line . At this point, the signal intensity is zero (18).

The null point can be used to create signal voids for various tissues. We can use the Equation (9) for TI(null) at which point the signal intensity is zero, from the equation (9) express as:

$$S_{IR} = K\rho e^{-TE/T_2} (1 - 2e^{-TI/T_1} + e^{-TR/T_1})$$

then,

$$S_{IR} = 0 = (1 - 2e^{-TI/T_1} + e^{-TR/T_1})$$

When, the limit of infinite TR, then  $e^{-TR/T_1} \cong 0$ , the solution to TI(null) is: (6)

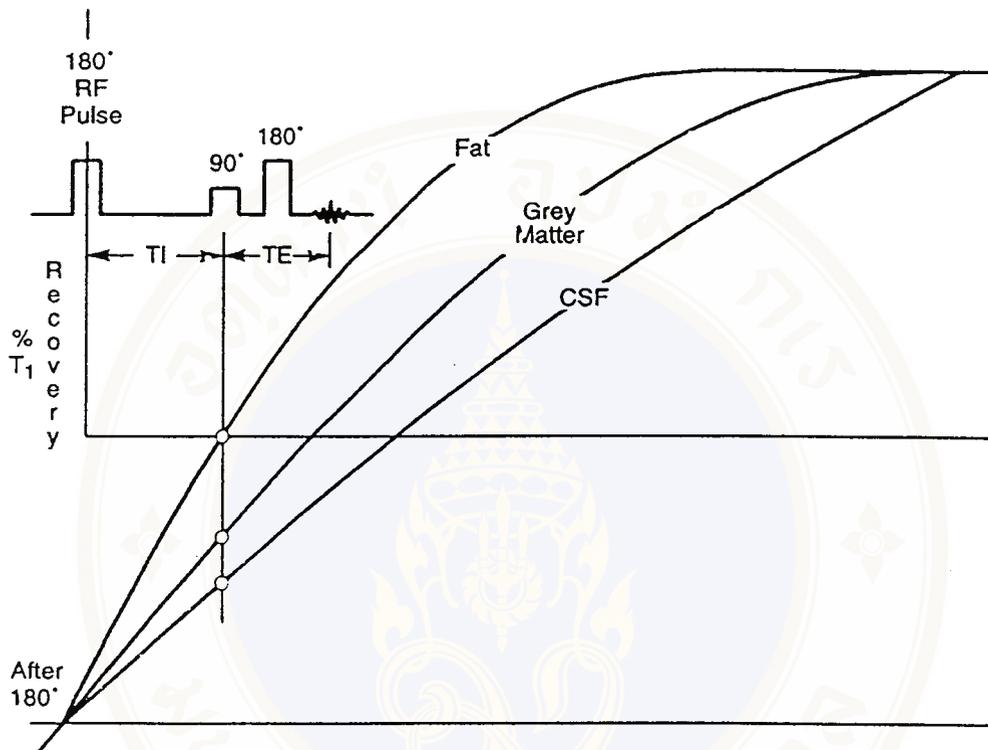

$$TI_{null} \cong (\ln 2) T_1$$

or

$$TI_{null} \cong 0.693 T_1 \quad (10)$$

Where,  $TI_{null}$  is the inversion time that, gives signal voids for tissues we need to suppress, and  $T_1$  is  $T_1$  relaxation time of suppressing tissues.

So, if the selected TI matches exactly with the time at which null point occurs, a signal void for that particular tissue will occur. This is because at the null point there is no longitudinal magnetization for  $90^\circ$  RF pulse to flip into the transverse plane, so no signal can be created. Here is an example; if we want to suppress fat tissue which has  $T_1$  approximately 250 msec at 1.5 Tesla, TI must be  $0.693 \times 250 = 173.25$  msec. Because we can suppress fat in an IR image, by using short TI, this technique is called Short-TI inversion recovery (STIR) (Figure 22).

**Figure 22.** Showing if TI is selected to match exactly with the time at null point of fat, fat can be suppressed (13).

3. IR pulse sequence provides heavily T<sub>1</sub> weighted images with long TR, allowing more imaging volume to be covered; as shown by equation of number of slices:

$$\text{number of slices} \cong \text{TR/TE} \quad (11)$$

In contrast to  $T_1$  weighted images of spin echo pulse sequence, short TR is used, limiting the number of slices.

### **The disadvantage of IR pulse sequences:**

The disadvantage of IR sequences is a very long acquisition time due to long TR for the longitudinal magnetization of each tissue to recover fully. Therefore, technique is developed by combining a fast spin-echo sequence with an inversion-recovery sequence (fast IR pulse sequence), to reduce the scanning time.

### **Fluid-Attenuated Inversion Recovery (FLAIR) pulse sequence.**

Fluid-Attenuated Inversion Recovery (FLAIR) pulse sequence is a magnetic resonance imaging (MRI) sequence designed to produce a heavily  $T_2$ -weighed image while suppressing the CSF signal. From the fundamental of an inversion recovery sequence, CSF suppression is achieved by using a  $180^\circ$  inversion recovery with an TI chosen to null the signal from CSF. We can desire TI depending on the  $T_1$  relaxation time of the CSF and TR chosen. Assuming the interval of  $T_1$  relaxation time for the CSF is 3050-3400 msec. We can designed interval of TI for suppressing CSF by calculation from the equation (10) expressing as:

$$T_{I_{\text{null of CSF}}} \cong 0.693 T_{1 \text{ of CSF}}$$

Therefore, interval of TI for suppressing signal of CSF is 2100 to 2400 msec. That means; when we apply  $180^\circ$  inverting RF pulse to invert the longitudinal

magnetization from the +Z direction to -Z direction, followed by exciting RF pulse at these TI, it allows the longitudinal magnetization of CSF return to the null point before spin echo imaging. At this point, all other brain tissues have almost complete recovery of longitudinal magnetization toward equilibrium (Figure 23).

So, this is result of FLAIR must used long TR, which it permits tissues with very long  $T_1$  relaxation time to completely recovery of magnetization before the next excitation, which long TR will result in better signal to noise ratio and increased contrast to noise ratio between the lesion, gray matter and white matter, and long TR also decrease  $T_1$  effect of non-CSF tissues, thus producing heavy  $T_2$ - weighted imaging that relative with long echo time of the FLAIR sequence.

The CSF signal is completely suppressed, and pathologic lesion, which typical, have increased  $T_2$  relaxation time in the brain, specially it adjacent to CSF interfaces, become easily to distinguish lesions from CSF interfaces when comparison with  $T_2$ - weighted spin echo.

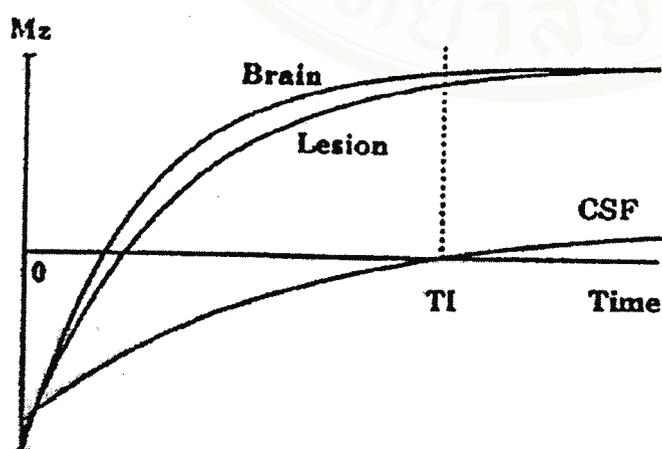

Figure 23. Showing the  $T_1$  recovery curves after inversion of  $180^\circ$  RF pulse. TI is set so that CSF is nulled (20).

**The advantage of FLAIR pulse sequence.**

1. The FLAIR pulse sequence requires long TR. The inversion null time of CSF is also long enough that almost all other tissues will have fully recovery. So that the sequence is suitable for “proton density” and “T<sub>2</sub> weighted ” clinical imaging of other tissues.

2. The FLAIR pulse sequence can effectively eliminate the bright “ghost” artifacts from pulsatile CSF motion, significantly increasing the diagnostic quality of clinical imaging of the central nervous system.

3. Finally, suppression of the bright CSF signal improves the dynamic range, thus it permits greater lesion conspicuity, specifically at brain-CSF interfaces and periventricular lesion.

**The disadvantage of the FLIR pulse sequence.**

The important disadvantage of conventional FLAIR sequences is a very long acquisition time, because of using long TR. Therefore we combine conventional FLAIR pulse sequences with fast-spin echo technique, calling fast FLAIR pulse sequences, for decreased acquisition time.

**Image assessment****1. Signal to noise ratio (SNR)**

Signal to noise ratio (SNR) is a term used to describe the relative contributions to a detected signal made by the true signal and random superimposing signals (noise). Noise composes of two types. The first, noise that result from variations in the

signal created by moving objects in the body. The second type of noise is inherent in the system.

#### Factors which affect SNR

##### 1. The magnetic field.

The increased strength of the magnetic field increases the detected signal.

##### 2. Voxel volume.

SNR may be improved by increasing the volume, because larger voxel volume will increase the number of proton spin to contribute to the signal intensity (Figure 24). The voxel volume is defined as: (13)

$$\text{Voxel volume} = \Delta x \cdot \Delta y \cdot \Delta z \quad (12)$$

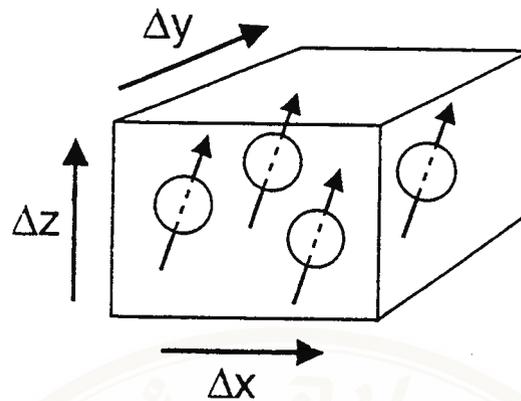

Where  $\Delta x$  is the pixel size in the x direction.

$\Delta y$  is the pixel size in the y direction.

$\Delta z$  is the slice thickness.

##### 3. Slice thickness.

SNR is improved by increasing the slice thickness because increasing the slice thickness increases the signal volume per image, resulting in a higher ratio. But a partial volume effect may degrade the image.

**Figure 24.** Voxel is a three-dimensional volume element with dimensions  $\Delta x$ ,  $\Delta y$  and  $\Delta z$ . The more spins in a voxel, the more signal. Therefore, increasing voxel size increases SNR (13).

#### 4. Repetition time (TR).

The increasing repetition time improves SNR by increasing the time that longitudinal magnetization is permitted to recover for all tissues. More signal will be obtainable to be flipped to the transverse plane during subsequent RF pulses.

#### 5. Echo time (TE).

The increasing TE decreases SNR by allowing more time for tissue vectors to dephase; resulting in signal loss.

#### 6. Number of acquisitions or excitations (NEX).

The number of acquisitions or excitations (NEX) represents the number of times that we collect data for a given phase encode value and average the information to represent one image. Signal increases linearity with increasing NEX but

noise is random. If we double NEX, the signal doubles and noise increases by  $\sqrt{2}$ , thus SNR increases by factor of  $\sqrt{2}$ . This calculates to an increase in SNR of about 41 percent. But doubling the acquisitions also doubles scan time, which may result in more artifact noise due to patient's movement.

#### 7. Bandwidth (BW).

The bandwidth is a range within a band of frequencies that a MRI system is tuned to receive frequencies. The received bandwidth of an image determines the number of frequencies encompassed in the image. The increasing BW will include more noise, and SNR decreases. Therefore, the decreasing BW will allow less noise, and the SNR increased SNR.

#### 8. Field of view (FOV).

Field of view is the area of the anatomy being image, it is determined by:

$$\text{FOV} = (\text{pixel size}) \times (\text{number of pixels}) \quad (13)$$

When FOV is decreased while maintaining the number of pixels, the pixel size becomes very small. Therefore, there is less signal per unit volume, and decreased SNR.

#### 9. Spatial resolution

Spatial resolution (pixel size) is the smallest distance that we can distinguish between two points on an image. The high resolution image is obtained with small voxels. When we look at the Equation (13), if we maintain the

FOV and increase number of pixels, the size of pixel is decreased, giving decreased SNR. Therefore high resolution image usually gives poor SNR.

#### 10. Artifact reduction techniques.

The elimination or reduction of artifacts will improve the image quality. Artifact reduction techniques are able to minimize flow (CSF and blood), breathing and other artifacts; such as flow compensation techniques. Flow compensation techniques use gradients to minimize motion artifacts created by the flow of slow moving blood and CSF. This technique can improve image quality by affecting the SNR of the image.

One method of measuring the signal to noise ratio consists of determining the ratio of mean signal intensity in the anatomic region of interest (ROI), divided by the standard deviation from a region outside the image boundaries that free of ghost artifacts ( $SD_{air}$ ), (8,21).

#### 2. Contrast ratio (CR)

Contrast ratio is ratio of signal difference between two tissues or regions to the sum of both signals, expressing as:

$$CR_{\text{tissue}(1,2)} = (S_{\text{tissue}(1)} - S_{\text{tissue}(2)}) / (S_{\text{tissue}(1)} + S_{\text{tissue}(2)}) \quad (14)$$

Where,  $CR_{\text{tissue}(1,2)}$  is contrast ratio between tissue<sub>1,2</sub> and  $S$  = signal intensity of individual types of tissue, assessed by region of interest measurement.

### 3. Contrast to noise ratio (CNR)

CNR is ratio of signal difference between two tissues to the standard deviation of the background air (noise) measured in areas free of ghost artifacts ( $SD_{air}$ ), expressing as:

$$CNR_{tissue(1,2)} = (S_{tissue(1)} - S_{tissue(2)}) / SD_{air} \quad (15)$$

CNR is one measurement of image quality. CNR is useful for comparing performance of different pulse sequences in to lesion detection. While contrast considers only the relative signal differences. From the equation (15), CNR considers the relative signal differences with standard deviation of the noise ( $SD_{air}$ ), if the images have high contrast with very high noise, then images may show low CNR (Figure 25).

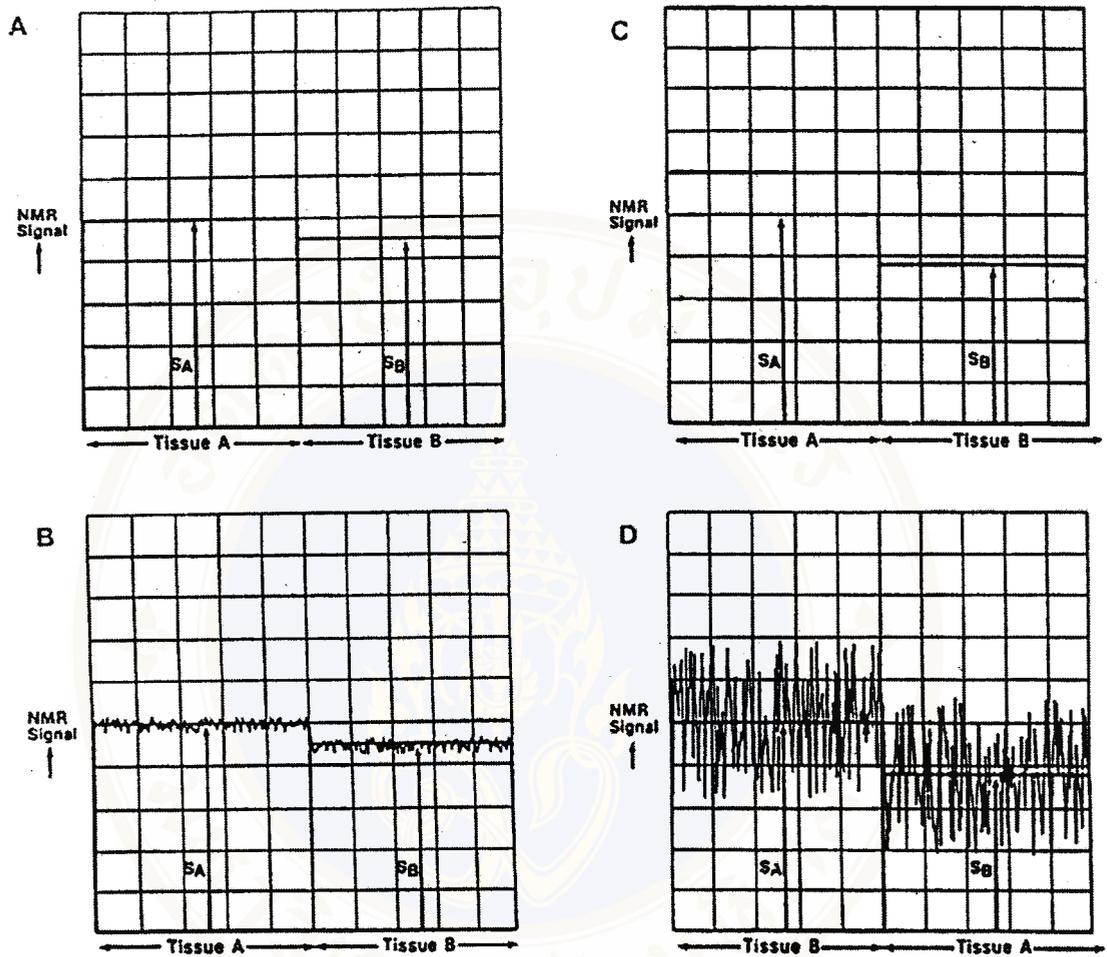

Figure 25. (A) and (C) show different contrast for two anatomic structures that (C) gives higher contrast. (B) and (C) show different contrast to noise ratio that (D) has higher constant than (B) but it gives lower contrast to noise ratio because of its higher noise level (21).

## CHAPTER IV

### MATERIALS AND METHODS

#### 4.1 The measurement of $T_1$ values of CSF.

##### 4.1.1 Materials

##### 4.1.1.1 Magnetic resonance unit

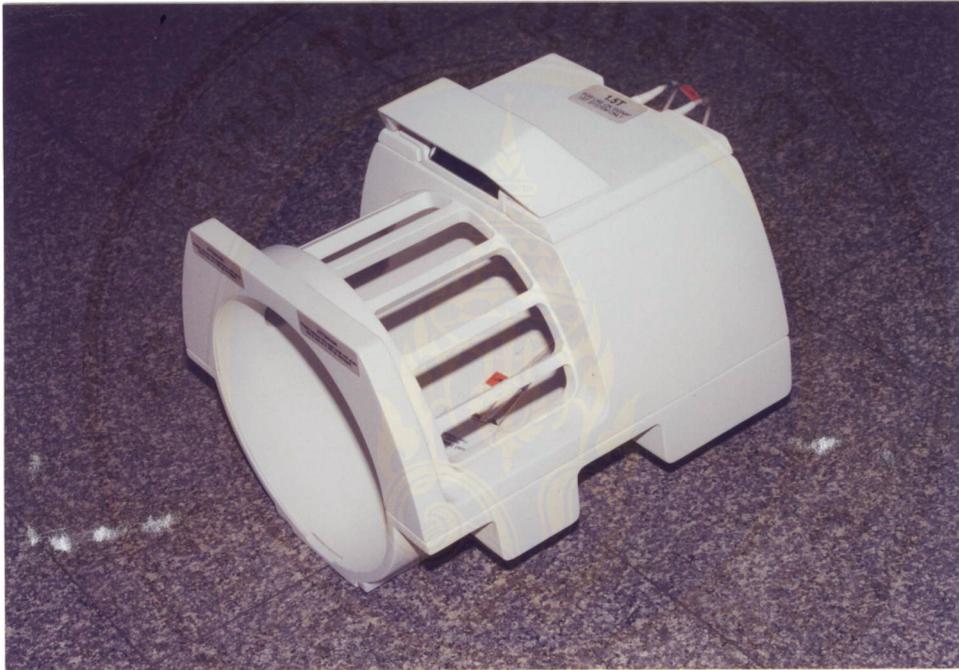

The magnetic resonance unit used in this study is a 1.5 Tesla superconductive magnet, manufactured by General Electric, Milwaukee, USA, model Signa Horizon (High speed) 1.5T with 5.8 software version (Figure 26).

**Figure 26.** The magnetic resonance unit used in the study.

#### 4.1.1.2 Coil

Head coil is used for  $T_1$  measurement of CSF. This coil is a one-piece device that both transmits and receives RF signals (Figure 27).

**Figure 27.** The head coil.

#### 4.1.1.3 Film.

Films used in this study are Konica's, LP 670-E. It is used for archiving the image of CSF in lateral ventricles for  $T_1$  measurement.

#### 4.1.1.4 Region of interest (ROI).

A ROI is a user-defined area on an acquired image used to measure SI and display statistical analysis. This key is found on top level display.

#### 4.1.1.5 Sampling unit.

$T_1$  relaxation time of CSF was measured in 20 healthy volunteers. The volunteer subjects (10 men, 10 women) ranged from 19 to 50 years in age (mean,  $32.9 \pm 10.3$ ). They are all Thais.

### 4.1.2 Methods.

#### 4.1.2.1 Imaging techniques.

All healthy volunteers had MR imaging at 1.5 T as follows:

##### 4.1.2.1.1 Sagittal $T_1$ -weighted scout location sequence.

Scanning parameters for sagittal  $T_1$ -weighted sequence were as follows: TR/TE/NEX = 300/8/1; imaging matrix = 256x192; FOV = 20x20; section thickness = 5 mm; and an acquisition time = 1 minute 4 seconds.

##### 4.1.2.1.2 Axial IR sequence.

Sagittal  $T_1$ -weighted scout image was used to select the axial IR images level that best demonstrates the lateral ventricles. Scanning parameters for axial IR image were as follows: TR/TE/NEX = 11,000/20/0.5; matrix = 256 x 128; thickness = 5 mm; giving a voxel size of  $0.78 \times 1.56 \times 5 \text{ mm}^3$  at a field of

view 20 x 20 cm. Three different TI values: 1500, 2000, 2600 msec are used. Total imaging time for the IR sequence was 46 minutes 12 seconds.

#### 4.1.2.2 Measurement of SI

SI was measured on each of three IR images with automated “Evaluated” features of the standard console. Two rectangles were placed within right and left anterior horns of lateral ventricles on the image which has minimized partial-volume contributions from choroid plexus, and then the rectangles were placed precisely at the same positions on other two images ( Figure 28).

ROI were routinely selected first on the 1500 msec TI image, on which contrast is clearest. The window and center setting were set as low as possible, so that the image appeared uniformly white; the center value was then increased until the ventricles became dark, and the ROI was placed in a uniformly dark area.

#### 4.1.2.3 Calculation of $T_1$

The values of SI acquired from the measurement described above were plotted versus TI by using the program package SPSS (ver.M, release 9.1 G). These curves were estimated by using logarithmic model that showed regrowth curve with increased TI. We can determine TI (null) by using constants that acquired from this program in the equation (16):

$$Y (SI) = B \ln TI + C \quad (16)$$

Where B and C are constant values. We know  $T_I$  (null), then we can solve the equation mathematically for  $T_1$  value by using the equation (10) expressing as:

$$T_{I_{\text{null of CSF}}} \cong 0.693 T_1 \text{ of CSF}$$

We can also determine  $T_1$  value by using curve with the point at which the SI is zero. The time at this null point is denoted  $T_I$  (null), then we can solve  $T_1$  values by using the equation (10) too. In this study we used former method. The example for  $T_1$  calculation was showed in Appendix A.

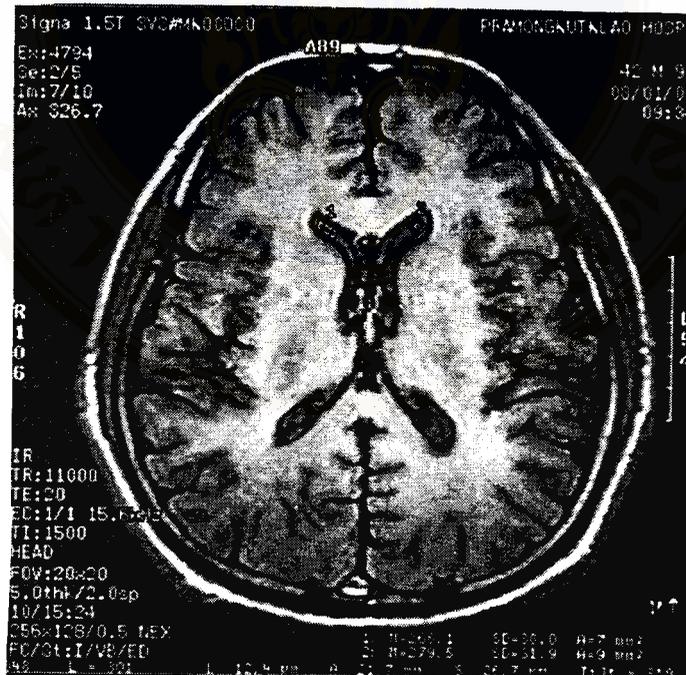

Figure 28. Showing the positions of the right and left anterior horns of lateral ventricles where  $T_1$  valued were calculated.

#### 4.1.2.4 Statistical Analysis

$T_1$  measurement was obtained in both sides of lateral ventricles (L/R ratio), to verify precision of the measurement technique within a single volunteer. Ratios of  $T_1$  measurements (left-to-right sided) were calculated in each subject (8).

Level of confidence and power of test can represent the statistical accuracy of  $T_1$  measurements.

## 4.2 Contrast optimization of fast FLAIR pulse sequence.

### 4.2.1 Materials

4.2.1.1 Magnetic resonance unit, Coil, Flim, and ROI are the same in the topic 4.1.1

### 4.2.1.2 Patients.

We studied 17 patients perventricular lesions (7 men and 10 women; ranging of age = 40 to 86 years old, mean age, 56 years) who were referred for MR brain imaging at Thai army hospital. The lesions selected for this study show hypersignal intensity both in  $T_2$ -weighted and fast FLAIR sequences; and touch CSF border, the total number of the lesions was 41.

#### 4.2.2 Methods.

All the patients had MR imaging at 1.5 T as follow :

##### 4.2.2.1 Imaging techniques.

###### 4.2.2.1.1 Sagittal T<sub>1</sub>-weighted scout location sequence.

Scanning parameters for sagittal T<sub>1</sub>-weighted sequences were as follows: TR/TE/NEX = 640/8/3; imaging matrix = 256x256; FOV = 22x22; section thickness = 5 mm; and an acquisition time of 2 minutes 47 seconds.

###### 4.2.2.1.2 Axial fast FLAIR sequences.

The axial images that best depicted the periventricular lesions were selected. Scanning parameters for axial fast FLAIR images were as follows: TR/TE /NEX = 11000/148/1 with ETL of 20; signal BW of  $\pm 32$  Khz; imaging matrix = 256 x 192; section thickness = 5 mm; giving a voxel size 0.78 x 1.33 x 5 mm<sup>3</sup> at a field of view 20 x 20 cm. To use five different TI values: 2000, 2100, 2200, 2300, and 2400 msec and total imaging time for the five IR series was 9 minutes 17 seconds.

###### 4.2.2.1.3 Axial T<sub>2</sub>-weighted FSE sequence.

Scanning parameters for axial T<sub>2</sub>-weighted FSE images were as follows: TR/TE/NEX = 4000/101/3 with ETL of 20; signal BW of  $\pm 32$  Khz; imaging matrix = 256 x 256; section thickness, 5 mm; giving a voxel size 0.78 x 0.78 x 5 mm<sup>3</sup> at a field of view 20 x 20 cm and total imaging time was 3 minutes 4 seconds.

#### 4.2.2.3 Measurement of standard deviation (SD) of background air

The SD of the mean SI of background air was used to estimate noise. This SD was measured in areas free of ghost artifacts ( $SD_{air}$ ), and then the rectangle was placed on precisely the same volume of background air on each the other images.

#### 4.2.2.4 The precision of random sampling for SI measurement.

To determine variation in random sampling for SI measurement, we measured SI in three different area within each lesion, CSF, and WM (Figure 30). The coefficient of variation (SD divided by the mean) of SI in three different areas within each lesion, CSF, and WM represents to the precision of random sampling.

#### 4.2.2.5 Objective image assessment.

For objective image assessment, SNR of the individual type tissues, CR and CNR of periventricular lesions to normal adjacent WM and CSF, were determined by following the equations(17), (14) and (15), respectively.

$$SNR_{tissue} = S_{tissue} / SD_{air} \quad (17)$$

$$CR_{tissue(1,2)} = (S_{tissue(1)} - S_{tissue(2)}) / (S_{tissue(1)} + S_{tissue(2)}) \quad (14)$$

$$CNR_{tissue(1,2)} = (S_{tissue(1)} - S_{tissue(2)}) / SD_{air} \quad (15)$$

Where SNR is signal to noise ratio.

CR is contrast ratio.

CNR is contrast to noise ratio.

S is signal intensity.

Then SNR, CR, and CNR were compared among all of the five different TI images to determine the TI that cause optimal CSF suppression.

The CR and CNR of the fast FLAIR images with the optimal inversion for CSF suppression with good lesions to CSF contrast obtained from our study and those of the fast FLAIR images with TR/TI 11000/2200 msec as recommended by Signa Horizon 1.5 Tesla protocol guide for optimal CSF suppression with good gray to white matter contrast (23) were compared by using a paired one-tailed  $t$  test (P-value < 0.05). Research of John N. Rydberg (5) recommended TR/TI exceeding 11000/2600 to provide 90% lesion (multiple sclerosis) to white matter contrast. So comparison between CR, CNR of images with TI 2400 msec and optimal TI for CSF suppression obtained from our study was done by using a paired one-tailed  $t$  test (P-value < 0.05). TI 2400 msec was used instead of TI 2600 because it is the maximal value in our study.

Last, the SNR, CR and CNR of the fast FLAIR images with optimal TI for CSF suppression and those of T<sub>2</sub>-weighted FSE images were compared by using a paired one-tailed  $t$  test (p-value < 0.05).

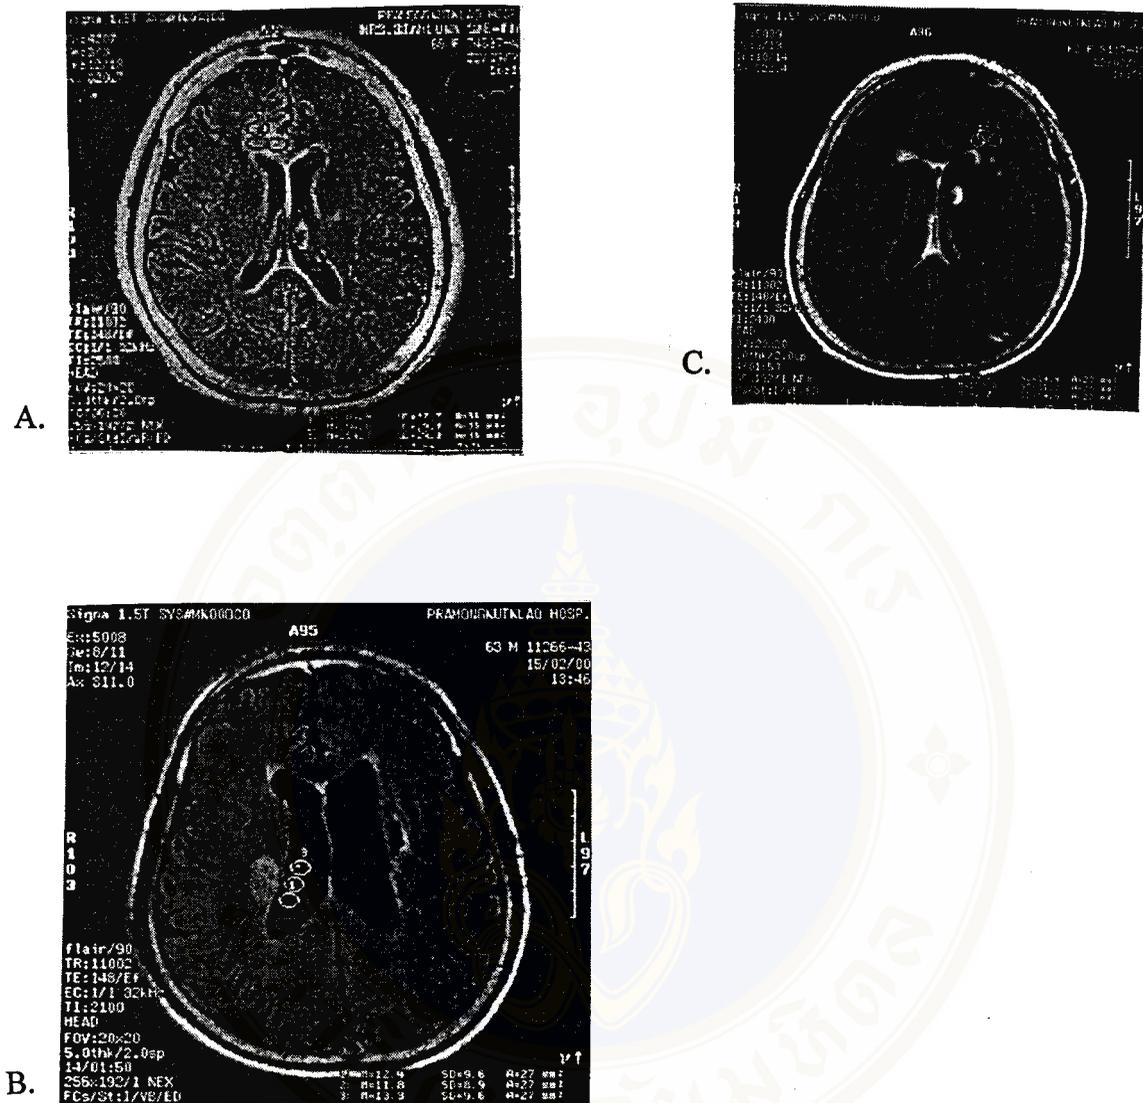

Figure 30. Showing the position of the random sampling to measure SI of each tissues in fast FLAIR images. (A) the position of the lesion which was measured by random sampling in three different areas. (B,C) the position of CSF and WM was measured by random sampling in three different areas, respectively.

## CHAPTER V

### RESULTS

#### 5.1. $T_1$ values of CSF in lateral ventricles.

$T_1$  value of CSF was measured in 20 healthy volunteers with IR technique. The volunteers subjects (10 men, 10 women) ranged in age from 19 to 50 years (mean,  $32.9 \pm 10.3$ ). They are Thais. The volunteers were performed with TR of 11,000 msec, and three different TI values of 1500, 2000, 2600 msec. The SI of CSF was measured on each of three IR images. The acquired data from measurement is plotted between SI values with difference TI and determinate  $T_1$  of CSF by using the SPSS program for window. When we know  $T_1$  value of CSF, we can calculate interval of TI value to get the signal from CSF to be null in the equation (1).

$T_1$  values of CSF were averaged from 14 healthy volunteers because lateral ventricles of six volunteer subjects are too small to measure the SI, which calculation of  $T_1$  represent in Appendix A.  $T_1$  value of CSF are shown in Table III, these data are normal distribution with 95% confidence level. The mean  $T_1$  value of CSF ( $\pm$  S.D) in 14 volunteer subjects is  $3225.7 \pm 173.8$  msec (3051.9 to 3399.5 msec), the coefficient of variance is 5.39%. The statistical accuracy of these data is 95% confidence level and 90% power of test, that maximum allowable error between this statistical sample value and the population value is 5% of mean statistical sample value.

**Table III.** T<sub>1</sub> of CSF in healthy volunteers

No.	AGE	SEX	T <sub>1</sub> of Lt. Ant. horn (msec.)	T <sub>1</sub> of Rt. Ant. horn (msec.)	L / R ratio	T <sub>1</sub> ( msec)
1	19	M	3339.3	3166.9	1.054	3253.1
2	22	F	3301.1	3420.7	0.965	3360.9
3	22	M	3198.4	3023.4	1.058	3110.9
4	22	M	3339.3	3141.1	1.063	3240.2
5	23	M	2853.5	2817.0	1.013	2835.2
6	23	M	3324.5	3281.4	1.013	3302.9
7	26	F	3352.3	3249.0	1.032	3300.7
8	34	F	3418.7	3298.5	1.036	3358.6
9	40	M	2903.0	3107.3	0.934	3005.2
10	42	M	3256.8	3170.7	1.027	3213.8
11	43	F	3423.8	3211.2	1.066	3317.5
12	43	M	3419.7	3567.1	0.959	3493.4
13	47	F	3072.4	2991.5	1.027	3031.9
14	50	M	3436.5	3233.2	1.063	3334.8
Mean					1.022	3225.7
Standard deviation					0.042	173.8
Variance						30189.1
Coefficient of variance						5.39%

The ratio of  $T_1$  CSF value in the left and right anterior horn of lateral ventricles (L/R ratio) is measured by the precision of the  $T_1$  measurement technique. This ratio is  $1.022 \pm 0.042$ . It is not significantly different from 1.000 indicating symmetrical of right to left hemisphere identity, suggesting that within - volunteer precision was excellent.

The result obtained in the our research, comparing the previous research, R. Grant Steen and Suzanne A. Gronemeyer (8). From previous research (8),  $T_1$  values of CSF were measured in 26 healthy volunteers, (14 men, 12 women) ranged in age from 18.2 to 59.6 years (mean 34.6 years  $\pm 9.8$ ).  $T_1$  of CSF from previous research were averaged from 20 volunteers because six subjects had ventricles too small for measurement of SI. These data are listed in Table IV and summarized in Figure 31.

**Table IV.** Mean  $T_1$  relaxation time of CSF ( $\pm$  S.D) of our and previous research (8).

Research	Mean $T_1$ (msec)	CV (%)	Range (msec)
Our research	$3,226 \pm 174$	5.4	2,835-3,494
Previous research	$4,282 \pm 1,552$	36.2	2,495-7,791

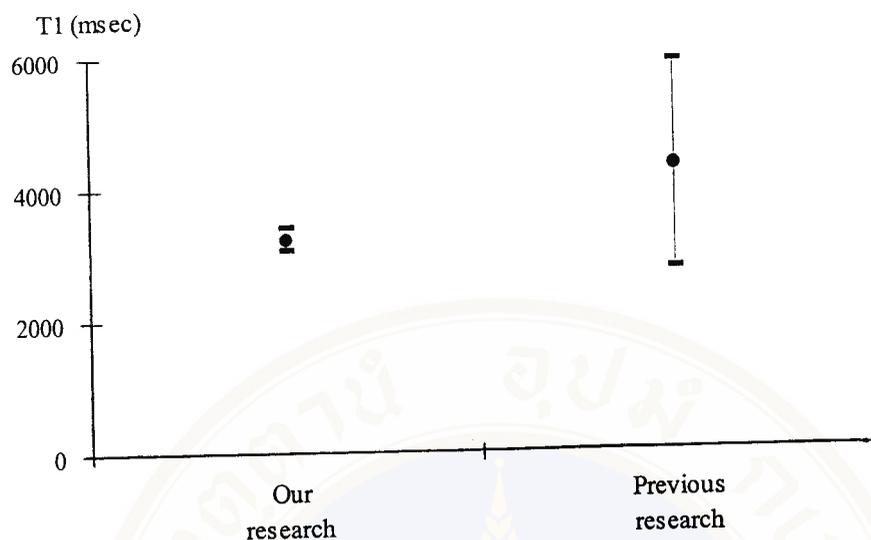

Figure 31. Showing the mean ( $\pm$  S.D) of  $T_1$  of CSF obtained in our research, is in interval of the mean ( $\pm$  S.D) $T_1$  of CSF obtained in previous research.

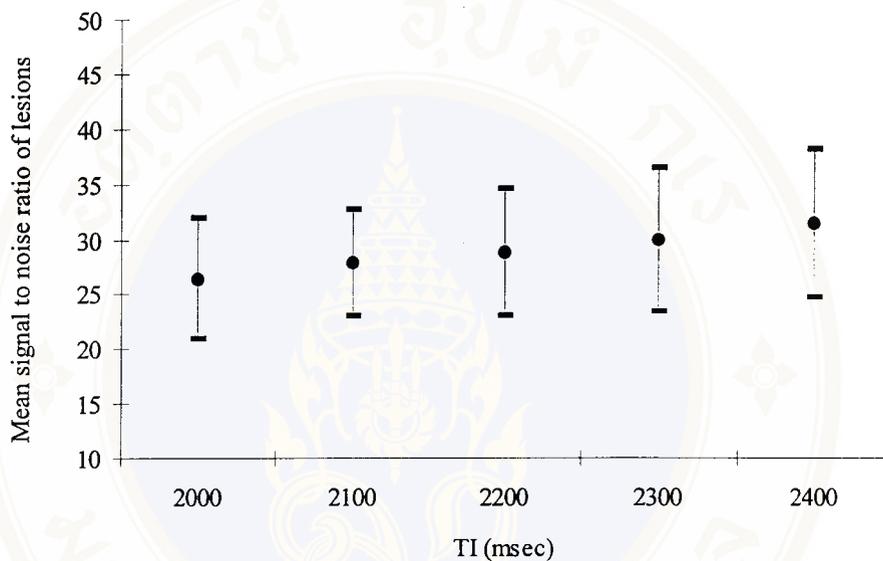

## 5.2 Image assessments of fast FLAIR pulse sequence in various TI

### 5.2.1 SNR

The data measurements of SI of individual type tissue are shown in Appendix D. The SI of each tissues is calculated for SNR. The precision of the random sampling for SI measurement data are shown in Appendix C. These data of SNR of individual types of tissue in various TI of fast FLAIR pulse sequence show in Appendix E. The SNR of individual types of tissue in various TI of fast FLAIR pulse sequence are normal distribution with 95% confidence level. The mean SNR of individual types of tissue ( $\pm$  S.D) versus various TI is plotted in Figure 32-34.

5.2.1.1 The mean SNR of the lesions versus various TI of FLAIR pulse sequence is shown in Figure 32. The mean SNR of the lesion were obtained from 41 lesions, those increased with TI. From the data, the fast FLAIR pulse sequence with a

lesions, those increased with TI. From the data, the fast FLAIR pulse sequence with a TI of 2000 msec, give minimum average SNR of the lesion. While the fast FLAIR pulse sequence with a TI of 2400 msec, give maximum average SNR of the lesion.

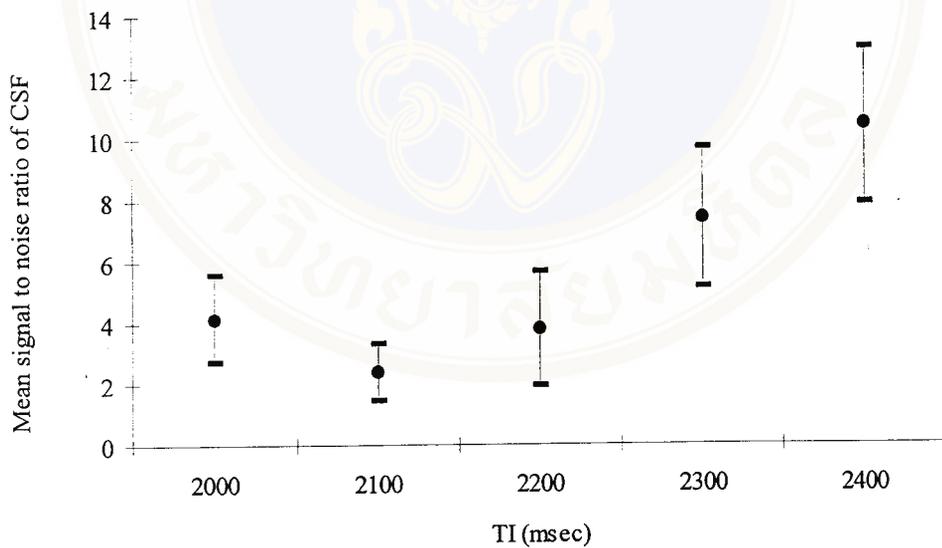

**Figure 32.** Plot of the mean SNR of the lesions ( $\pm$  SD) versus different TI. The mean SNR of the lesions increased with TI.

5.2.1.2 The mean SNR of CSF versus various TI of the fast FLAIR pulse sequence is shown in Figure 33. The mean SNR of CSF were obtained from 41 CSF areas. The fast FLAIR pulse sequence with a TI of 2100 msec, give minimum mean SNR of CSF. The fast FLAIR pulse sequence with TI higher than 2100 msec is increasing the value of mean SNR of CSF depend on the value of TI that is maximum at 2400 msec. We calculated TI values that nulls the CSF signal from the equation (10), expressing as:

at 2400 msec. We calculated TI values that nulls the CSF signal from the equation (10), expressing as:

$$TI_{(null)} \cong 0.693 T_1$$

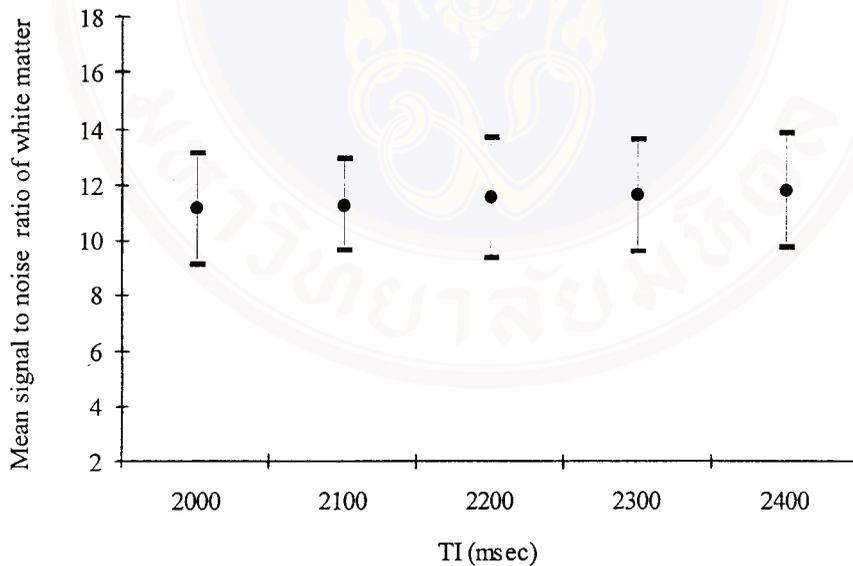

This performance is consistent with a mean  $T_1$  of healthy volunteer from this experiment (3225.7 msec). Therefore TI that nulls the CSF signal that calculate from the equation (10) is  $0.693 \times 3225.7 \text{ msec} = 2235 \text{ msec}$ . But TI of CSF that gives near zero or minimum of  $SNR_{CSF}$  from this experiment of FLAIR pulse sequence in different TI, is TI of 2100 msec. It values difference from the null TI of CSF in calculation from the equation (10) approximate 4%.

**Figure 33.** Plot of the mean SNR of CSF ( $\pm$  SD ) versus different TI. The fast FLAIR pulse sequence with a TI of 2100 msec, give minimum mean SNR of CSF. The fast FLAIR pulse sequence with TI higher than 2100 msec, these values increased with TI that is maximum at TI 2400 msec.

FLAIR pulse sequence with TI higher than 2100 msec, these values increased with TI that is maximum at TI 2400 msec.

5.2.1.3 The mean SNR of WM versus various TI of the fast FLAIR pulse sequence is shown in Figure 34. The mean SNR of WM were obtained from 36 WM areas. They increased with TI. From the data, the fast FLAIR pulse sequence with a TI of 2000 msec, give minimum average SNR of the WM. While the fast FLAIR pulse sequence with a TI of 2400 msec, give maximum mean SNR of the WM.

**Figure 34.** Plot of the mean SNR of WM ( $\pm$  SD ) versus different TI. The mean SNR of WM increased with TI. These means that, for the fast FLAIR pulse sequence with a TI of 2000 msec, give minimum mean SNR of WM. While the fast FLAIR pulse sequence with a TI of 2400 msec, give maximum mean SNR of WM.

The difference of the SNR in the lesion, CSF, and WM in various TI is shown in Figure 35. The fast FLAIR pulse sequence of TI 2100 msec gives the maximum difference of SNR between the lesions and CSF, while TI of 2400 msec gives the minimum. Unlike the difference of SNR between lesion and WM, the difference of SNR between the lesion and WM is maximum in TI 2400 msec, and minimum in TI 2000 msec.

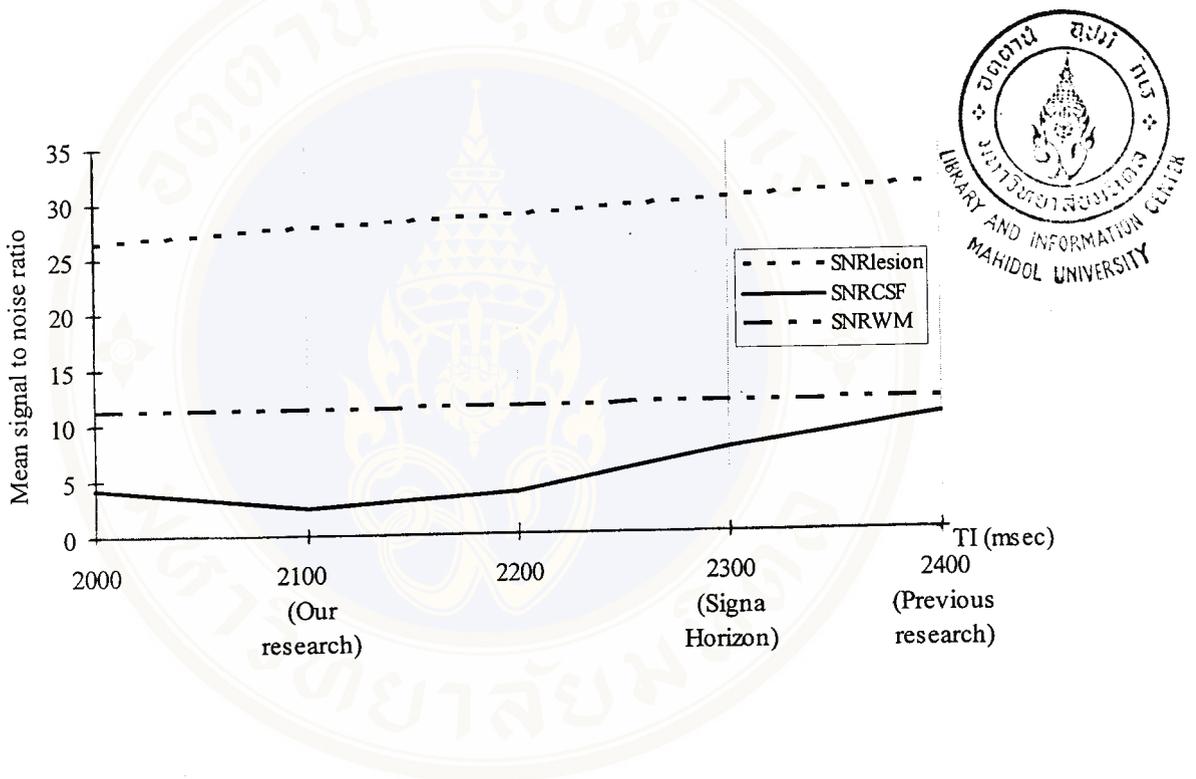

Figure 35. Plot of the difference of the SNR in the lesion, CSF, and WM in different TI.

### 5.2.2 CNR

#### 5.2.2.1 The CNR of the lesions to CSF are shown in Appendix E.

These data are normal distribution with 95% confidence level. The mean CNR of lesions to CSF ( $\pm$  S.D) versus various TI of the fast FLAIR pulse sequence were obtained from 41 CNR of lesions to CSF, that are shown in the Figure 36. The fast FLAIR pulse sequence provided the highest CNR of lesions to CSF in TI 2100 msec, and the lowest CNR of lesions to CSF in TI 2400 msec. This means that, the fast FLAIR pulse sequence with a TI of 2100 msec gives the maximum increasing lesion conspicuity in the periventricular region. This result is similar to the different SNR between the lesions and CSF.

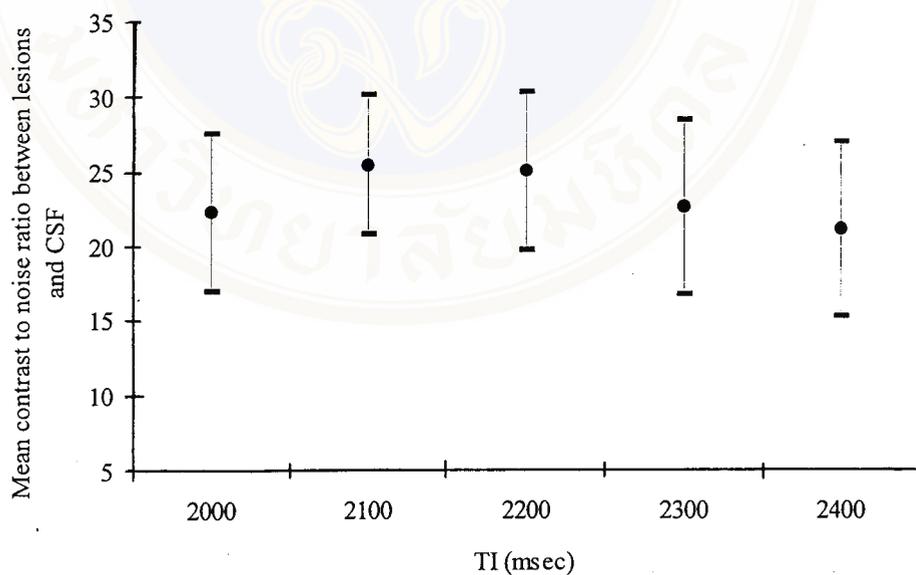

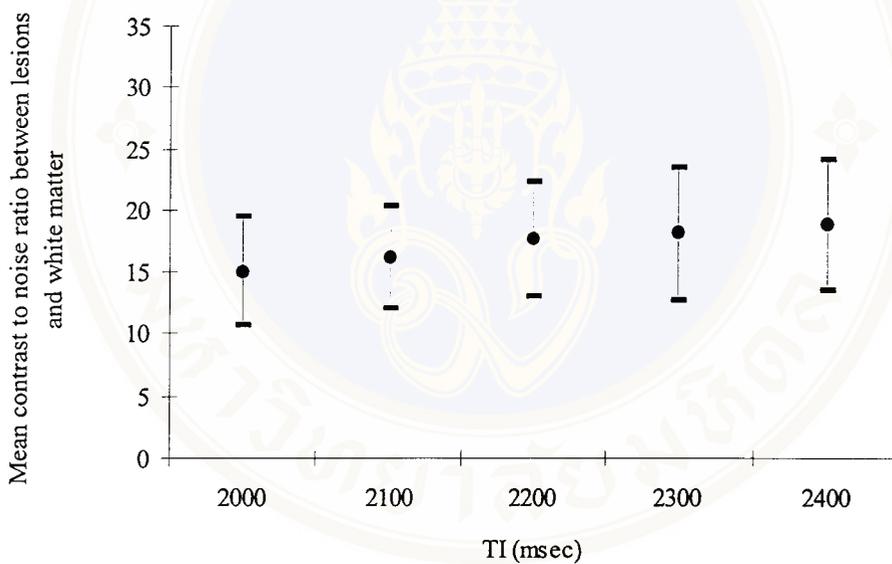

Figure 36. Plot of the mean CNR between the lesions and CSF versus different TI.

5.2.2.2 The CNR of the lesions to WM are shown in Appendix E.

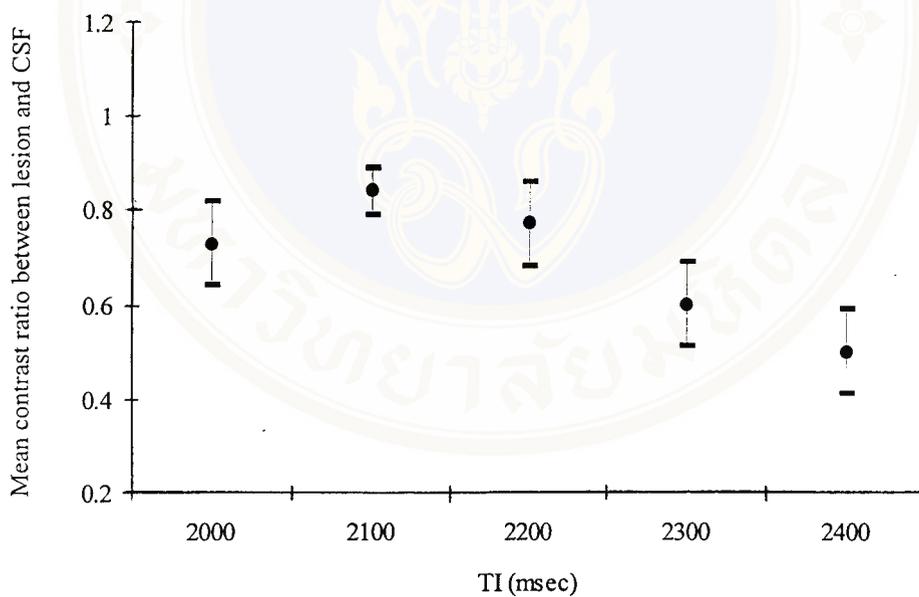

These data are normal distribution with 95% confidence level. The mean CNR of lesions to WM ( $\pm$  S.D) versus various TI of the fast FLAIR pulse sequence were obtained from 36 CNR of lesions to WM, that are shown in the Figure 37. The fast FLAIR pulse sequence with TI 2400 msec provided the highest CNR of lesions to WM and the lowest CNR of lesions to WM in TI 2000 msec. This result is similar to the different SNR between the lesions and WM.

**Figure 37.** Plot of the mean CNR between the lesions and WM versus different TI. The fast FLAIR pulse sequence of TI 2400 msec provided the highest CNR of the lesions to WM, and the lowest CNR of the lesions to WM in TI 2000 msec.

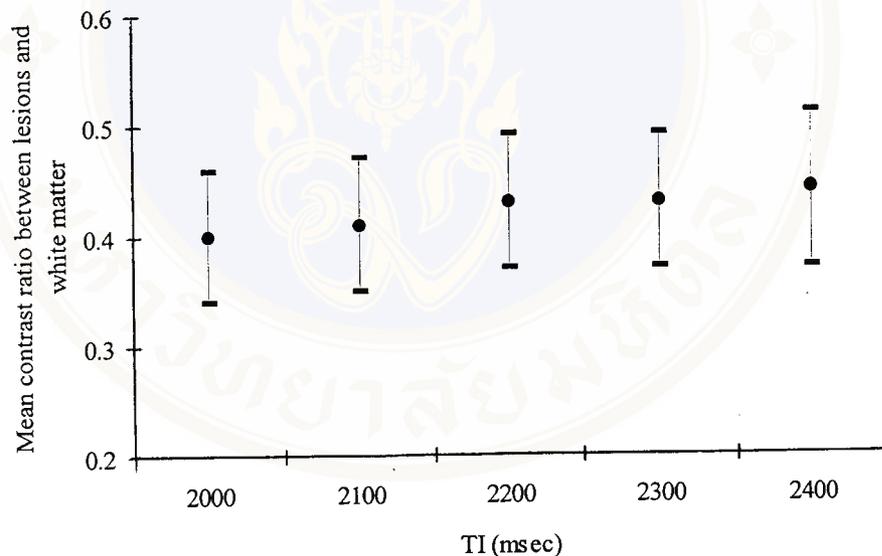

### 5.2.3 CR

5.2.3.1 The CR of the lesions to CSF is shown in Appendix E. These data are normal distribution with 95% confidence level. The mean CR of the lesions to CSF ( $\pm$  S.D) versus various TI of the fast FLAIR pulse sequence were obtained from 41 CR of the lesions to CSF, that are shown in Figure 38. The fast FLAIR pulse sequence with TI 2100 msec provided the highest CR of the lesions to CSF, and the lowest CR of the lesions to CSF in TI 2400 msec. The result is similar to the CNR of the lesion and CSF.

**Figure 38.** Plot of the mean CR between the lesions and CSF versus different TI. The fast FLAIR pulse sequence of TI 2100 msec provided maximum the mean CR of the lesions to CSF, and minimum the mean CR of the lesions in TI 2400 msec.

5.2.3.2 The CR of the lesions to WM is shown in Appendix E. These data are normal distribution with 95% confidence level. The mean CR of the lesions to WM ( $\pm$  S.D) versus various TI of the fast FLAIR pulse sequence were obtained from 36 CR of the lesions to WM, that are shown in Figure 39. The fast FLAIR pulse sequence of TI 2400 msec provided the highest CR of the lesions to WM, and the lowest CR of the lesions to WM in TI 2000 msec. The result is similar to the CNR between the lesions and WM.

**Figure 39.** Plot of the mean CR between the lesions and WM versus different TI. The fast FLAIR pulse sequence of TI 2400 msec provided the highest CR of the lesions to WM and the lowest CR of the lesions to WM in TI 2000 msec.

Images of fast FLAIR pulse sequence in difference TI from one patient studies with periventricular lesion are shown in Figure 40( A-E ). The Figure 40B shows that the fast FLAIR image with TI 2100 msec gives the best contrast enhancement of the lesion to interfaces of CSF. The Figure 40 E shows that the fast FLAIR image with TI 2400 msec gives poor contrast enhancement of the lesion to interfaces of CSF.

The optimization of contrast is considered to the fast FLAIR pulse sequence, specifically the contrast of the periventricular lesions to CSF. Our research show that fast FLAIR images with TI 2100 msec provides the better CR and CNR of the periventricular lesions to CSF than fast FLAIR images with TI 2000, 2200, 2300, and 2400 msec.

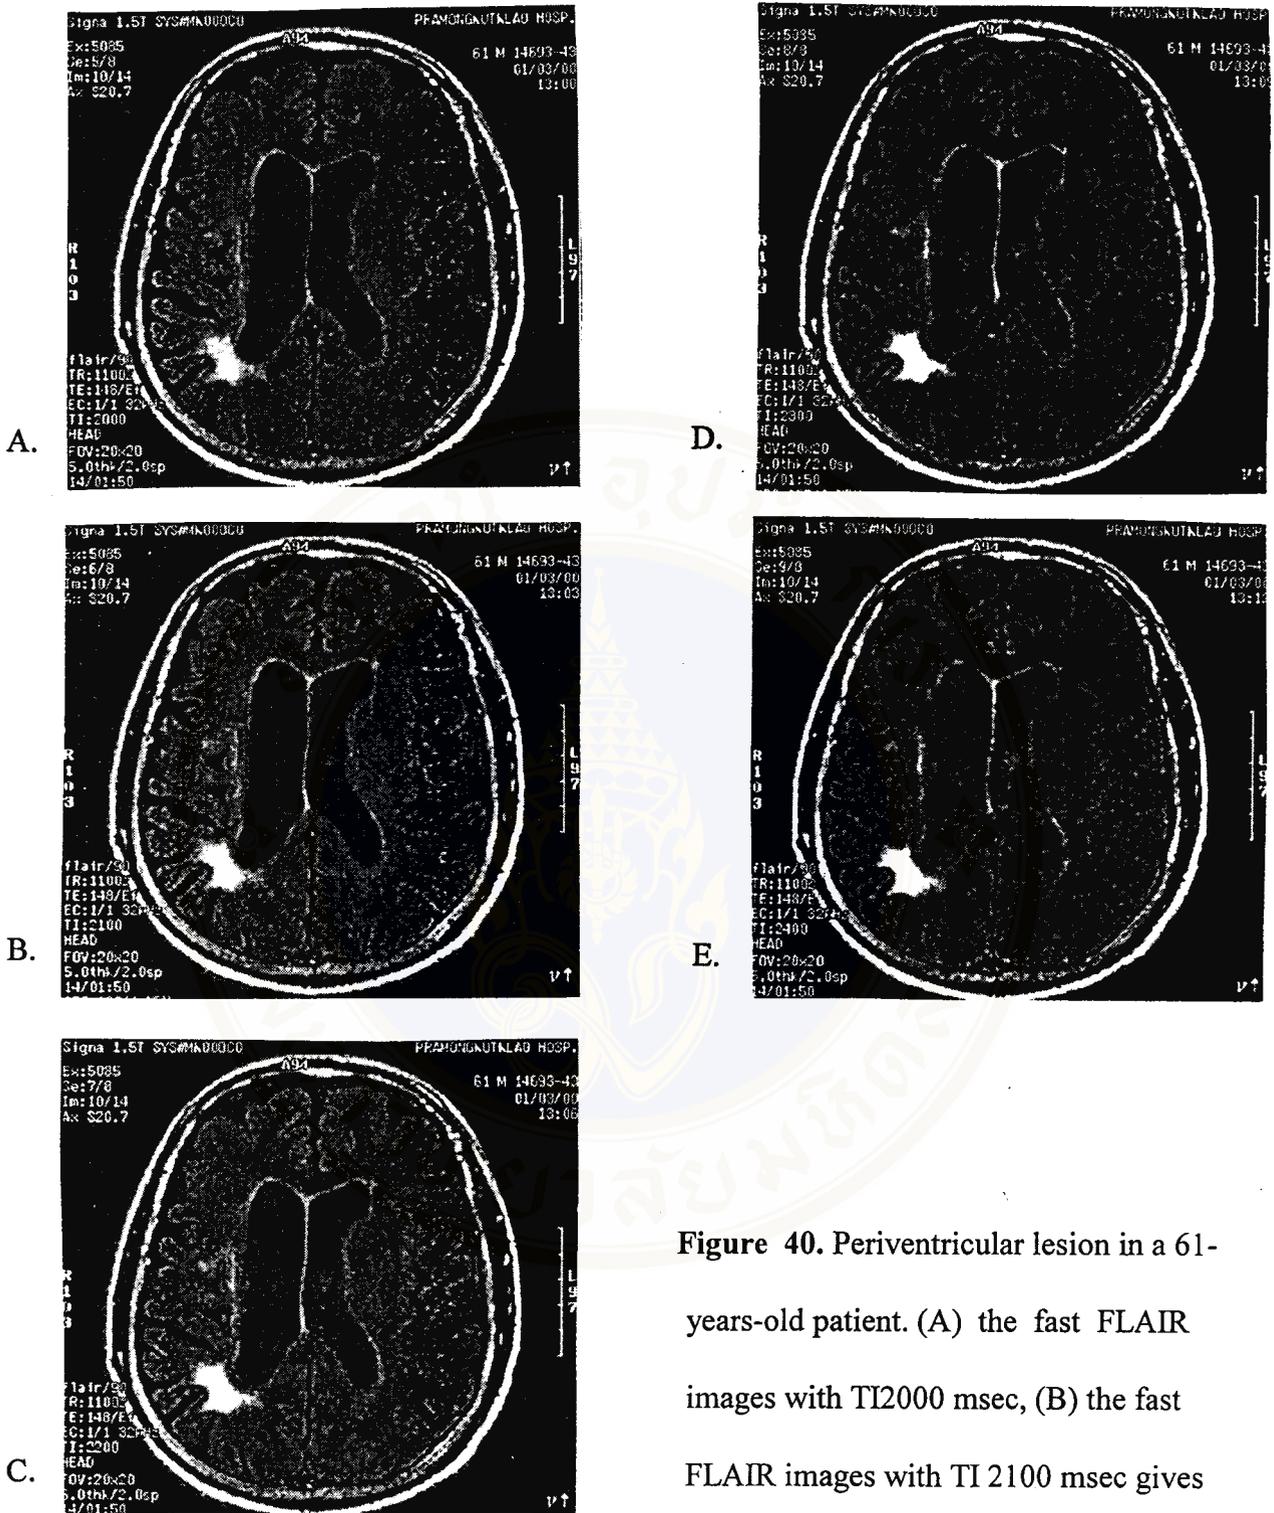

Figure 40. Periventricular lesion in a 61-years-old patient. (A) the fast FLAIR images with TI2000 msec, (B) the fast FLAIR images with TI 2100 msec gives the best contrast enhancement of the lesion to interfaces of CSF, (C,D) the fast FLAIR images with TI 2200, 2300 msec, (E) the fast FLAIR images with TI 2400 msec gives poor contrast enhancement of the lesion to interfaces of CSF.

### 5.3 Image assessments of T<sub>2</sub>-weighted FSE images.

#### 5.3.1 SNR

The SNR of individual type tissue for T<sub>2</sub>-weighted FSE techniques are normal distribution with 95% confidence level. These data represent in Appendix F .

#### 5.3.2 CNR and CR.

The CNR and CR of the lesions to CSF and WM for T<sub>2</sub>-weighted FSE pulse sequence are normal distribution with 95% confidence level. These data represent in Appendix F.

### 5.4 Comparing of the SNR, CNR and CR on the fast FLAIR images with optimal TI for CSF suppression that obtained by our research, Signa Horizon 1.5 Tesla protocol guide (23), previous research (5) and T<sub>2</sub>-weighted FSE images.

Our study shows that the fast FLAIR with optimal TI 2100 msec provides CSF suppression with good lesion to CSF contrast. The Signa Horizon 1.5 Tesla protocol guide (23) recommend that the fast FLAIR with optimal TI 2200 msec for CSF suppression with good gray to white matter contrast. The previous research (5) recommended TR/TI exceeding 11000/2600 to provide 90% lesion (multiple sclerosis) to WM contrast.

The SNR, CR, and CNR of FLAIR with optimal TI 2100 that obtained by our research were compared with those of FLAIR with optimal TI 2200 as recommended by Signa Horizon (23), FLAIR with optimal TI 2400 (TI 2400 msec was used instead of TI 2600 because it is the maximal value in our study) as recommended by previous research (5), and T<sub>2</sub>-weighted images.

5.4.1 The SNR of the lesions, WM, and CSF.

The mean SNR of individual types tissue ( $\pm$  S.D) for fast FLAIR with TI 2100, 2200, 2400 msec and T<sub>2</sub>-weighted FSE images are shown in TableV.

**Table V.** The SNR (mean  $\pm$  S.D) of individual types of the fast FLAIR images with TI 2100, 2200, 2400 msec and T<sub>2</sub>-weighted FSE images.

SNR of tissues	T <sub>2</sub> -weighted FSE	FLAIR FSE with TI 2100 msec (Our research)	FLAIR FSE with TI 2200 msec (Signa)	FLAIR FSE with TI 2400 msec (Previous research)
SNR <sub>lesion</sub>	39.04 $\pm$ 8.43	27.84 $\pm$ 4.82	28.77 $\pm$ 5.72	31.23 $\pm$ 6.65
SNR <sub>WM</sub>	14.44 $\pm$ 1.97	11.28 $\pm$ 1.68	11.51 $\pm$ 2.15	11.78 $\pm$ 2.07
SNR <sub>CSF</sub>	60.28 $\pm$ 7.41	2.41 $\pm$ 0.91	3.80 $\pm$ 1.85	10.39 $\pm$ 2.51

Note.- FSE indicates fast spin-echo

The fast FLAIR images with optimal TI 2100 msec for CSF suppression that obtained by our research gives the maximum difference of the SNR between the lesions and CSF, while those of T<sub>2</sub> -weighted FSE images is minimum.

These result are shown in Figure 41.

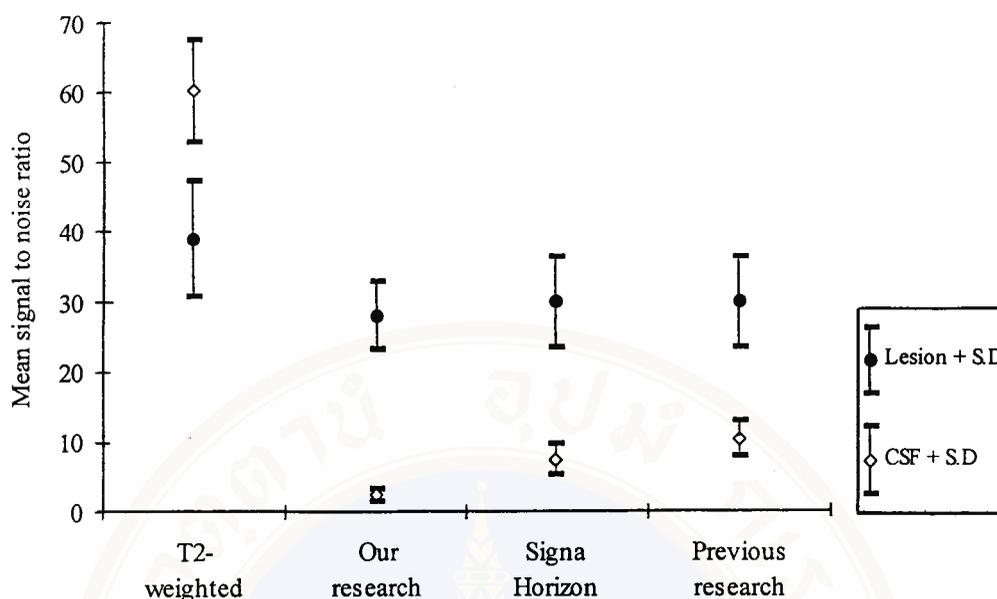

Figure 41. Plot of the mean SNR ( $\pm$  S.D.) of the lesions and CSF in different techniques.

#### 5.4.2 The mean CNR of the lesions to CSF.

The mean CNR of lesions to CSF of the fast FLAIR images with optimal TI 2100 msec for CSF suppression that obtained by our research was greater than those of the fast FLAIR images with TI 2200 msec as recommended by Signa horizon (23) for CSF suppression, but this difference was not significant ( $p$ -value  $> 0.05$ ).

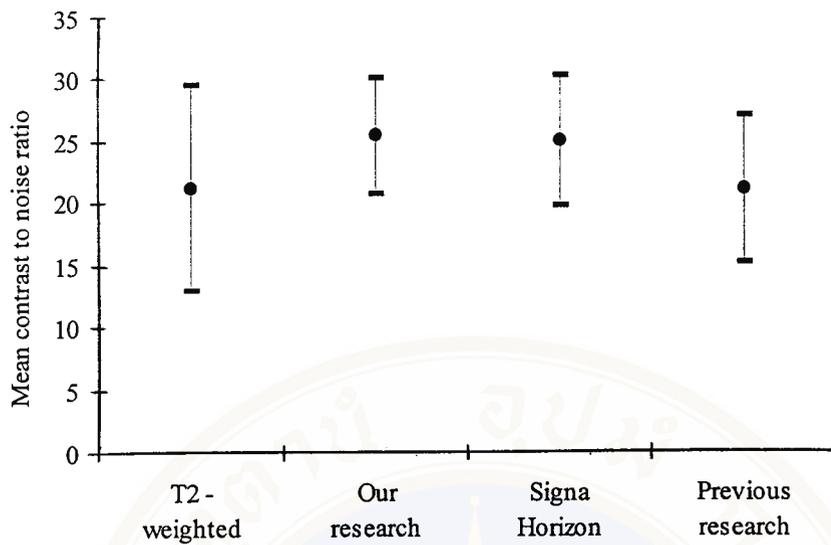

The CNR of the lesions to CSF of FLAIR with TI 2100 (our research), and FLAIR with TI 2200 (Signa Horizon) were significantly superior to  $T_2$ -weighted images ( $p$ -value  $< 0.05$ ). Conversely, FLAIR images with TI 2400 (previous research) is less CNR of the lesions to CSF than  $T_2$ -weighted images, but this

difference was not significant (p-value > 0.05). These results are summarized in Table VI and Figure 42.

**Table VI.** The CR and CNR (mean ± S.D) of the lesion to CSF and WM of the fast FLAIR with TI 2100, 2200, 2400 msec and T<sub>2</sub>-weighted FSE images.

	T <sub>2</sub> -weighted FSE	FLAIR FSE with TI 2100 msec (This research)	FLAIR FSE with TI 2200 msec (Signa) *	FLAIR FSE with TI 2400 msec
Lesion to CSF				
CR ± SD	0.22 ± 0.09	0.84 ± 0.05	0.77±0.09	0.50±0.09
CNR ± SD	21.24 ± 8.26	25.42 ± 4.68	24.98±5.26	21.01±5.87
Lesion to WM				
CR ± SD	0.44 ± 0.07	0.41 ± 0.06	0.43±0.06	0.44±0.07
CNR ± SD	23.71 ± 7.70	16.17 ± 4.06	17.67±4.62	18.87±5.30

Note.- \* Signa indicates Manufacturer recommendation.

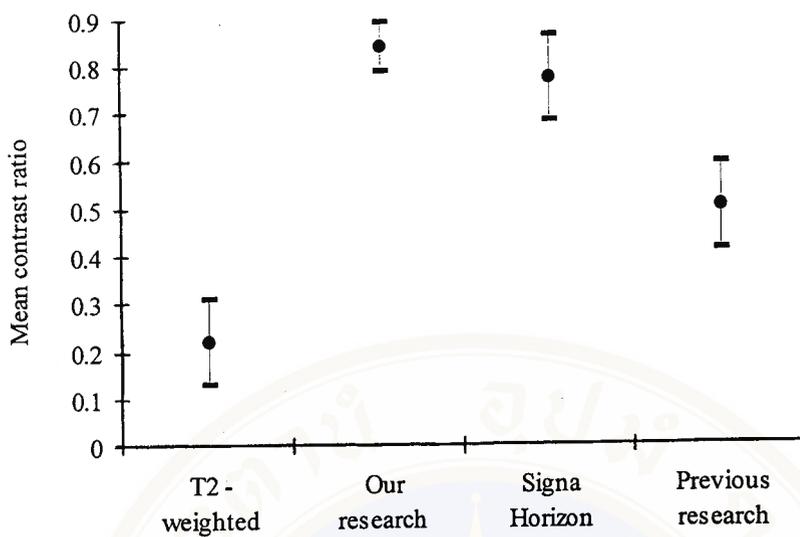

**Figure 42.** Plot of the mean CNR ( $\pm$ S.D) of the lesions to CSF versus different techniques.

#### 5.4.3 The mean CR of the lesions to CSF.

The mean CR of the lesions to CSF, fast FLAIR images with TI 2100 msec was significantly superior to fast FLAIR images with TI 2200 (p-value < 0.0005).

The mean CR of the lesions to CSF of FLAIR with TI 2100 (our research), FLAIR with TI 2200 (Signa Horizon) were significantly superior to T<sub>2</sub>-weighted images (p-value < 0.0005). These results are shown in Table VI and Figure 43.

**Figure 43.** Plot of the mean CR ( $\pm$ S.D) of the lesions to CSF versus different techniques.

#### 5.4.4 The mean CNR of the lesions to WM.

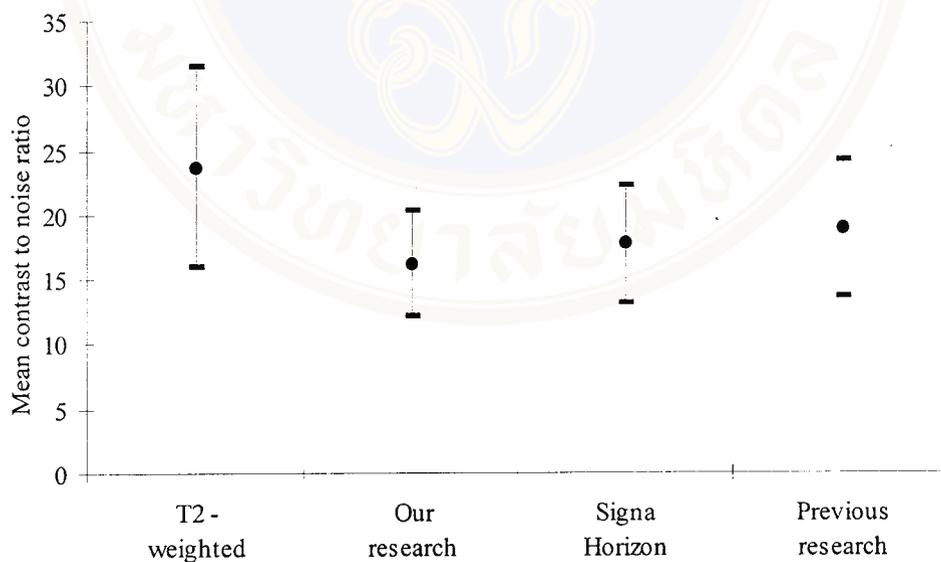

The mean CNR of the lesions to WM of the fast FLAIR images with TI 2200 msec as recommended by Signa Horizon 1.5 Tesla protocol guide (23) for CSF suppression were significantly superior to the fast FLAIR images with TI 2100 msec that obtained by our research for CSF suppression (p-value < 0.0005).

When we consider Figure 37 and 38, CNR and CR between the lesions to WM was increased with TI that those maximum with TI 2400 msec. Then we can estimate values of the CNR and CR between the lesion to WM from these curve that fast FLAIR sequence with TI higher than 2400 msec should increased with along TI. This result is consistent with previous research, John N. Rydberg (5)

recommend that TR/TI times exceeding 11000/2600 msec provide about 90% of the lesion (multiple sclerosis) to WM contrast possible theoretically.

The mean CNR of the lesions to WM of the fast FLAIR images with TI 2400 msec as recommended by previous research (5) were significantly superior to the fast FLAIR images with TI 2100 msec that obtained by our research for CSF suppression (p-value < 0.0005).

The CNR of the lesions to WM of T<sub>2</sub>-weighted were significantly superior to the FLAIR with TI 2100 (Our research), FLAIR images with TI 2200 (Signa Horizon), and FLAIR images with TI 2400 (Previous research)(p-value < 0.0005). These result are shown in Fig. 44.

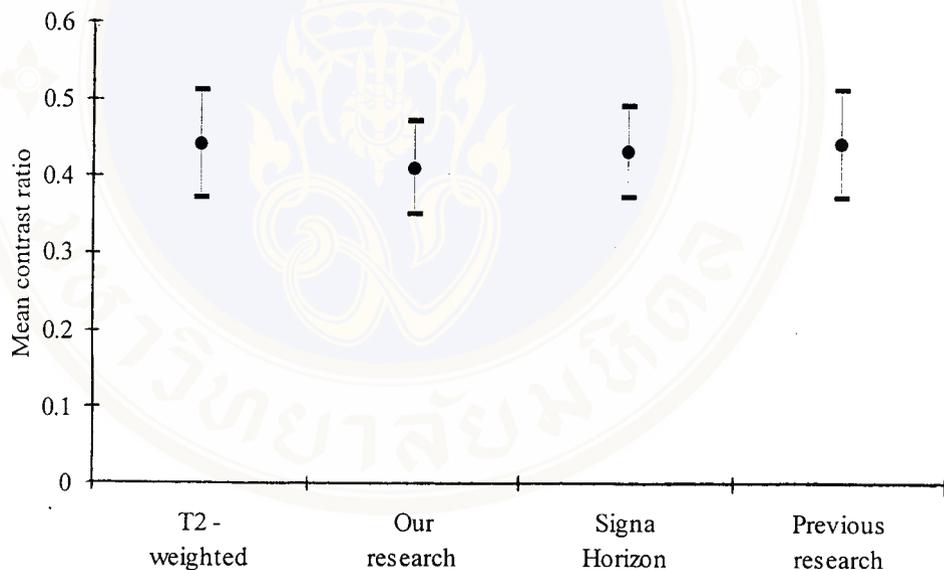

**Figure 44.** Plot of the mean CNR ( $\pm$ S.D) of the lesions to WM versus different technique.

#### 5.4.5 The mean CR of the lesions to WM.

The mean CR of the lesions to WM, fast FLAIR images with TI 2200 and TI 2400 msec was significantly superior to fast FLAIR images with TI 2100 (p-value < 0.005).

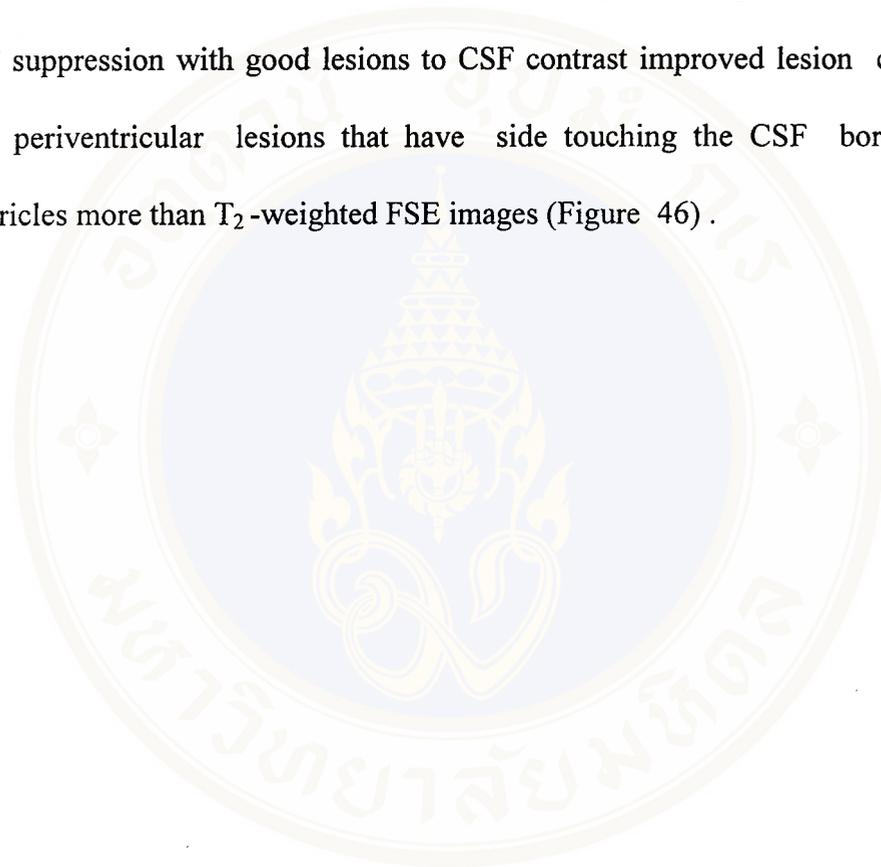

The CR of the lesions to WM of T<sub>2</sub>-weighted were significantly superior to the FLAIR with TI 2100 (Our research), and FLAIR images with TI 2200 (Signa Horizon) (p-value < 0.005). Comparing FLAIR with TI 2400 (Previous research) and T<sub>2</sub>-weighted images, CR of the lesions to WM were similar for both sequences without statistical significance. These results are shown in Figure 45.

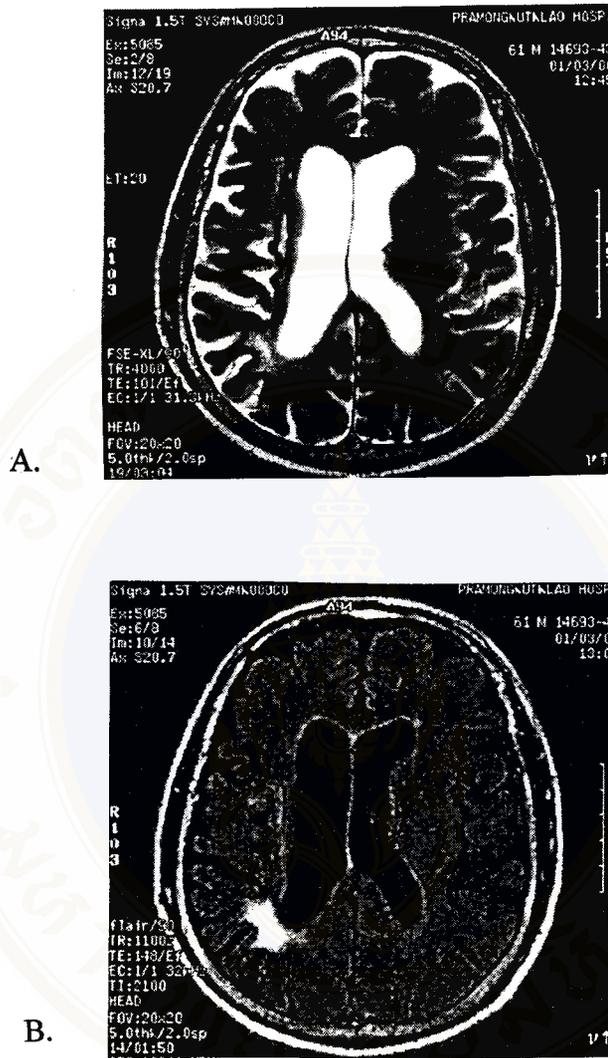

**Figure 45.** Plot of the mean CR ( $\pm$ S.D) of the lesions to WM versus different technique.

Therefore the fast FLAIR images with TI 2100 msec provides the better optimal TI for CSF suppression with good periventricular lesions to CSF contrast than fast FLAIR with TI 2000 (Signa Horizon), and with TI 2400 msec (Previous research).

In addition to, the fast FLAIR images with optimal TI 2100 msec for CSF suppression with good lesions to CSF contrast improved lesion conspicuity of the periventricular lesions that have side touching the CSF border of lateral ventricles more than  $T_2$ -weighted FSE images (Figure 46).

**Figure 46.** Periventricular lesions in a 61-years-old patient. (A) T<sub>2</sub>-weighted FSE axial image (TR/TE = 4000/101) demonstrates a lesion at the periventricular WM of right parietal lobe. (B) fast FLAIR axial image (TR/TE/TI = 11,000/148/2100) shows the same lesion with T<sub>2</sub>-weighted image that it clearly visible than T<sub>2</sub>-weighted image at the same level.

## CHAPTER VI

### DISCUSSION

#### 6.1 $T_1$ values of CSF in lateral ventricles.

Our research showed that the mean ( $\pm$ S.D) of  $T_1$  relaxation time of CSF in lateral ventricles of 14 healthy volunteers is  $3,225.7 \pm 173.8$ . However,  $T_1$  of CSF (mean $\pm$ SD) obtained by previous research (8) was  $4,282 \pm 1,552$  msec. Our result is consistency with previous research, R. Grant Steen and Suzanne A. Gronemeyer (8) that the mean ( $\pm$  S.D)  $T_1$  of CSF obtained in our research is in interval of the mean ( $\pm$  S.D)  $T_1$  of CSF obtained in previous research (8). The mean  $T_1$  of CSF obtained in our research is 24.7 % less than that obtained in previous research (8), perhaps because of difference in the method. Our research,  $T_1$  was calculated by using the equation [10] expressing as:

$$TI_{\text{null}} \cong 0.693 T_1$$

When we know  $TI(\text{null})$  of CSF, then we can solve this equation for  $T_1$  value of CSF. We determine  $TI(\text{null})$  by using the program SPSS 7.5 for window to estimate the logarithmic curves that were plotted between SI of CSF and different TI. But in the previous research (8),  $T_1$  value was calculated by using the mean SI values of CSF in

different TI that were fitted to the following equation (18), adapted for the SigmaPlot program (Jandel Scientific, San Rafael, Calif) on a MacIntosh Iivx;

$$SI = N(H) [ 1 + 2e^{-(TR-TE/2)/T_1} - e^{-TR/T_1} - 2e^{-TI/T_1} ] e^{-TE/T_2} \quad (18)$$

Where N(H) is the spin-density factor, TR is 2,500 msec, TE is 20 msec, and TI is 100, 500, 900, or 2,460 msec.

However, the major disadvantage of the IR technique is that it takes a lot of time, because it is necessary to use several different inversion time, and a long examination caused problems in a clinical setting. Therefore, the next study should improve to decrease the total examination time required for IR measurement of human brain  $T_1$ , while maintaining the precision and accuracy inherent in the technique (8).

## 6.2 Image assessments of fast FLAIR pulse sequence in various TI.

### 6.2.1 SNR

The mean SNR of the lesion and WM increase with TI that is maximum in fast FLAIR pulse sequence with TI 2400 msec, and minimum with TI 2000 msec. The longer TI allows the longitudinal magnetization of the lesions that are flipped  $180^\circ$  to more recover along a  $T_1$  growth curve before applying a  $90^\circ$  RF pulse (2). The amount of magnetization flipped into the x-y plane will depend on the amount of the longitudinal magnetization that has recovered during time TI. We measure this flipped magnetization. Therefore, at this point we get a free induction decay proportional to the longitudinal magnetization flipped into the x-y plane.

When we compare the mean SI between the lesion and WM at the same TI, the mean SI of the lesion is greater than WM. Most pathological lesions have slower T<sub>1</sub> recovery curves than those of WM because of their vasogenic edema (which contains H<sub>2</sub>O) and also have a longer T<sub>2</sub> than that WM (13). Then after the lesions and WM have flipped 180<sup>0</sup>, the T<sub>1</sub> recovery curve for the lesion begins lower that is more negatives along the Z axis than is WM. The longitudinal magnetization for the lesion grows along its T<sub>1</sub> recovery curve until it reaches its maximum. The T<sub>1</sub> growth curve for WM, because of its shorter T<sub>1</sub>, it recovers more rapidly along its T<sub>1</sub> curve than does the lesion to reach its maximum. FLAIR sequence uses a long TE to enhance the T<sub>2</sub> effect, so at the time TI, a 90<sup>0</sup> excitation pulse is applied. The lesion and WM will have longitudinal magnetization that will flip into the x-y plane and give off a signal according to their T<sub>2</sub> curves. The lesions have the lesser dephasing, and thus longer T<sub>2</sub> decay curve than WM (Figure 16). Therefore the lesions are brighter than WM and have SI more than WM. The relationship between increased inversion time and signal intensity is that when TI is increased, the SI of WM is less increased than SI of the lesion because WM has shorter T<sub>1</sub> and recovers more rapidly along its T<sub>1</sub> curve than lesions to reach its maximum (17).

The mean SI of CSF is minimum (near zero) in the fast FLAIR pulse sequence with TI 2100 msec. This TI valued is difference from the null TI of CSF in calculation in the equation (10) approximate 4%, these difference is not significant. However, when we consider the Figure 33, it shows the null SI of CSF is between TI 2100 and 2200 msec. So the next study should measurement the mean SI of CSF in FLAIR

pulse sequence with TI values between TI 2100 and 2200 msec to provide the null SI of CSF

### 6.2.2 CNR and CR

Our research showed that the fast FLAIR pulse sequence with optimal TI 2100 msec for optimal CSF suppression, provided the highest CNR and CR between lesions to CSF. While Signa Horizon 1.5 Tesla protocol guide recommend fast FLAIR sequence with TI 2200 msec for optimal CSF suppression. Comparing of both techniques, lesions to CSF contrast to noise ratio was greater for the fast FLAIR with TI 2100 msec than for the fast FLAIR sequence with TI 2200 msec, but this difference was not significant ( $p\text{-value} > 0.05$ ). Lesions to CSF contrast ratio was significantly higher for the fast FLAIR with TI 2100 msec than for the fast FLAIR sequence with TI 2200 msec ( $p\text{-value} < 0.0005$ ).

These difference may be because Signa Horizon 1.5 Tesla protocol guide is considered for the TI that is optimal suppression with good gray-white matter contrast (23). While this research is considered for the TI that is optimal CSF suppression with good lesion to CSF contrast.

The result shows the fast FLAIR with TI 2100 msec provides the optimal TI for CSF suppression with good periventricular lesions to CSF more than fast FLAIR with TI 2200 msec (Signa Horizon) and TI 2400 msec (Previous research). However, Figure 36 and 37, show that the fast FLAIR sequence with TI 2100 and 2200 msec provides the higher CNR and CR than another TI. Then further study should study the CNR and CR between the lesion to CSF in fast FLAIR sequence with

TI values between TI 2100 and 2200 msec to provide the best optimal TI for CSF suppression with good periventricular lesions to CSF.

### **6.3 Image assessments of the lesion to CSF contrast optimized of the fast FLAIR images and T<sub>2</sub>-weighted FSE images.**

The SNR of the lesion, CSF and WM on T<sub>2</sub>-weighted FSE images were greater than on the fast FLAIR images with TI 2100 (Our research), TI 2200 (Signa Horizon), and TI 2400 msec (Previous research) (p-value < 0.0005). Low SNR of lesion and WM on fast FLAIR images with different TI because 90° RF exciting pulse is applied at a TI, after the 180° inverting pulse. This 90° RF exciting pulse flips the partially recovery of longitudinal magnetization into the transverse plane. So the signal of the lesion and WM on the fast FLAIR images decrease.

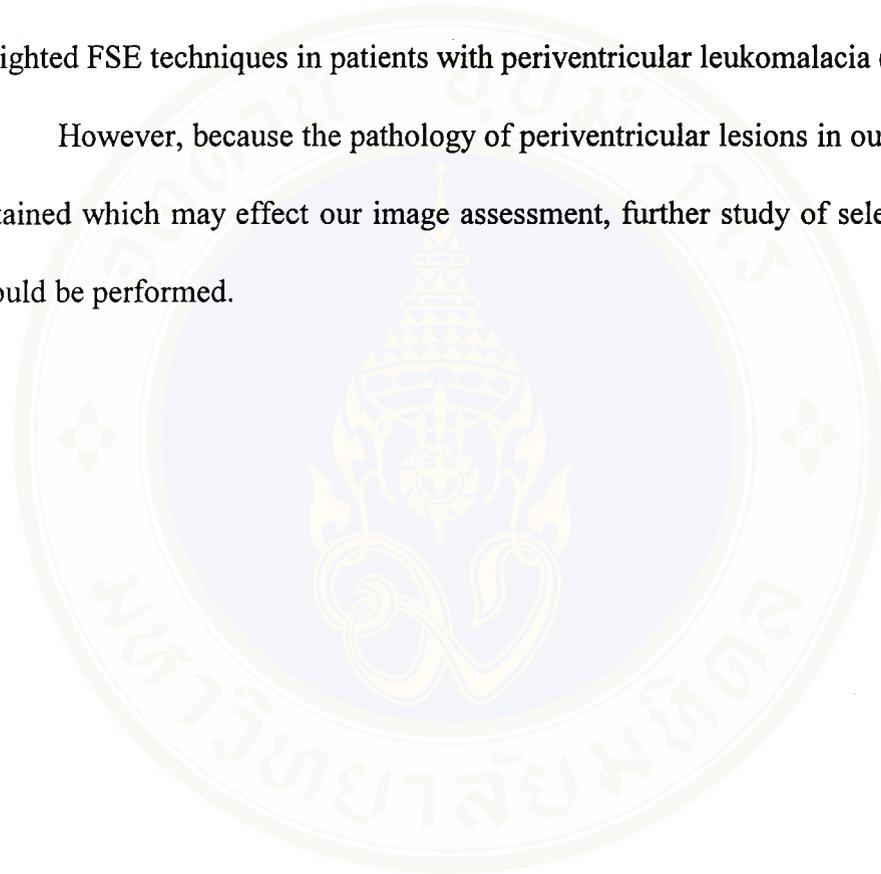

The CNR between the periventricular lesions to CSF on the fast FLAIR images with TI 2100 msec (Our research) was significantly superior to T<sub>2</sub>-weighted FSE images (p-value < 0.05). The CNR values between the periventricular lesions to CSF depend on CR of the lesions to CSF, and SNR of both tissues. When we consider Fig.41, it shows our research technique provides the higher difference between the SNR of the lesions and CSF than T<sub>2</sub>-weighted FSE sequence. Although the T<sub>2</sub>-weighted FSE sequence provides the high SNR of both tissues more than our research techniques, but the effect of the difference between the SNR of the lesion and CSF is more than those of the SNR of both tissues.

In contrast, the CNR and CR between the periventricular lesion to WM on T<sub>2</sub>-weighted FSE images was significantly superior to the fast FLAIR images with TI

2100 msec ( $p$ -value  $< 0.005$ ). The data in appendix E and F show  $T_2$ -weighted FSE images provides the high difference between the SNR of the lesion and WM, and SNR of both tissues more than fast FLAIR images with TI 2100 msec.

These result; are consistent with previous research, T OKUDA and Y KOROGI (24) that evaluate the usefulness of FLAIR techniques comparing with  $T_2$ -weighted FSE techniques in patients with periventricular leukomalacia (PVL) .

However, because the pathology of periventricular lesions in our study was not obtained which may effect our image assessment, further study of selected pathology should be performed.

## CHAPTER VII

### CONCLUSION

This study demonstrates that the optimal inversion time for optimum CSF suppression with good periventricular lesions to CSF for fast fluid-attenuated inversion recovery (FLAIR) pulse sequence is 2100 msec. We found the fast FLAIR pulse sequence with TI 2100 msec was superior to T<sub>2</sub>-weighed fast spin echo pulse sequence in demonstrating periventricular lesions located near the interfaces of CSF.

The limitation of this study are small sample size and nonselected pathologies lesion which may have effect upon the image assessments. Further study with larger sample size and base on selected pathologies lesion may be needed for better analysis of the accuracy of the optimization of the periventricular lesions to CSF contrast for the FLAIR technique compare to T<sub>2</sub>-weighed spin echo technique.

## APPENDIX A

### THE EXAMPLE OF T<sub>1</sub> CALCULATION.

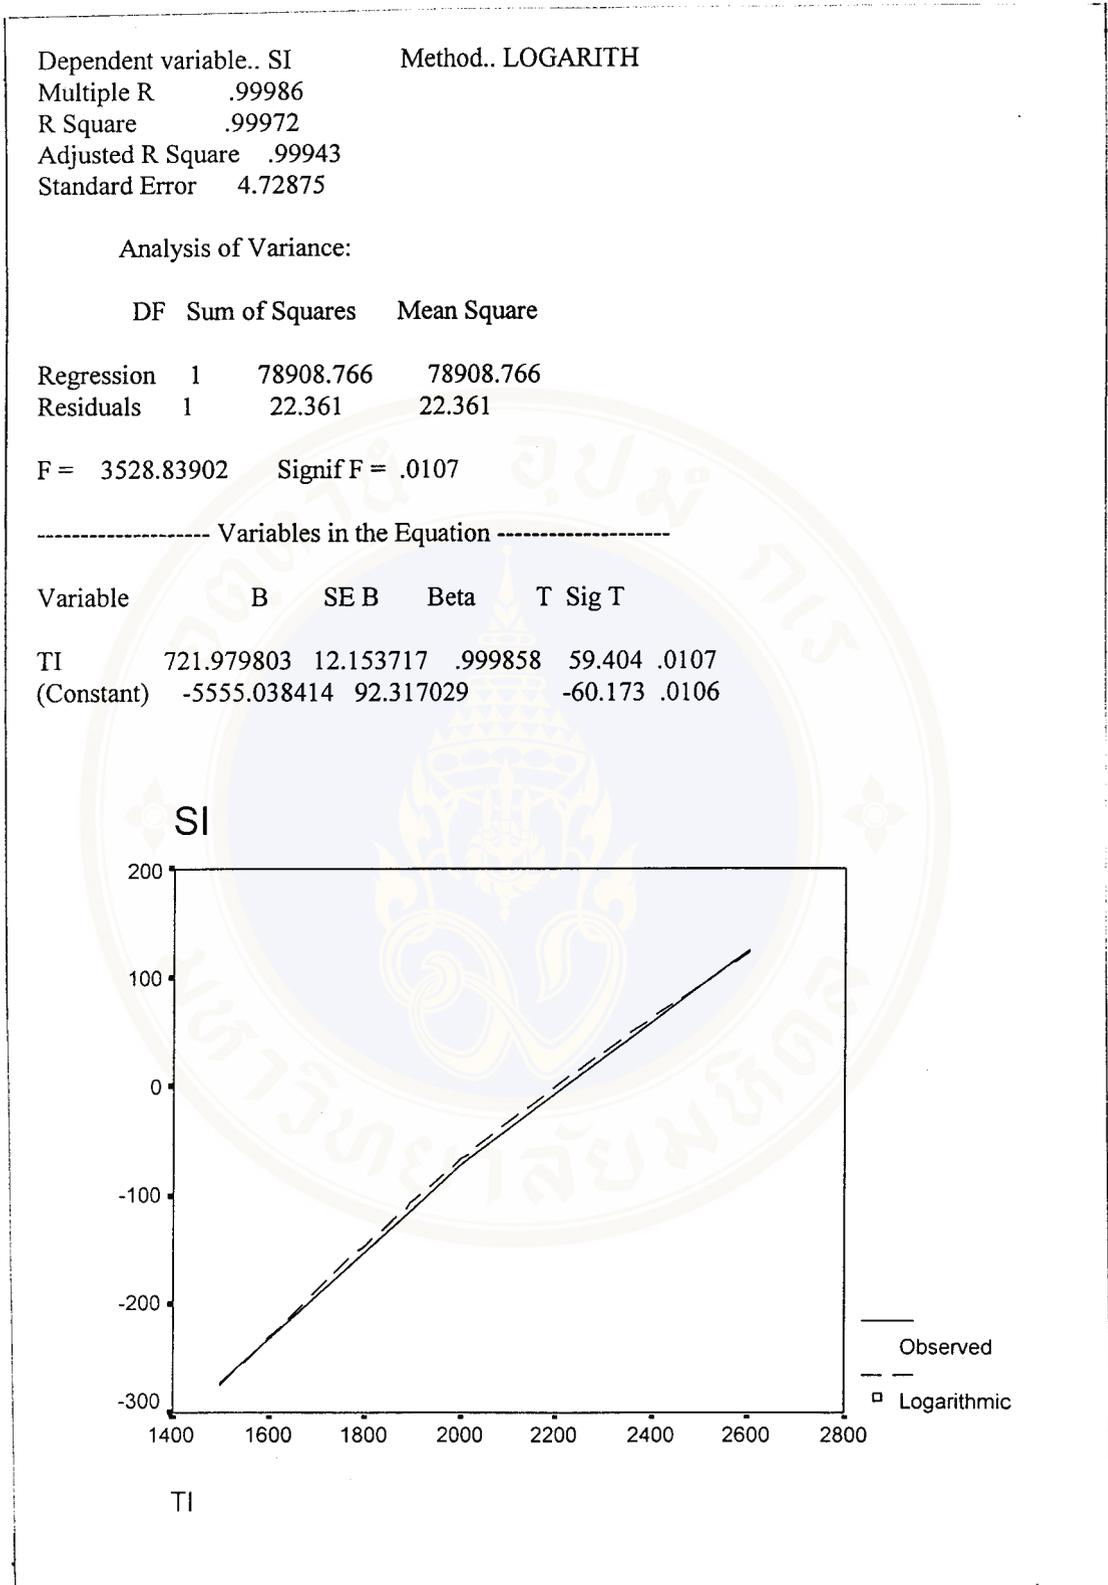

Table A. SI of CSF was measured on each of three IR images of a single volunteer.

TI (msec)	SI	Area (mm <sup>2</sup> )
1500	-273.2	3
2000	-71.2	3
2600	124.1	3

The values SI acquired from the measurement were plotted versus TI by using the program package SPSS 7.5 for window (Fig.42). This program will show logarithmic curve, variables and constant of logarithmic curve. We can determine TI (null) by using constants of logarithmic curve in the equation (16) :

$$Y (SI) = B \ln TI + C$$

Where, B (722.869) and C (-5581.75) are constants that show in Figure 47.

**Fig. 47** Showing logarithmic curve and its constant of data in Table A that is estimated by SPSS program for window.

At null point, the SI is zero, then

$$0 = 722.869 \ln T_{I_{\text{null}}} + (-5581.75)$$

$$T_{I_{\text{null}}} = 2313.69 \text{ msec}$$

We calculate  $T_1$  of CSF in the equation (10) :

$$T_{I_{\text{null}}} \text{ of CSF} = 0.693 \times T_1 \text{ of CSF}$$

$$T_1 \text{ of CSF} = 2313.69 / 0.693 \text{ msec}$$

$$T_1 \text{ of CSF} = 3338.66 \text{ msec.}$$

Therefore  $T_1$  of CSF of a single volunteer is 3338.66 msec.

## APPENDIX B

### SCAN PARAMETERS WHICH AFFECT SNR

The important scan parameters in MR. imaging that control and adjust SNR were voxel volume, NEX, number of phase encoding steps ( $N_y$ ), bandwidth (BW).

SNR is given by equation (18):

$$\text{SNR} \propto (\text{voxel volume}) \sqrt{(N_y) (\text{NEX}) / \text{BW}} \quad (18)$$

Where, voxel volume is  $\Delta X \cdot \Delta Y \cdot \Delta Z$  that,  $\Delta X$  is pixel size in the x direction.

$\Delta Y$  is pixel size in the y direction.

$\Delta Z$  is slice thickness.

$N_y$  is number of phase-encoding steps

NEX is number of excitation

BW is bandwidth

The pixel size along x-direction ( $\Delta X$ ) is given by equation (13):

$$\text{FOV} = (\text{pixel size}) \times (\text{number of pixels})$$

Therefore, the pixel size along x-direction ( $\Delta X$ ) is given by equation (20):

$$\Delta X = \text{FOV}_x / N_x \quad (20)$$

Where,  $\text{FOV}_x$  is field of view along x-direction

$N_x$  is number of frequency-encoding steps

The pixel size along y-direction ( $\Delta Y$ ) is given by equation (21): (13)

$$\Delta Y = \text{FOV}_y / N_y \quad (21)$$

Where,  $\text{FOV}_y$  is field of view along y-direction

Incorporating equations (20) and (21) into equation (17) gives us another way of expressing SNR:

$$\text{SNR} = (\text{FOV}_x / N_x) \cdot (\text{FOV}_y) \cdot \Delta Z \sqrt{(NEX) / (N_y)} \cdot (BW) \quad (22)$$

Difference of scanning parameters between fast FLAIR pulse sequence and  $T_2$ -weighted FSE pulse sequence were NEX and  $N_y$ .

Then, 
$$\text{SNR} = K \sqrt{(NEX) / (N_y)}$$

Where,  $K$  is constant that is  $[(\text{FOV}_x / N_x) \cdot (\text{FOV}_y)] / \sqrt{(BW)}$

So, SNR(3NEX, 256x256) of T<sub>2</sub>-weighted FSE pulse sequence must transfer to SNR at same NEX and N<sub>y</sub> with fast FLAIR pulse sequence ( 1 NEX, 256 x 192) as follow:

$$\frac{\text{SNR of T}_2\text{-weighted images}_{(1\text{NEX}, 256 \times 192)}}{\text{SNR of T}_2\text{-weighted images}_{(3\text{NEX}, 256 \times 256)}} = \frac{K\sqrt{(NEX=1) / (N_y(192))}}{K\sqrt{(NEX=3) / (N_y(256))}}$$

$$\frac{\text{SNR of T}_2\text{-weighted images}_{(1\text{NEX}, 256 \times 192)}}{\text{SNR of T}_2\text{-weighted images}_{(3\text{NEX}, 256 \times 256)}} = \frac{\sqrt{(1) / (192)}}{\sqrt{(3) / (256)}}$$

$$\frac{\text{SNR of and T}_2\text{-weighted images}_{(1\text{NEX}, 256 \times 192)}}{\text{SNR of and T}_2\text{-weighted images}_{(3\text{NEX}, 256 \times 256)}} = 0.666667$$

$$\text{SNR of and T}_2\text{-weighted images}_{(1\text{NEX}, 256 \times 192)} = (0.666667) \times \text{SNR of and T}_2\text{-weighted images}_{(3\text{NEX}, 256 \times 256)}$$
