Anawat Thivasasith 2010: DFT Study of the Gas-Selective Metallopolymers.  
Master of Science (Chemistry), Major Field: Chemistry, Department of  
Chemistry. Thesis Advisor: Mr. Pipat Khongpracha, Ph.D. 70 pages.

Density functional theory using the B3LYP functionals was performed to investigate NO, CO, NO<sub>2</sub> and O<sub>2</sub> gas-selective property of the metal-containing conductive polymer. The complexes of Co, Ni and Cu with N,N'-propylenebis (salicylideneimine) ligand (salpn) and modification 3,4-(ethylenedioxy)thiophene ((salpn)-EDOT) were modeled as their active center for molecular gas sensing. All the metal active centers were assigned to have low spin state. The optimized geometry of the Co(II)(salpn) complex is considered to be distorted square planar while that of Ni(II)(salpn) and Cu(II)(salpn) complexes are square planar. The adsorption of NO, CO, NO<sub>2</sub> and O<sub>2</sub> onto the metal active center disturbed their local geometry. Co, Ni and Cu active centers adopt distort square pyramidal geometry in the adsorption complex. The adsorption energy for Co(II), Ni(II) and Cu(II)(salpn)/NO are about -10.47, -10.43 and -4.28 kcal/mol, respectively. When modification EDOT in to metal(II)(salpn) is slightly enhances their adsorption energy. The adsorption energy for Co(II), Ni(II) and Cu(II)(salpn)-EDOT are about -13.33, -10.56 and -5.39 kcal/mol, respectively. The results, were vary gas such as CO, NO<sub>2</sub> and O<sub>2</sub> onto the metal(II)(salpn)-EDOT. The adsorption energy for Co(II)(salpn)-EDOT/CO, NO<sub>2</sub> and O<sub>2</sub> are about -4.88, -14.13 and -3.98 kcal/mol, respectively. The adsorption energy for Ni(II)(salpn)-EDOT/CO, NO<sub>2</sub> and O<sub>2</sub> are about -5.82, -19.76 and -4.57 and Cu(II)(salpn)-EDOT/CO, NO<sub>2</sub> and O<sub>2</sub> are about -3.67, -20.17 and -4.01. The adsorption of gas molecule onto metal active center significantly reduces the energy gap of the complex for NO and NO<sub>2</sub> molecules, and thus enhances their electrical conductivity.

## ACKNOWLEDGMENTS

First, I would like to thank my advisor, Dr. Pipat Khongpracha for his considerably helpful comment, excellent advice, discussion and support throughout the duration of my graduate study and research. Professor Jumras Limtrakul, my co-advisor, is gratefully thank for his excellent opportunity, valuable assistances, direction and support during these years. I also thank my co-advisor, Dr. Somkiat Nokbin, for his helpful advice, comment and suggestion to fulfill this thesis work.

I would like to acknowledge the National Science and Technology Development Agency (2009 NSTDA Chair Professor funded by the Crown Property Bureau under the management of the National Science and Technology Development Agency and NANOTEC Center of Excellence funded by the National Nanotechnology Center), the Commission on Higher Education, Ministry of Education, under the Postgraduate Education and Research Programs in Petroleum and Petrochemicals, and Advanced Materials, as well as the Thailand Research Fund (TRF) for financial support. The Laboratory for Computational and Applied Chemistry (LCAC), Kasetsart University, Kasetsart University Research and Development Institute (KURDI) are gratefully acknowledged for research facilities. The Kasetsart University Graduate School is also acknowledged.

Finally, I wish to thanks my lovely parents for their encouragement and support.

Anawat Thivasasith

## DFT STUDY OF THE GAS-SELECTIVE METALLOPOLYMERS

### INTRODUCTION

Air pollution has been generated from human activities, such as industrial manufactures, fuel combustion in automobiles and tremendously increasing of the population. The released toxic gases effect to every creature on earth. Among several toxic gases, nitric oxide, carbon monoxide, nitrogen dioxide are released from wide range of human biological processes. In the 1990s, electrode and microsensor made from gold and platinum was developed for detecting NO gas, but it was not chemical robust. Recently, conducting metallopolymer was reported as a gas sensors based on either conducting polymers or polymer hybrid material. It was then shifted to the generation of redox matched conducting metallopolymer system and the application of NO sensor in solutions.

The metallopolymer or metal-containing polymer is a new class of materials that can be used in many fields of application such as sensor semiconductor and catalysis. This hybrid metallopolymer can be constructed by the incorporation of discrete transition metal active center into conjugate polymeric system. Particular feature of interest include transition metal's ability to bind anions and small molecules (CO, NO, NO<sub>2</sub>, etc.). The metal active center can enhance the electron transfer between guest molecules and the polymer backbone. The coupling of the metal and polymer backbone redox potentials provides a conductivity enhancement beyond a simple additive combination. Kingsborough et al. 1999 reported the conductivity of the metal active center such as Co, Ni, Cu onto the EDOT (3,4-(ethylenedioxy)thiophene)-modified *N,N'*-ethylene bis(salicylidene), *N,N'*-*o*-phenylene bis(salicylidene), and *N,N'*-*trans*-cyclohexylene bis(salicylidene) complexes. The Co integrated polymer complexes had high sensitivity to small interchain spacing (250 S cm<sup>-1</sup>), The Ni integrated polymer complexes had less sensitive. The conductivity of Cu integrated polymer complexes decreased with increasing interchain spacing (92 S cm<sup>-1</sup>)(Kingsborough *et al.*, 1999).

In recent years, the Co-containing EDOT (3,4-(ethylenedioxy)thiophene)-modified  $N,N'$ -propylenebis(salicylideneimine) complex so call Co(II)(salpn)EDOT, has been applied for sensing NO in solution and showed the successful of a selective sensing for NO detection system based on chemoresistive changes in a cobalt-containing metallopolymer film device. These films have shown effective detected resistance changes of NO as low as 1 ppm (Holliday *B.J. et al.*, 2005 and 2006). Its performance outperformed the regular poly-EDOT. Moreover, the salpn chelating ligand is very suitable to be applied as metal anchoring site due to their several superiority such as chemically robustness (in neutral or basic media), high thermal stability up to 250-300 °C and high conductivity ( $250 \text{ S cm}^{-1}$ ) (Leung A.C.W. *et al.*, 2006). Furthermore, it is able to accommodate different metals and form coordinatively unsaturated metal complexes, and had well characteristics for NO detection.

**Figure 1** The synthesize of metal onto the EDOT (3,4-(ethylenedioxy)thiophene)-modified  $N,N'$ -ethylene bis(salicylidene) complex

The monomeric Co(II)(salpn)EDOT complexes were prepared by Kingsborough and co-workers in 1999 by condensation of 2 equivalent of

bis(bromosalicylaldehyde)-3,4-(ethylenedioxy)thiophene with appropriate diamine and insoluble chelate of transition metal were synthesized (Figure 1). The coordination geometry of the chelated metal ions via electronic reflectance spectroscopy and magnetic susceptibility measurements. It was reported that the  $\text{Co}^{2+}$  metal center in the polychelates adopts a distorted square-planar or tetrahedral geometry, while  $\text{Cu}^{2+}$  ions and  $\text{Ni}^{2+}$  are square-planar geometry (Böttcher A. *et al.*, 1993; Patel V.J. *et al.*, 1989).

In this work, the transition metals were coordinated with the chelating unit of the conductive polymers to permit these materials acting as molecular gas sensors. Structural and electronic properties of the metal(II)(salpn) and metal(II)(salpn) EDOT complexes prior and consequent to the adsorption of small gas molecule were investigated by the density functional theory.

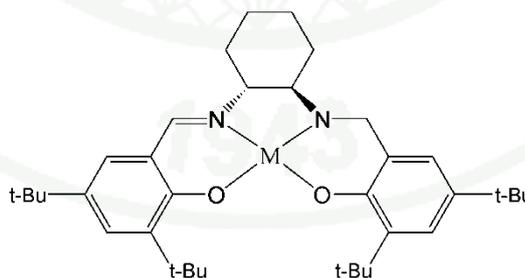

## LITERATURE REVIEW

Methods for detecting nitric oxide (NO), carbon dioxide (CO), nitrogen dioxide (NO<sub>2</sub>) etc., in biology and medicine are well established such as spectrophotometry, chemilluminescence, and paramagnetic resonance. These techniques require that a sample of biological fluid such as the extracellular fluid in a tissue or the support buffer in a suspension of cells must be analyzed and removed from its biological context. Measurements made on such samples reflect NO, CO and NO<sub>2</sub> concentration at a single time, and when assembled in a series make a discontinuous record. Therefore, these methods are not ideal for following rapid processes because changes in NO, CO and NO<sub>2</sub> concentrations are not observed if they occur between sampling points.

Shibuki electrode have been developed in 1990, it uses a Pt electrode to oxidize nitric oxide at 800 mV and to record the resulting oxidation current (Shibuki, 1990). But this sensor is of limited utility because it is subject to the destructive buildup of oxidation products from nitric oxide within the enclosed electrolyte surrounding the Pt electrode. More recently Malinski *et al.* (1992) have developed method for the measurement of nitric oxide by using the electrochemical method. This microsensor measured in situ the NO released from a single cell with a response time of less than 10 ms. The microsensor consists of p-type semiconducting polymeric porphyrin and a cationic exchanger (Nafion) deposited on a thermally sharpened carbon fiber with a tip diameter of approximately 0.5 microns. The microsensor measurements of nitric oxide with good sensitivity and selectivity have been reported using this porphyrinized electrode. However, this measurement has the difficulty in handling the fragile micron-diameter carbon fibers, which require manipulation under a microscope with cold illumination (or under water) to eliminate thermal convection currents that disturb the fibers. Other methods for nitric oxide detection has been introduced, include using electrodes constructed of gold or platinum (Pariante *et al.*, 1994; Bedioui *et al.*, 1994) and a porphyrinic-based platinum-iridium electrode (Miyoshi *et al.*, 1994).

Conducting metallopolymer have been developed and used as sensory devices for determining the presence of verity of analytes. These polymers typically include organic structures possessing a degree of unsaturation to allow electronic communication throughout a polymeric structure. Because polymers in general are synthesized from monomer components, the design of the conducting properties of a conducting polymer can be facilitated by engineering the monomer component to a desired specificity (Swager, 2003). Moreover, polymers containing both organic and metal ion components afford a larger number of variables over organic-based polymers through the incorporation of a diverse number of metal ions.

Metal complexes of the synthetic salen ligand have been studied by chemists for over six decades, but the application of chiral salen derivatives began in earnest only in the 1990s (Katsuki, 2003). Salen ligands bind metal ions securely through four atoms. This tetradentate binding motif is reminiscent of the porphyrin framework in heme-based oxidative enzymes. Indeed, the design of the chiral manganese-salen complex (Figure 2) was originally inspired by consideration of the oxo-transfer mechanism of heme-containing enzymes such as cytochrome P-450. However, salen derivatives are more easily synthesized than porphyrins, and their structures are more easily manipulated to create an asymmetric environment around the metal active site.

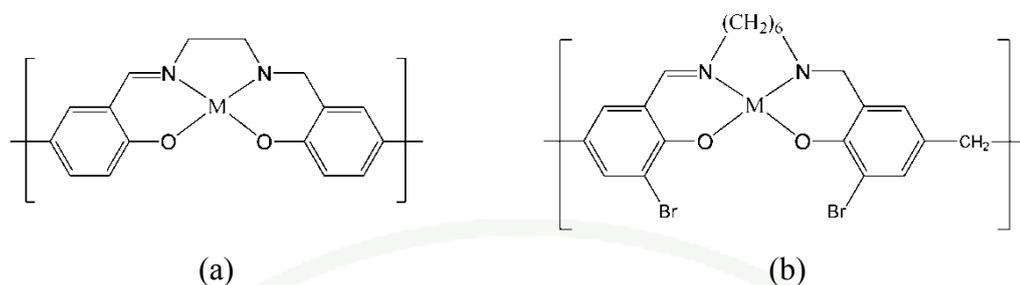

**Figure 2** Manganese containing  $N,N'$  – cyclohexene bis(salicylidene) complexes

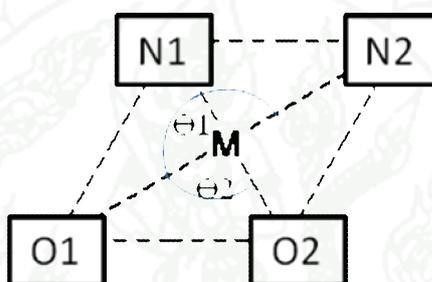

A variety of conducting polymers of different compositions and physical properties have been reported. Zotti *et al.* (1995) disclosed in situ conductivity of some polypyrroles and polythiophenes redox modified with pendant ferrocene groups.

It was found that the electron hopping rate through the conductive polymer backbone is increased by a decrease of the ferrocene backbone distance and by conjugation of ferrocene with the backbone itself. Audebert *et al.* (1992) have reported series of conducting polymers based on metal salpn containing units comprising mononuclear  $\text{Cu}^{2+}$ ,  $\text{Co}^{2+}$ ,  $\text{Ni}^{2+}$  and  $\text{Zn}^{2+}$  complexes. A highly conductive polymer composition is formed upon doping with an oxidizing dopant, typically iodine and ferric chloride. The composition has been improved to form a highly conductive film or coating. Holliday *et al.* (2006) described the EDOT (3,4-(ethylenedioxy) -thiophene) polymerizable groups, which lowers the oxidation potential necessary for electropolymerization relative to thiophene or unfunctionalized salpen (*N,N'*-propylenebis (salicylideneimine) ligands and matches the ultimate redox potential of the polymer backbone to that of the metal center.

The coordination geometry of chelated metal ions via absorption and EPR spectra, Bottcher *et al.* (1993) reported the geometry of Co, Ni and Cu into the salen ligand (backbone is ethylene, shown in figure 3), it was a square planar complexes because the backbone of ligands are very strong. In 1989, Patel *et al.* prepared schiff base ligand (backbone is hexane, shown in figure 3) and reported the results of chelated metal ions via electronic reflectance spectroscopy and magnetic susceptibility measurements, the  $\text{Cu}^{2+}$  and  $\text{Ni}^{2+}$  metal center in the polychelates adopts a square-planar geometry, while  $\text{Co}^{2+}$  ions are tetrahedral. From this result, the coordination geometry of Schiff base ligand are square planar or distort square planar depend the natural of metal atom such as Co(II) ion 4-coordination is form tetrahedral with neighbor atom (distort square planar in schiff base ligand) and Ni(II), Cu(II) ion 4-coordination are form square planar with neighbor atom (square planar in Schiff base ligand). The square planar and distort square planar complexes have been defined in Figure 4.

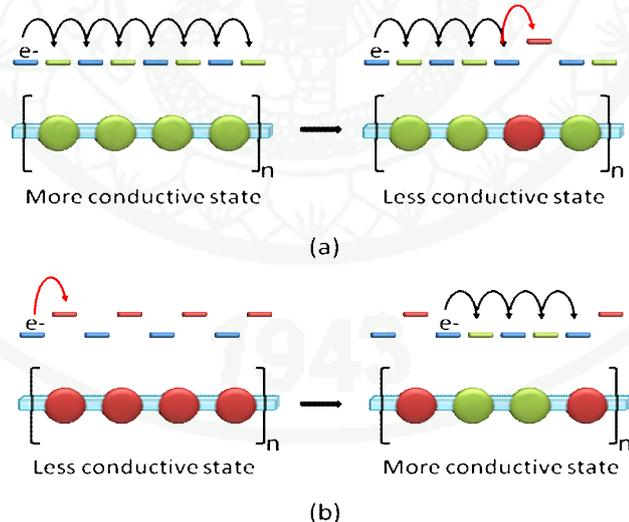

**Figure 3** Metal Schiff base ligand (a)  $N,N'$ -ethylenebis(salicylideneimine) (b)  $N,N'$ -hexanebis(salicylideneimine)

**Figure 4** The metal on 2N2O plane configuration in Metal Schiff base ligand complex. The angles of square planar geometry,  $O1 \cdots M \cdots N2$  is  $165^\circ$ - $180^\circ$  and  $O1 \cdots M \cdots O2$  is  $80^\circ$ - $90^\circ$ . The angles of distort square planar geometry are out of range of square planar geometry

The receptor in conducting polymer frameworks has been shown to produce materials which provide changes in physical characteristics upon binding of targeted analytes. Devynck *et al.* (1990) reported a material containing Co(III) porphyrin sites. Variations in the Co(III)/Co(II) redox couple were observed upon exposure to pyridine and with changing pyridine concentrations. Grate (1989) discloses a chemical microsensor fabricated using Langmuir-Blodgett techniques. The chemical microsensor was a film based on dithiolene transition metal complexes that displayed differing degrees of current changes upon exposure to varying concentrations of a gas or vapor.

For sensing, Holliday *et al.* (2005 and 2006) studied and reviewed chemoresistive gas-phase nitric oxide sensing with metal containing *N,N'*-ethylenebis (salicylideneimine) film, they have illustrated how strong electronic coupling between the transition metal centers and the organic conducting polymer backbone facilitates electronic charge transport. For example, the redox potential of a coordinatively unsaturated transition metal will be highly sensitive to small molecule or ion binding. The matching of the metal center's and organic polymer's redox potentials can be either increased or decreased depending on whether the binding event shifts the redox potential of the metal center into a state of better overlap with the polymer backbone or worse overlap. A single binding event can disrupt a critical transport pathway and lead to a drastic reduction in conductivity thereby providing an ultrasensitive system for detecting small molecules. Alternatively, if the initial state of the conducting metallopolymer displays partial or no redox matching of the organic polymer and metal centers, a low conductivity charge localized material would be observed. In this situation, a single binding event can create favorable redox matching that will enhance local transport (Figure 5).

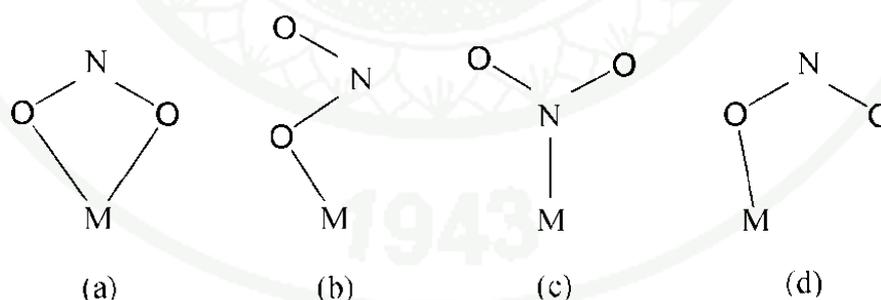

**Figure 5** Chemoresistive sensing schemes with conducting metallopolymer demonstrating how analyte induced energetic changes can produce a response

Theoretical study of sensing of metal–schiff base(salen) began in 2006-2008. Coradie *et al.* (2007) studied and reported about spin-crossover complex Fe(salen)/NO by DFT and comparative any function. Pure functionals PW91 and BLYP, the hybrid functional B3LYP, the newer pure functionals OLYP and OPBE, based on the OPTX exchange functional as well as the reparametrize B3LYP\* hybrid functional (which has 15% Hartree-Fock exchange, compared with 20% for B3LYP) predict nearly isoenergetic  $S = 1/2$  and  $3/2$  states, as required for a spin-crossover complex. Intriguingly, the OLYP and B3LYP\* spin density profiles for the  $S = 1/2$  state of Fe(salpn)/NO are substantially dissimilar. Sears and Sherrill (2008) used the B3LYP method with the lanl2dz basis set for metal atoms and with 6-31g(d) basis set for organic atoms to calculate the geometries and relative energies of a commonly-employed model complex of the salen ligand [salen = bis(salicylaldehyde) ethylenediamine] with the  $d^2$ -metals Ti(II), V(III), Cr(IV), Zr(II), Nb(III), and Mo(IV). They reported that B3LYP was observed to provide geometries and relative energies close to benchmark values for the remainder of the systems examined although that systematic error in popular DFT method may become increasingly problematic as the size of the system increases. Eshtiagh-Hosseini *et al.* (2008) studied the Co(III)-containing N,N'-dipyridoxy(1,3-propylenediamine) salen complex by IR, UV-vis,  $H^1$  NMR and Mass spectrophotometer. The results were compared with theoretical calculations of harmonic frequencies at the fully optimized geometries of the H<sub>2</sub>PS ligand and its Co(III) complex using the B3LYP level. They reported the DFT calculated structure parameters of H<sub>2</sub>PS and Co(III) complex are in good agreement with experimental data for similar compounds.

Wang *et al.* (2006) explored a novel sensor to detect the gaseous molecules. They investigated reactivities of the intrinsic and aluminum doped (Al doped) single-walled (8,0) carbon nanotube (SWCNT) with CO using density functional theory (DFT) calculations. The Al-doped SWCNT presents high sensitivity to CO, compared with the intrinsic SWCNT, as indicated by the calculated geometrical structures and electronic properties such as binding energy, energy gaps, electronic density of state (DOS) and partial density of state (PDOS) for these systems. They found that Al-doped SWCNTs are good for detecting the presence of CO. Kornviga *et al.* (2007)

investigated the Au/bp-octaTh for sensing small gases using DFT with B3LYP hybrid function. The Stuttgart RSC 1997 basis set was used to describe valence electrons in the neutral Au atom while core electrons were removed and represented by relativistic accounted effective core potential (ECP). The Au/bp-octaTh has high sensitivity to CO because it shows the strongest interaction, the most obvious electronic change (energy gap) and also the notably dipole moment change.

The interaction of NO molecule with metal atom has been investigated by DFT hybrid function B3LYP using the CEP-121 basis set. It was found that NO adsorbed on Co, Ni, and Cu have bended structure and the bond angles vary in the range of  $120^\circ < \theta < 177^\circ$  (Erkoç, 2001). Two possible adsorption configurations of NO, namely, N-down and O-down configurations were found. Pipat *et al.* (2005) used the DFT calculation and reported the N-down configuration to be much more stable than the O-down configuration. The adsorption configurations of CO are similar to that of NO. Panek *et al.* (2000) studied the interaction of NO<sub>2</sub> with aluminum and gallium based on topological analysis of electron density and electron localization function using DFT with B3LYP/6-311+G(3df). They reported that the adsorption structure a) of NO<sub>2</sub> with metal (Figure 6) was the most stable configuration.

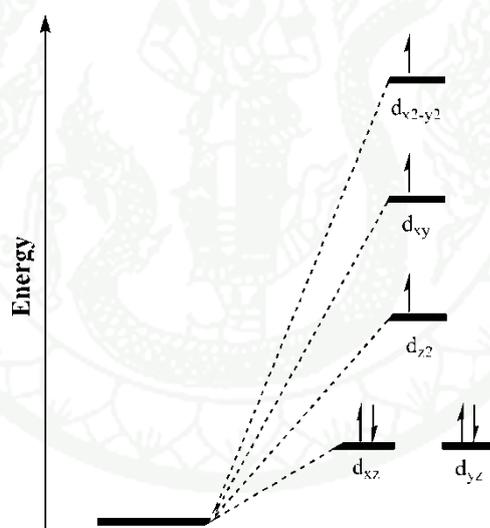

**Figure 6** Schematic drawings of M-NO<sub>2</sub> (M=Al, Ga) structures

The electronic configuration, Metal-ligand bonding in a coordination complex was described in molecular orbital theory and ligand field theory. The bonding model based on molecular orbital theory assumes that the metal and the ligand bond through the molecular orbitals formed by atomic orbital overlap between metal and ligand.

The ligand field model, in contrast, focuses on repulsion (and destabilization) of electrons in the metal coordination sphere. The ligand field model also assumes that the positive metal ion and the negative ligand lone pair are attracted electrostatically; that is, the bond arises when a positively charged metal ion attracts a negative ion or the negative end of a polar molecule.

The Co(II)(salpn) complexes. Assume the ligands in a square-planar complexes lie along the x-, y- and z-axes. These results in the five d orbital (Figure 7) being subdivided into two sets: the  $d_{x^2-y^2}$  and  $d_{x^2}$  orbitals in one set and the  $d_{xy}$ ,  $d_{xz}$  and  $d_{yz}$  orbitals in the second. The  $d_{x^2-y^2}$  and  $d_{z^2}$  orbitals are directed along the x-, y- and z-axes, whereas the orbitals of the second group are aligned between these axes (John C. Kotz, *et al.*, 2008).

**Figure 7** Splitting of the d orbitals in square planar geometries

In an isolated atom or ion, the five d orbitals have the same energy. For a metal atom or ion in a coordination complex, however, the d orbitals have different energies. According to the ligand field model, repulsion between d electrons on the metal and electron pairs of the ligands destabilized electrons that reside in the d orbitals, that is, it causes their energy to increase. Electrons in the various d orbitals are not affected equally, however, because of their different orientations in space relative

to the position of the ligand lone pairs (Figure 7). Electrons in the  $d_{x^2-y^2}$  and  $d_{xy}$  orbitals experience a larger repulsion because these orbitals point directly at the incoming ligand electron pairs. A smaller repulsive effect is experienced by electrons in the  $d_{xy}$ ,  $d_{xz}$  and  $d_{z^2}$  orbitals. The difference in degree of repulsion means that an energy difference exists between the two sets of orbitals. This difference, called the ligand field splitting and denoted by the symbol  $\Delta_{ij}$ , is a function of the metal and the ligands and varies predictably from one complex to another.

A different splitting pattern is encountered with square-planar complexes (figure 7). Assume that the four ligands are along the x- and y-axes. The  $d_{x^2-y^2}$  orbital also points along these axes, so it has the highest energy. The  $d_{xy}$  orbital (which also lies in the xy-plane, but does not point at the ligands) is next highest in energy, followed by the  $d_{x^2}$  orbital. The  $d_{xz}$  and  $d_{yz}$  orbitals, both of which partially point in the z-direction, have the lowest energy.

Electron fills in electronic configuration, A gaseous  $\text{Co}^{2+}$  ion has the electron  $[\text{Ar}]3d^7$ . The term “gaseous” in this context is used to denote a single, isolate atom of ion with all other particles located an infinite distance away. In these situation, the five 3d orbitals have the same energy, the seven electron reside singly and doubly in different d orbital, according to Hund’s rule and the  $\text{Co}^{2+}$  ion has tree unpaired electrons.

When the  $\text{Co}^{2+}$  ion is part of an square-planar complex, the five d orbitals do not have identical energies. As illustrated in Figure 7, these orbitals divide into four sets, with the  $d_{xz}$ ,  $d_{yz}$  orbital having a lower energy than the  $d_{z^2}$ ,  $d_{xy}$  and  $d_{x^2-y^2}$ , respectively. Having four sets of orbitals means that four different electron configurations are possible (Figure 7). Four of the seven d electrons in  $\text{Co}^{2+}$  are assigned to the lower-energy  $d_{xz}$ ,  $d_{yz}$  orbitals and three electrons are assigned to the higher-energy  $d_{z^2}$ ,  $d_{xy}$  and  $d_{x^2-y^2}$ , respectively. For  $\text{Ni}^{2+}$  and  $\text{Cu}^{2+}$  are same electron fill with  $\text{Co}^{2+}$ .

## METHODS OF CALCULATIONS

### 1. Computational methods

To achieve a better understanding of the gas-selective metallopolymers, the geometry optimizations and electronic structure analysis of were carried out by using B3LYP functional. The Los Alamos basis sets and corresponding effective core potentials developed by Hay and Wadt were used for all transition-metal atoms and 6-31G\*\* basis sets were used for all other atoms. All Density functional theory (DFT) calculations were performed by Gaussian03 package. Geometries optimizations were carried out with respected to the total energy for singlet, triplet, and quintet states, separately. The nature of the stationary points was verified by analytic frequency calculations. The adsorption energies ( $E_{ads}$ ) of NO molecule on the metal active center (Co, Ni and Cu) of metallopolymers, HOMO and LUMO orbital energies, and the natural bond orbital (NBO) analysis were evaluated.

The adsorption energies ( $E_{ads}$ ) are defined according to the followed equations:

$$E_{ads} = E_{(complex)} - E_{(ligand)} - E_{(gas\ molecule)}$$

Where  $E_{(complex)}$  is the total energy of a gas molecule adsorbed on the Co(salpn) or Co(salpn)-EDOT,  $E_{(ligand)}$  is the total energy a salpn ligand or EDOT functionalize salpn ligand and  $E_{(gas\ molecule)}$  is the total energy of a gas molecule.

The nature of interaction of metal(salpn) and gas molecule could be clearly described by the natural bond orbital (NBO) analysis. The NBO analysis can illustrate electron transfer from gas to metal ( $\sigma$ -donation) and metal to gas (back bonding). The magnitude of the second-order perturbation energy ( $\Delta E_{ij}$ ) would indicate the strength of donor-acceptor orbital interaction. For each donor NBO ( $i$ ) and acceptor NBO ( $j$ ), the stabilization energy  $\Delta E_{ij}$  associated with delocalization ("2e-stabilization")  $i \rightarrow j$  is estimated as,

$$\Delta E_{ij} = q_i \frac{F_{(i,j)}^2}{\varepsilon_j - \varepsilon_i}$$

Where  $q_i$  is the donor orbital occupancy,  $\varepsilon_i$ ,  $\varepsilon_j$  are diagonal elements (orbital energies) and  $F(i,j)$  is the off-diagonal NBO Fock matrix element.

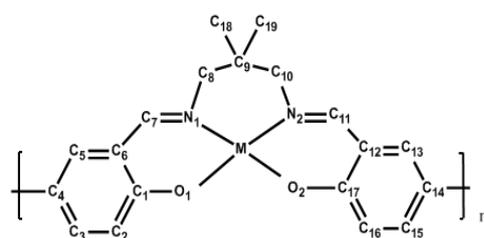

The natural population analysis (NPA) difference was used to describe electronic charge concentration and charge depletion. It can be defined as

$$\Delta q_i = q_i (\text{in complex}) - q_i (\text{in isolated})$$

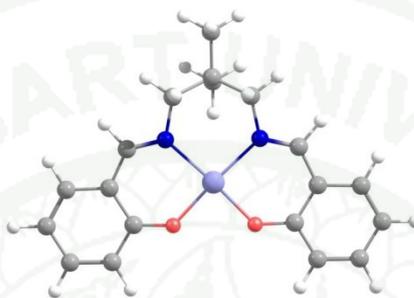

The electronic configurations for Co, Ni and Cu metals are  $3d^7 4s^2$ ,  $3d^8 4s^2$  and  $3d^{10} 4s^1$ , respectively. The metallopolymer base on metal salpn containing units comprising mononuclear Co(II)(salpn), Ni(II)(salpn) and Cu(II)(salpn) complexes, the electronic configurations for those transition metal ions are  $3d^7 4s^0$ ,  $3d^8 4s^0$  and  $3d^9 4s^0$ , respectively. Once the NO molecule was adsorbed, the favorable electronic states for Co(II)(salpn)/NO, Ni(II)(salpn)/NO and Cu(II)(salpn)/NO were turned out to be  $3d^8 4s^0$ ,  $3d^9 4s^0$  and  $3d^{10} 4s^0$ , respectively. The model of metal chelating ligand complexes and their standard labeling are illustrated in Figure 7. For the gas adsorption complexes, the gas molecule was restricted to adsorb on top of the metal center atom.

## 2. Computational models

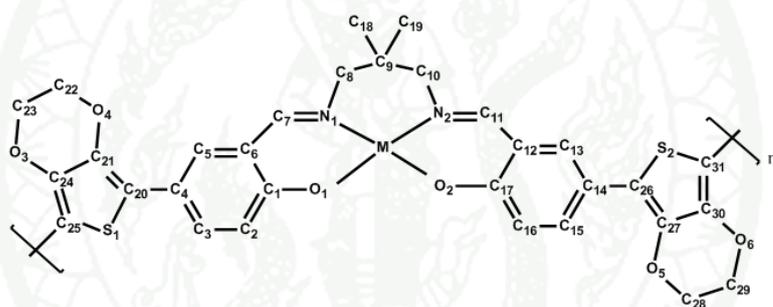

The model of metal chelating ligand complexes and their standard labeling are illustrated in Figure 8. For the gas adsorption complexes, the gas molecule was restricted to adsorb on top of the metal center atom.

## RESULTS AND DISCUSSION

These results were separated the topic into 3 parts. In the first part, I have discussed the electronic and geometrical structures of gas molecule (NO, CO, NO<sub>2</sub> and O<sub>2</sub>) onto 3d transition metal (Co, Ni, Cu). In second part, the favorable characteristics of their geometrical and electronic properties of Co, Ni and Cu N,N'-propylene-bis(acetylacetonimine) and adsorption of gas molecule. In third part, the EDOT-modification into metal N,N'-propylene-bis(acetylacetonimine) and compare electronic properties with metal N,N'-propylene-bis(acetylacetonimine). Finally many gas molecules are adsorbed onto metal N,N'-propylenebis(acetylacetonimine)-EDOT-modification.

### 1. Metal atom/NO, CO, NO<sub>2</sub> and O<sub>2</sub>

1.1 The optimized structures, bonding and energetic of NO molecule onto metal neutral and metal cation.

The optimized structures of 3d-metal mononitrosyls MNO (M = Co, Ni, Cu), the MNO neutral and MNO<sup>+</sup>, MNO<sup>2+</sup> cations are computed using the density functional theory (Gutsev *et al.*, 2003) with the B3LYP function. The optimized structures are mostly in the bent form. The structure parameters of the optimized structures are given in Table 1. The geometry is shown in Figure 9. The bond angle, in the bended structures, vary in the range  $130 \leq \Theta \leq 175$  (Erkoç, 2001). The small or large bond angle is considered that the total charge and natural bond orbital of the system.

**Figure 9** The structure of M...NO trimer with geometrical parameters

The bond lengths of the state obtained from the rotation spectra (Sakamoto *et al.*, 2008)  $r(\text{Co}\cdots\text{N})$  of 1.584 Å and  $r(\text{N}\cdots\text{O})$  of 1.182 Å, are in good agreement with our values of 1.728 Å and 1.198 Å, respectively. In addition, the distance of  $r(\text{M}\cdots\text{NO})$  decreases when charge of all system MNO is increased, which is corresponding with the increasing of adsorption energy (see table 1).

For NO molecule, it has one more electron than CO, which occupies the antibonding  $\pi^*$  orbital; the nitrogen atom however is more electronegative than carbon. According to ESR spectral studies, 60% of the spin density belongs to the N atom (Uzunova, 2009). In addition, the interactions between NO and metal can be described by  $\sigma$ -donating and  $\pi$ -back bonding. The shortening of NO bond upon the adsorption, the blue-shift of NO stretching mode and together with the NBO analysis (Figure 10) illustrate that the sigma donation from a hybrid orbital of N to d-orbital of exchanged M neutral dominates the M-NO interaction. On the other hand, two  $\pi$ -back bonding occurring between d-orbital of M and both  $\pi_x^*$  and  $\pi_y^*$  of NO as a consequence from the bent  $\angle\text{Co}\cdots\text{N}\cdots\text{O}$  are quite small compare to the sigma donation. Ni and Cu have similar  $\angle\text{Co}\cdots\text{N}\cdots\text{O}$ .

**Figure 10** Natural Bond Orbital(NBO) Plots showing the interaction between an exchanged Co neutral and an adsorbed NO : a) The sigma interaction between  $s^{71.62\%}p^{5.54\%}d^{22.84\%}$ (Co) and  $s^{3.43\%}p^{96.52\%}d^{0.05\%}$ (N) b) The  $\pi$ -back bonding electron transfer between  $s$ (Co) and  $\pi^*$ (NO)

<sup>a</sup>The CoN bond length was calculated from the ab initio calculation (Sakamoto *et al.*, 2008)

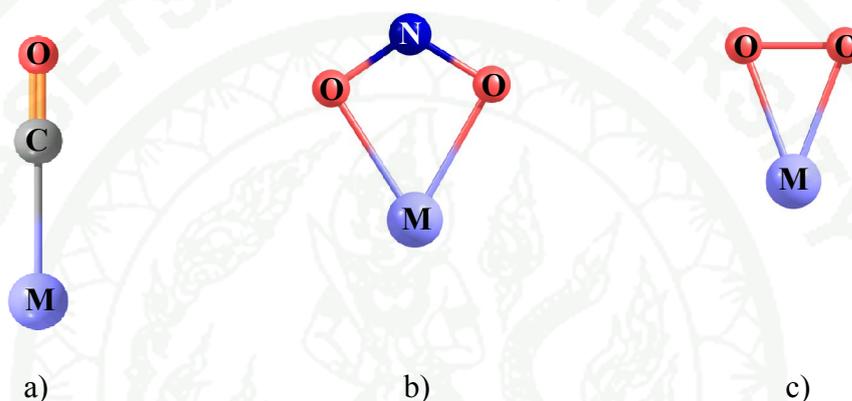

Cobalt nitrosyl: The electronic state of  $\text{Co}\cdots\text{NO}$  is  $3d^84s^0$ . The triplet state is a result of antiferromagnetic coupling with the unpaired electron of NO. The bent form of Co nitrosyls, the  $\text{Co}\cdots\text{NO}^{2+}$  1.614 Å bond is considerably shorter than the  $\text{Co}\cdots\text{NO}^{1+}$  bond (1.689 Å) and the  $\text{Co}\cdots\text{NO}$  bond (1.728 Å) and all of data shown in table 1. The natural charge distribution indicates that a charge-transfer component dominates in the  $\text{Co}\cdots\text{N}$  bond formation. Their corresponding adsorption energy are -102.22, -20.96 and -4.17 kcal/mol. The bent form causes very significant electron redistribution at the Co atom. Electron density is transferred from the  $\sigma$  orbital of NO to vacant 3d orbitals at Co via nitrogen. Back-donation from the metal to the ligand results in depopulation of the 4s orbital and increased local negative charge of the oxygen atom. The strong  $\sigma$ -donation in the adsorption complexes results in a significant shortening of the  $\text{N}\cdots\text{O}$  bond distance with respect to that in the isolated NO gas (1.159 Å).

Nickel nitrosyl and Copper nitrosyl: For the electronic state of  $\text{Ni}\cdots\text{NO}$  is  $3d^94s^0$ . The doublet state is a result of antiferromagnetic coupling with the unpaired electron of NO. The bent form of Ni nitrosyls, the  $\text{Ni}\cdots\text{NO}^{2+}$  bond is considerably shorter, 1.700 Å, than the  $\text{Ni}\cdots\text{NO}^{1+}$  bond, 1.710 Å and the  $\text{Ni}\cdots\text{NO}$  bond, 1.711 Å. Their corresponding adsorption energy are -195.74, -71.52 and -29.76 kcal/mol. While the electronic state of  $\text{Cu}\cdots\text{NO}$  is  $3d^{10}4s^0$ . The singlet state is a result of antiferromagnetic coupling with the unpaired electron of NO. The bent form of Cu nitrosyls, the  $\text{Cu}\cdots\text{NO}^{2+}$  bond is considerably shorten, 1.902 Å, than the  $\text{Cu}\cdots\text{NO}^{1+}$  bond, 1.940 Å and the  $\text{Cu}\cdots\text{NO}$  bond, 1.958 Å. Their corresponding adsorption energy are -174.16, -47.21 and -15.03 kcal/mol. The natural charge distribution of Ni-NO and  $\text{Cu}\cdots\text{NO}$  are the same characterize with  $\text{Co}\cdots\text{NO}$ .

There for, the neutrals, cations of the MNO species. For Co, Ni and Cu have been studied at the same level of theory. In general, the computed results are in good agreement with previous calculations and the experimental values (distance, angle and adsorption energies).

## 1.2 The optimized structures, bonding and energetic of CO, NO<sub>2</sub> and O<sub>2</sub> molecule onto metal neutral and metal cation.

The optimized structures of CO with metal are in linear form. The adsorption structure of NO<sub>2</sub> with metal show in Figure 11 was the most stable configuration and O<sub>2</sub> have side on configuration for with metal and metal cation. The all of structure parameters of the optimized structures are given in Table 2-4.

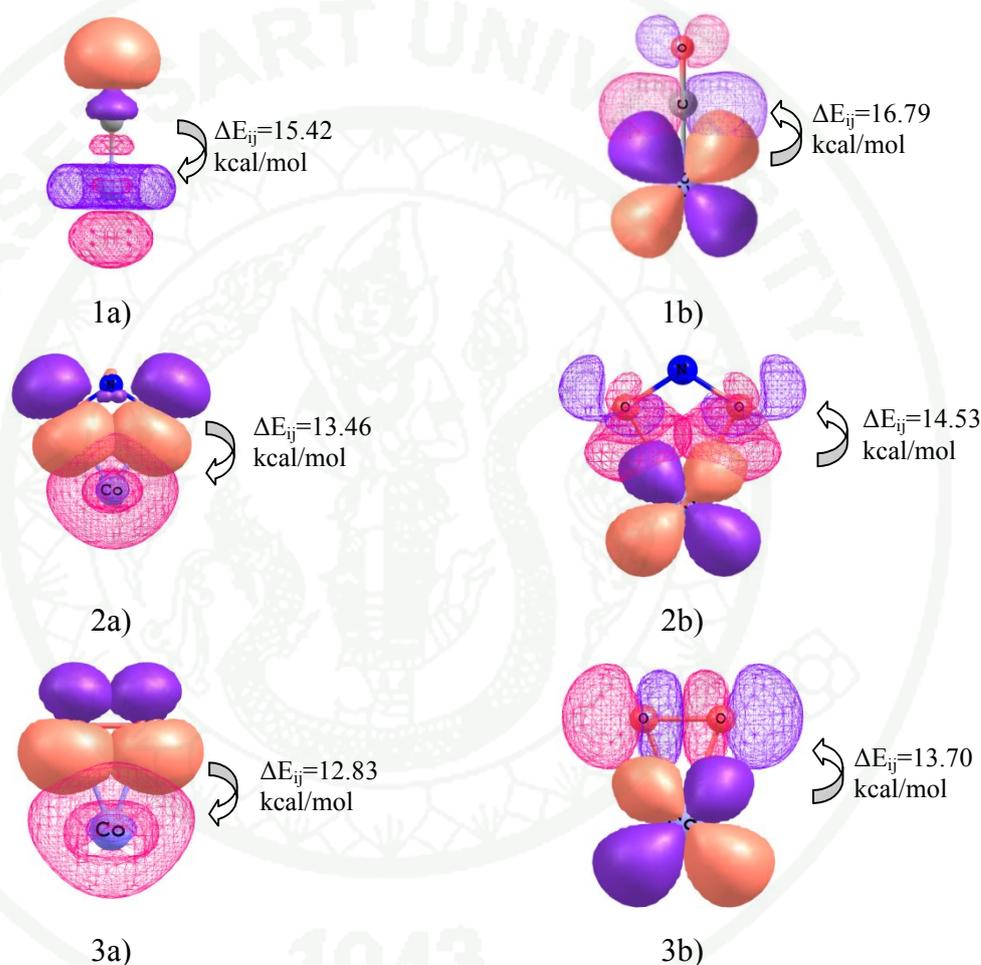

**Figure 11** The optimize structures and illustration standard labeling of a) the CO with metal, b) NO<sub>2</sub> with metal, and c) O<sub>2</sub> with metal (M=Co, Ni and Cu)

The bond lengths of CO, NO<sub>2</sub> and O<sub>2</sub> with metal of the state obtained from the rotation spectra are in good agreement with our results (show in table 2-4). In addition, the distance of  $r(\text{M}\cdots\text{gas})$  is decreased when charge of all system MNO are increase, which their corresponding adsorption energies (see table 2).

The linear form of MCO causes very significant electron redistribution at the metal atom. Electron density is transferred from the  $\sigma$  orbital of carbon to vacant 4s orbitals at metal via carbon molecule. Back-donation from the metal to the ligand results in depopulation of the 3d orbital and increased local negative charge of the oxygen atom, shown in Figure 12. While the MNO<sub>2</sub> and MOO have a O-O bound cause very significant electron redistribution at the metal atom and electron density is transferred from the  $\sigma$  orbital of 2 oxygen to vacant 4s orbitals at metal via oxygen

molecule. Back-donation from the metal to the ligand results in depopulation of the 3d and 4s orbital and increased local negative charge of the nitrogen atom (for  $\text{NO}_2$ ).

The strong  $\sigma$ -donation in the adsorption complexes results in a significant shortening of the gas bond distance with respect to that in the isolated gas molecules.

**Figure 12** The interaction orbital of gas with metal, 1a-3a) donating orbital of  $\text{CO}$ ,  $\text{NO}_2$  and  $\text{O}_2$  to metal, 1b-3b) back donating orbital of metal to  $\text{CO}$ ,  $\text{NO}_2$  and  $\text{O}_2$

## 2. Metal(II)(salpn) and metal(II)(salpn)/NO complexes

### 2.1 Geometry optimization of metal(II)(salpn) and metal(II)(salpn)/NO

To confirm the methodology for calculation metal(II)(salpn) complexes, DFT/B3LYP have been to calculation the metal(II)(salpn) complexes. These results from table 5 showed the structure of Co(II)(salen) complex from experimental and calculation. The calculation data is good agreement with experimental data(< 10%) for similar compounds. The selected parameters obtained in the calculation are tabulated in the table 5 and displayed in the Figure 13.

**Figure 13** Label geometries of metal containing *N,N'* propylenebis(salicylideneimine), M represents Co, Ni and Cu

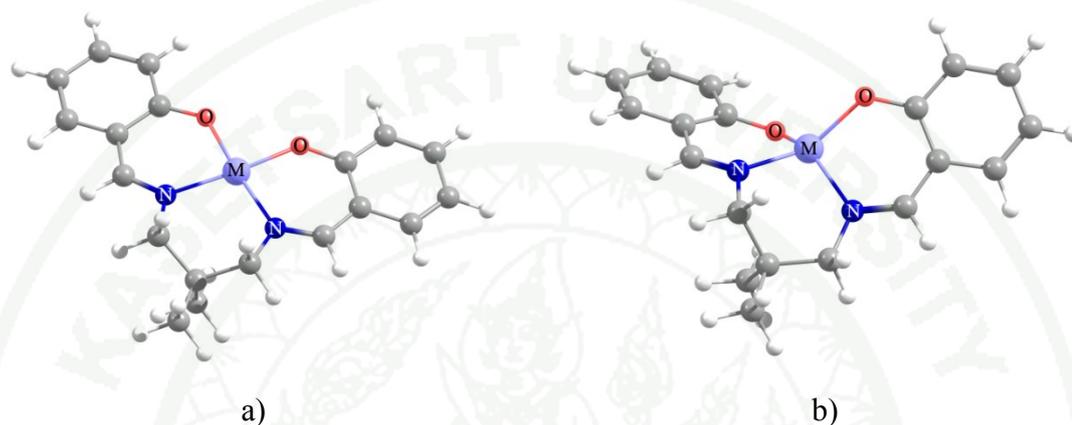

**Table 5** DFT/ECP optimized geometrical of the Co on N,N'-propylene-bis (salicylideneimine) system compare with geometry from experiment (bond lengths are in Å and bond angles in degrees)

<sup>a</sup>The X-ray study for Co containing Salpn complex (Bottcher *et al.*, 1993)

From the minimized structure of metal(II)(salpn) complexes (Figure 14), it could be noticed that the metal centers can adopt either the distorted square planar or square planar geometry depends on each metal centers as shown in Table 6. The Co(II)(salpn), the most stable geometry is a distorted square planar conformation that is more stable than square planar conformation the by 5.29 kcal/mol. On the other hand, the square planar conformation is more stable by 8.93 kcal/mol when the metal

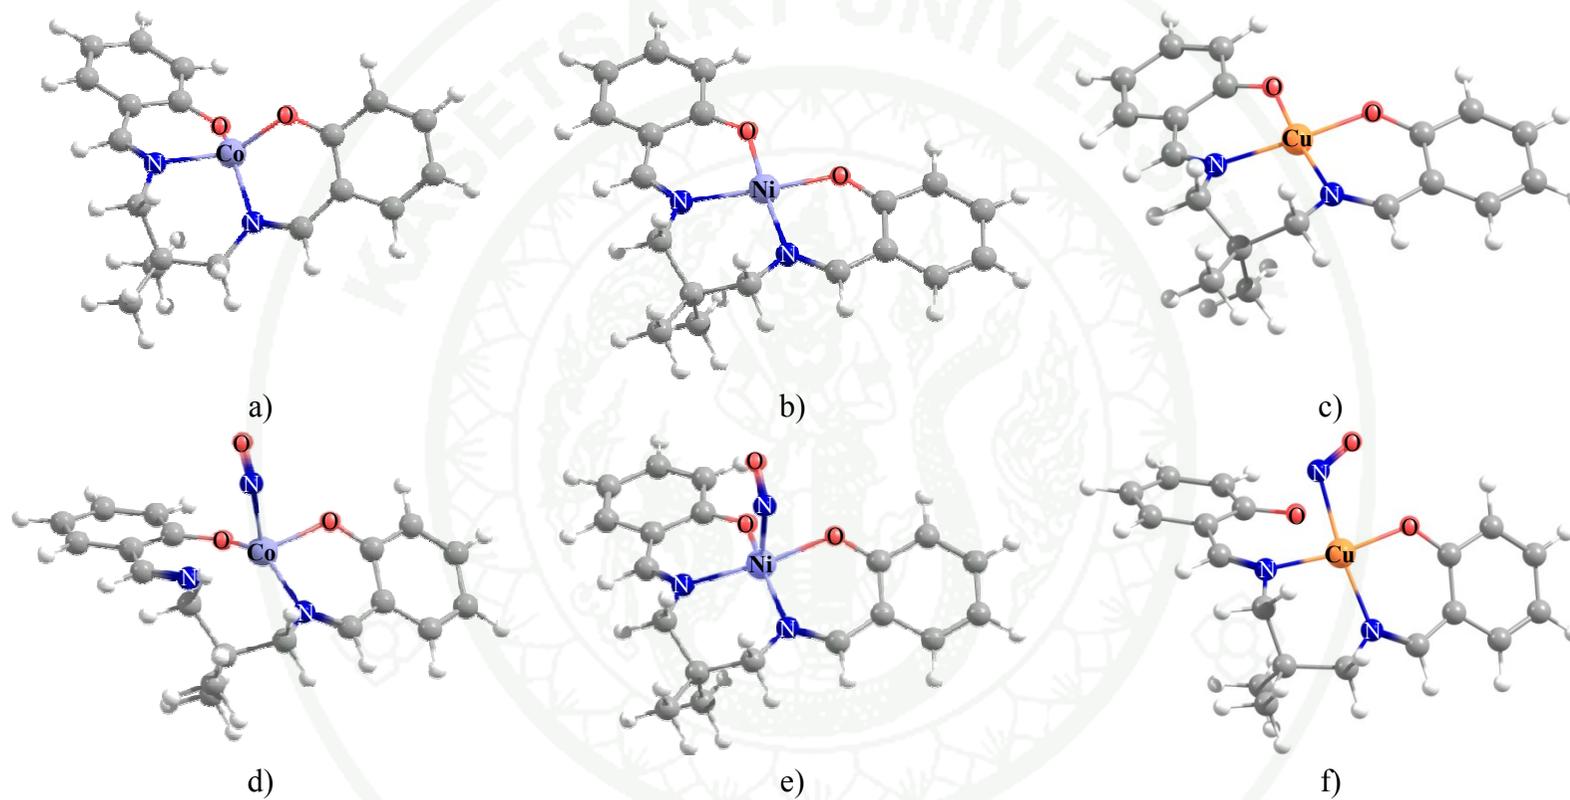

center is Ni. In case of Cu (II)(salpn) complex, both distorted square planar and square planar geometries have comparable relative energies with a small difference of 0.15 kcal/mol. However, the local geometry of all metal(II)(salpn) complexes is disturbed by NO adsorption.

**Figure 14** The optimize geometry of metal(salen) a) square planar b) distort square planar (M=Co, Ni and Cu)

**Table 6** Relative total energy of stable and less stable of metal(salpn) complexes

Metal	Schiff base	Structure	Distort	Square-planar
Co	(salpn)	Distort	0	5.29
Ni	(salpn)	Square-planar	8.93	0
Cu	(salpn)	Square-planar	0.15	0

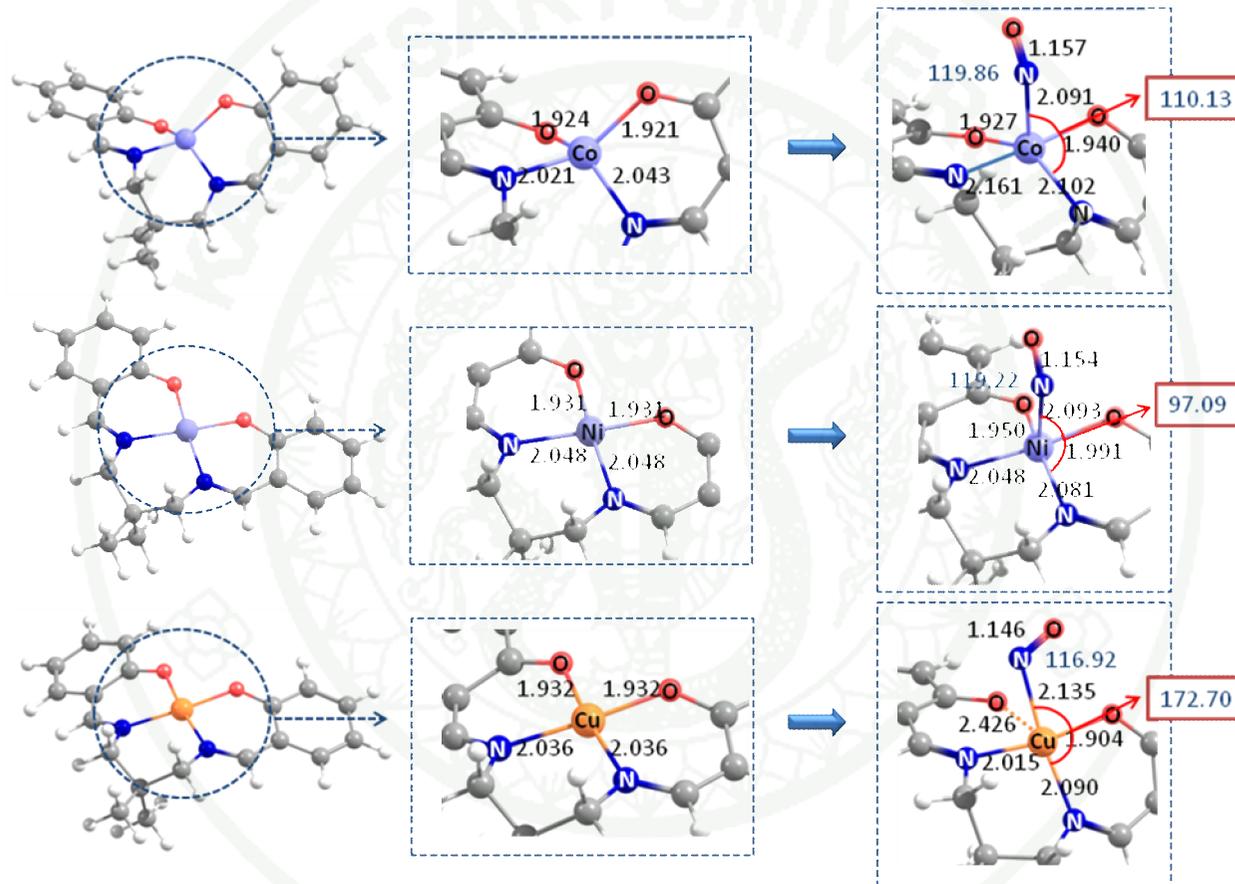

**Figure 15** Configurations of a) distort square planar Co(II)(salpn), b) the square planar Ni(II)(salpn), c) the square planar Cu(II)(salpn) d) distort square pyramidal Co(II)(salpn)/NO, e) distort square pyramidal Ni(II)(salpn)/NO, and f) distort square pyramidal Cu(II)(salpn)/NO complexes

## 2.2 Electronic properties of metal(II)(salpn) and metal(II)(salpn)/NO

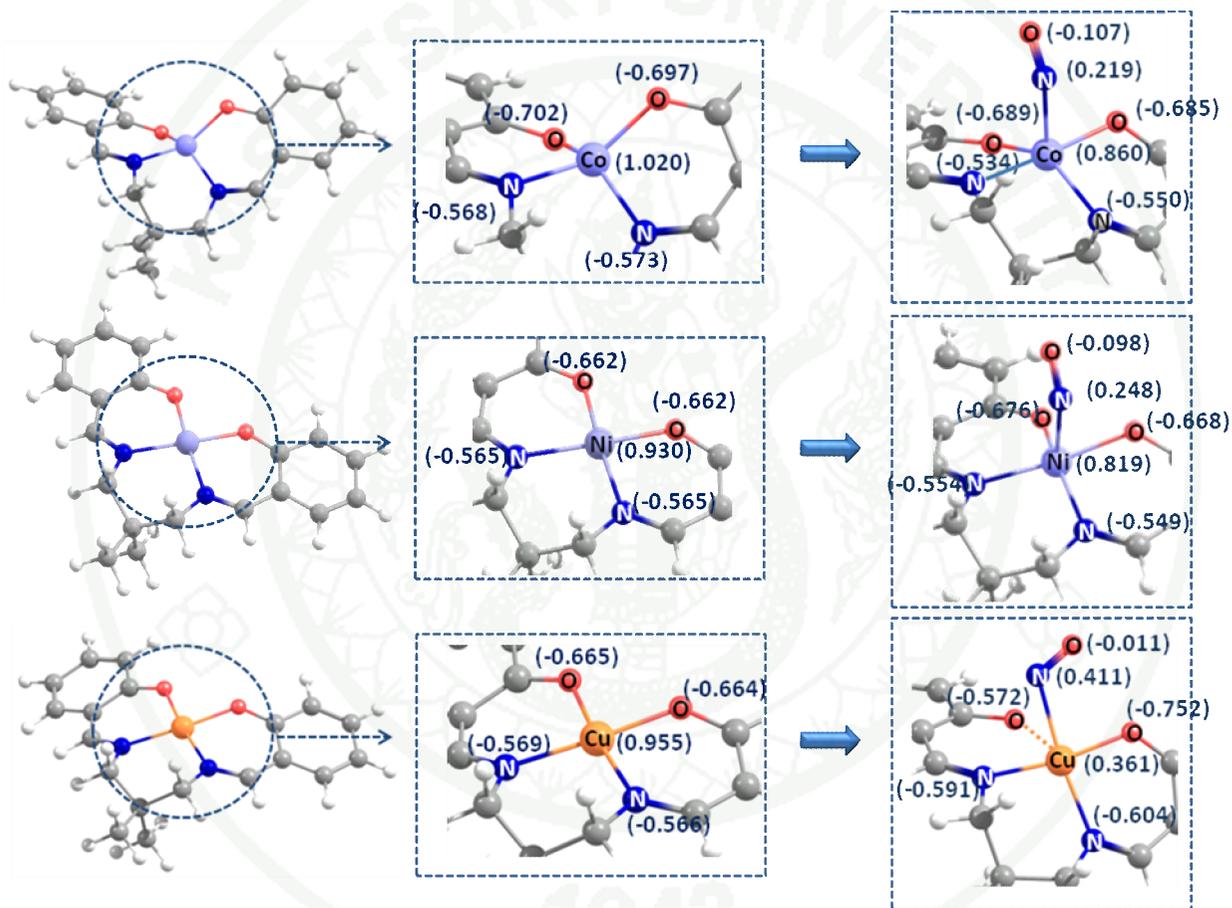

### 2.2.1 Adsorption energy

The adsorption of NO molecule, the coordinative bonds connecting between the metal center atom and the chelating ligand increase by about 0.03-0.10 Å as compared to that of isolate metal(II)(salpn) complexes. To accommodate an adsorbing NO molecule, the metal center adopts distort square pyramidal geometry. The tip of the pyramid is engaged by the NO molecule. From several directions of trial adsorption configuration, NO preferably adsorbs on the metal center with the N-bound configuration in a bent fashion with the O-N-M (where M = Co, Ni and Cu) bond angle of about 120° (see also Figure 16 and Table 6). Even though the atomic radii of Co, Ni and Cu are about the same value (Slater, J.C. et al. 1964), their interatomic distances with NO in the adsorption complex can be different. The N...Co distance (2.091 Å) is slightly shorter than the N...Ni distance (2.093 Å) and N...Cu distance (2.135 Å), respectively (shown in Figure 16). Their corresponding adsorption energies are -10.47, -10.43 and -4.28 kcal/mol for NO on Co(II)(salpn), Ni(II)(salpn) and Cu(II)(salpn) complexes, respectively, shown in table 7.

From this results, the adsorption of the NO onto the Co(II)(salpn) and Ni(II)(salpn) complexes showed the distort square pyramidal complexes (Co-2N2O/NO) while the NO molecules use oxygen atom to bind on Cu-2N2O site. The structure of Cu(II)(salpn) then was violently distorted. The violent distortion of Cu-2N2O plane affected to the weak adsorption of NO molecule. For the atomic charge of metal(II)(salpn)/NO, the Co(II) received electron about -0.160 a.u. from NO molecule and no significant electron transfer to ligand (2N2O-plane) was found while Ni(II) received electron around -0.011a.u. from NO molecule and further transfer to ligand. The Cu(II) received more electron about -0.954 a.u. from NO molecule. The Cu(II) received more electron from NO molecule because the structure of Cu(II)(salpn) was violently distorted and not deriver electron to other atoms, shown in Figure 17.

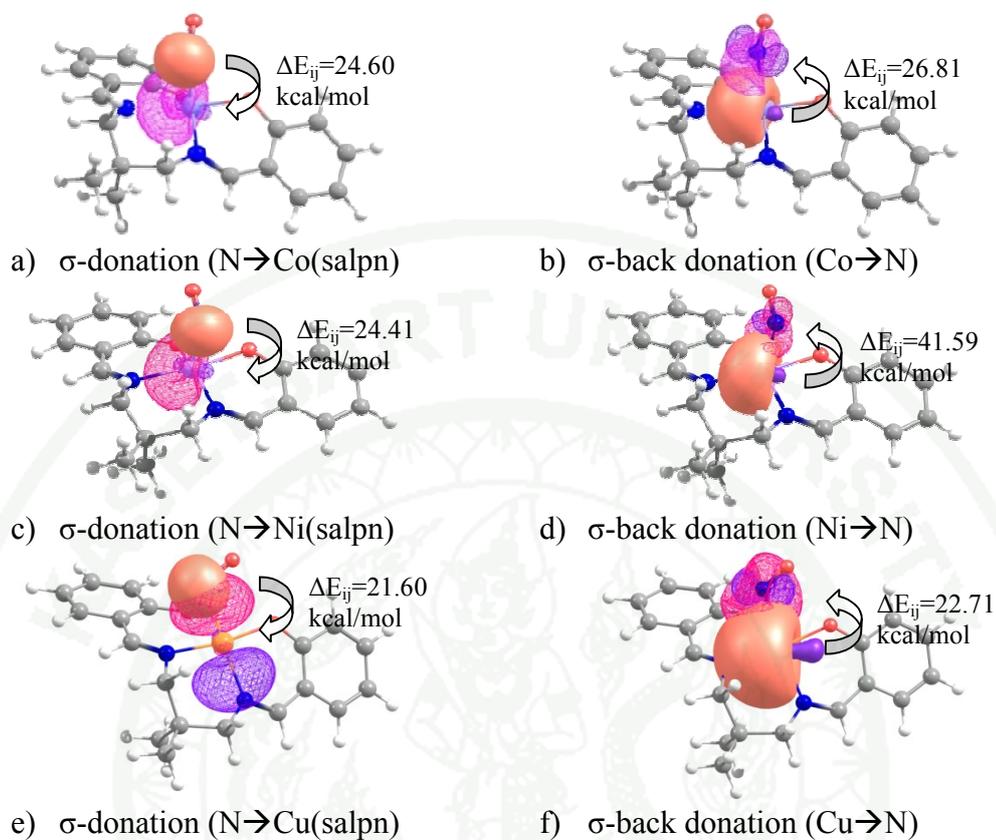

**Figure 16** Distance and angles of metal(II)(salpn) and metal(II)(salpn)/NO complexes

**Figure 17** Atomic charge of metal(II)(salpn) and metal(II)(salpn)/NO complexes

### 2.2.2 Natural bond orbitals

The natural bond orbital analyses show that the bonding between NO and the metal center predominantly involves the electron transfer from an lone pair orbital of N to an anti-lone pair orbital of the metal center ( $\sigma$ -donation) whereas the electron transfer from the metal back to NO ( $\sigma$ -back-donation) is considerably small. The orbitals that are involved in the  $\sigma$ -donation and  $\sigma$ -back-donation are illustrated in Figure 18. For Co(II)(salpn), the  $\sigma$ -donation involves the electron transfer from the  $sp^{0.33}$  hybrid lone pair orbital of N to the  $sp^{0.50}$  Rydberg orbital of Co, while in the case of Ni(II)(salpn), it takes place through the electron transfer from the  $sp^{0.36}$  hybrid lone pair orbital of N to the  $sp^{0.36}$  Rydberg orbital of Ni, and the Cu(II)(salpn), the  $\sigma$ -donation involves the electron transfer from the  $sp^{1.58}$  hybrid lone pair orbital of N to the  $sp^{1.00}$  Rydberg orbital of Cu. Therefore, the different orbital of gas molecule are resulting to different conformation of the gas adsorption and the stabilize energy of electrons. I found that the  $\sigma$ -donation on Co, Ni and Cu are calculated to be 24.60, 24.41 and 21.60 kcal/mol, respectively and the  $\sigma$ -back-donation from Co, Ni and Cu to N is calculated to be 26.81, 41.59 and 22.71 kcal/mol, respectively. This agrees well with the less positive charge on Co Ni and Cu subsequent to the adsorption of the NO molecule. The strong  $\sigma$ -donation in the adsorption complexes results in a significant shortening of the N-O bond distance with respect to that in the isolated NO gas (1.159 Å). All selected structural parameters of the adsorption complexes of NO with Co(II)(salpn), Ni(II)(salpn) and Cu(II)(salpn) are documented in Table 8.

**Figure 18** Natural bond orbitals (NBOs) involved in the  $\sigma$ -donation (a, c, e) and the  $\sigma$ -back donation (b, d, f) for the NO adsorption on Co(II)(salpn) (top), Ni(II)(salpn) (middle) and Cu(II)(salpn) (bottom)

### 2.2.3 Energy gaps

To study the gas-selective properties of the metallopolymers, the sensitivity of the metal-salpn complexes is examined by evaluating the energy gap ( $E_g$ ) of the adsorption complexes at the frontier molecular orbitals. Figure 19 shows frontier molecular orbitals of an isolated NO gas, metal-salpn complex and the metal-salpn/NO adsorption complex. The energy gaps are calculated from the energy difference between the lowest-unoccupied molecular orbital (LUMO) and the highest-occupied molecular orbital (HOMO). It can be seen that the adsorption of the NO molecule onto the metal center results in a widening of the energy gap of the metal-salpn complexes. However, an emergence of unoccupied states between the HOMO and LUMO orbitals of the metal-salpn complexes upon the adsorption of NO could facilitate an electron hop along the metal-salpn complex, and hence enhance its electrical conductivity. These unoccupied states, which are mostly purely contributed from the NO molecule, act as electron accepting sites, and as the same they can function as an electron donor

In this part for NO adsorption, results from the density functional theory calculation show that the NO gas molecule can reasonably adsorb onto the metal center of the Co(II)(salpn), Ni(II)(salpn) and Cu(II)(salpn) complexes, an adsorption center model of the metallopolymers. The emergence of unoccupied states in the frontier region upon the adsorption of NO could enhance an electrical conductivity along the chain of metallopolymers. This phenomenon could be useful in the design of the metallopolymers for gas-sensing applications.

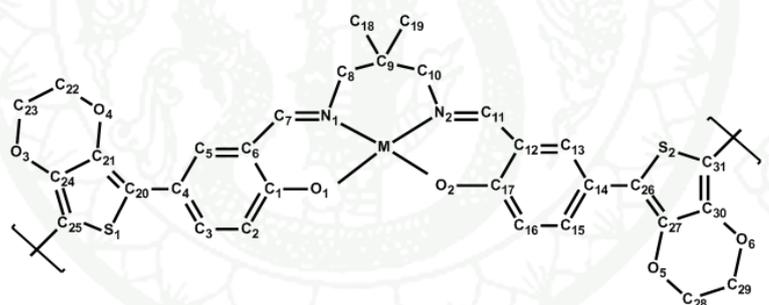

**Figure 19** Frontier molecular orbitals of an isolated NO gas, metal(II)(salpn) complexes, and their NO adsorption complexes, Energies are in eV.

### 3. Metal(II)(salpn)-EDOT complexes and metal(II)(salpn)-EDOT/NO complexes

#### 3.1 Geometry optimization of metal(II)(salpn)-EDOT and metal(II)(salpn)-EDOT/NO

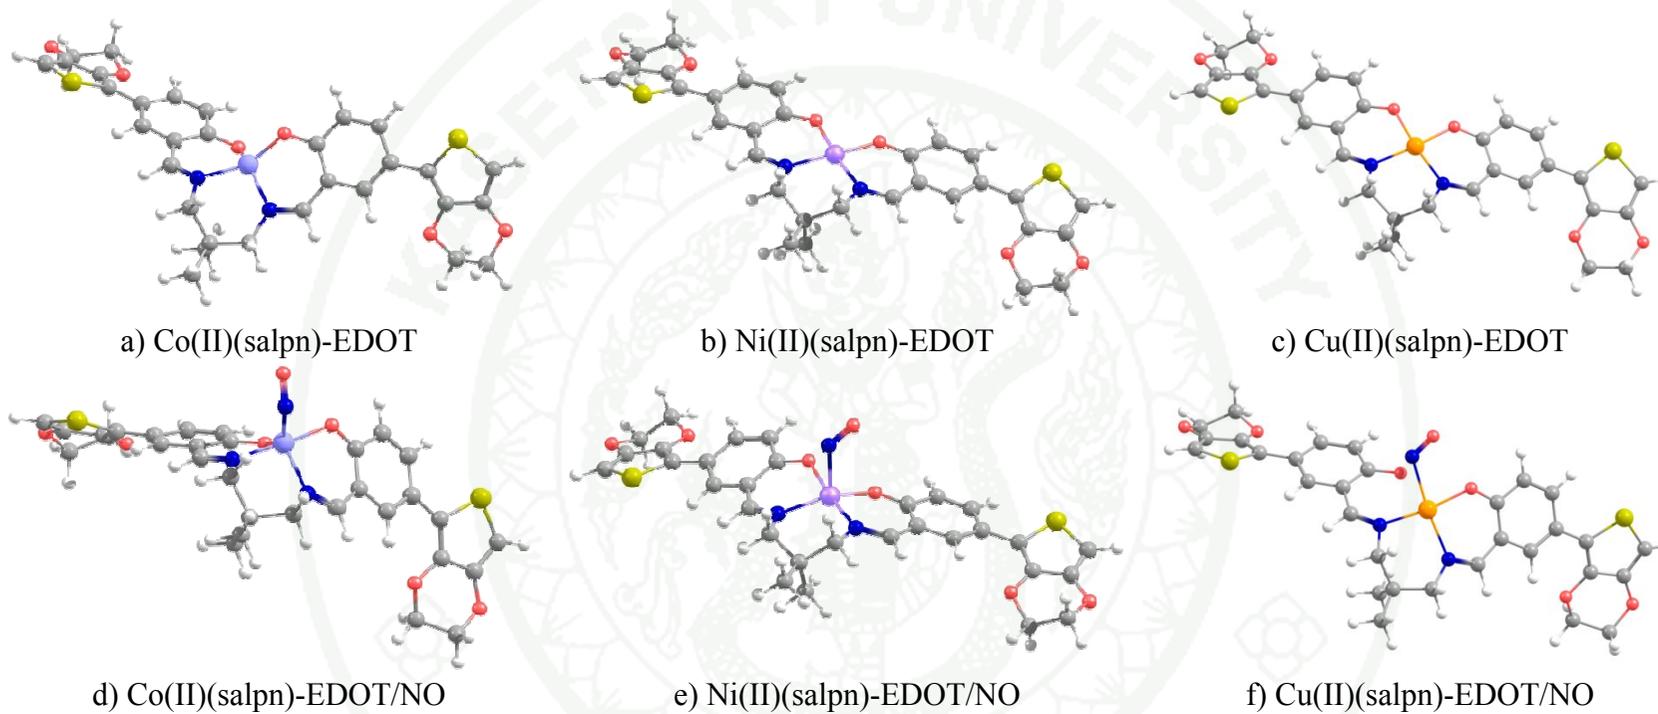

In the actual application, the active center must be integrated in the conjugate polymeric system. Therefore, the studied system has to be improved to a more reasonable model. The effects of the EDOT polymeric host on the geometric and electronic properties of metal(II)(salpn) complexes were examined. The minimized structure of functionalize the EDOT on the metal(II)(salpn) complexes are similar with metal(II)(salpn) complexes. The centers can adopt either the distorted square planar geometry for Co(II)(salpn)-EDOT and square planar geometry for Ni(II) and Cu(II)(salpn)-EDOT as shown in Figure 21. The selected parameters obtained in the calculation are tabulated in table 9 and Figure 20.

### 3.2 Electronic properties of metal(II)(salpn)-EDOT and metal(II)(salpn)-EDOT/NO

#### 3.2.1 Adsorption energy

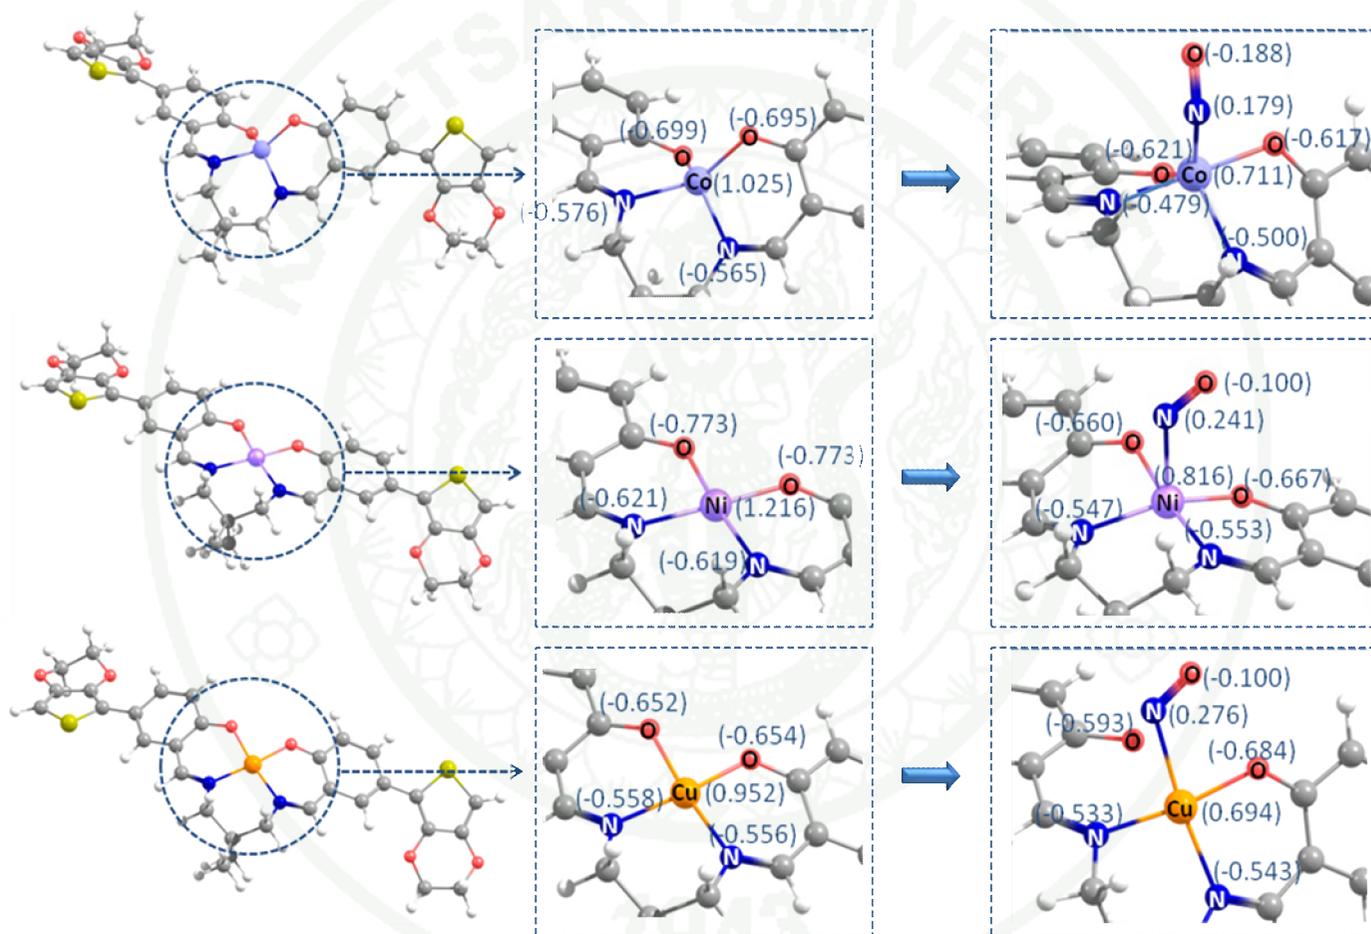

To accommodate an adsorbing NO molecule, the metal center adopts a distorted square pyramidal geometry. The atomic radii of Co, Ni and Cu are about the same value, their interatomic distances with NO in the adsorption complex can be different. For metal(II)(salpn)EDOT, we found that the N $\cdots$ Co(II)(salpn)EDOT distance (1.860 Å), N $\cdots$ Ni(II)(salpn)EDOT distance (2.091 Å) and N $\cdots$ Cu(II)(salpn)EDOT distance (2.140 Å) are shorter than all of the N $\cdots$ Metal(II)(salpn), shown in Figure 22, and the adsorption energy of NO onto Co(II), Ni(II) and Cu(II)(salpn)-EDOT complexes are increase about 2.86, 0.13 and 1.11 kcal/mol as compare with NO onto Co(II), Ni(II) and Cu(II)(salpn) complexes, shown in table 10.

From this results, The NO adsorption, the local geometry of metal(II)(salpn)-EDOT complexes slightly changed compare with metal(II)(salpn). The adsorption of the NO onto the Co(II) and Ni(II)(salpn)-EDOT complexes showed the distort square pyramidal complexes while the geometry of Cu(II)(salpn) complex showed violent distortion. The violent distortion of Cu-2N2O plane affected to weak adsorption of NO molecule.

The atomic charge of metal(II)(salpn)-EDOT/NO, The Co(II) received electron about -0.314 and Ni(II) received electron about -0.400 a.u from NO molecule and these structure not diffused electron to ligand (2N2O-plane). The Cu(II) received electron about -0.258 a.u. from NO molecule less than Co(II) and Ni(II), the Cu(II) small received electron from NO molecule because the structure of Cu(II)(salpn) was violently distorted, not diffused electron to other atom and Cu cation larger than Co(II) and Ni(II), shown in Figure 23.

**Figure 22** Distance and angles of metal(II)(salpn)-EDOT and metal(II)(salpn)-EDOT/NO complexes

**Figure 23** Atomic charge of metal(II)(salpn)-EDOT and metal(II)(salpn)-EDOT/NO complexes

Cu(salpn)-EDOT/NO	-5.39	1.594	2.140	1.146	116.92	0.694

### 3.2.2 Natural bond orbitals

The natural bond orbital analyses show that the bonding between NO and the metal center predominantly involves the electron transfer from an lone pair orbital of N to a Rydberg orbital of the metal center ( $\sigma$ -donation) whereas the electron transfer from the metal back to NO ( $\sigma$ -back-donation) is considerably small. The orbitals that are involved in the  $\sigma$ -donation and  $\sigma$ -back-donation are illustrated in Figure 24. For Co(II)(salpn)-EDOT, the  $\sigma$ -donation involves the electron transfer from the  $sp^{0.49}$  hybrid lone pair orbital of N to the  $sp^{1.14}$  hybrid Rydberg orbital of Co, while in the case of Ni(II)(salpn)-EDOT, it takes place through the electron transfer from the  $sp^{0.33}$  hybrid lone pair orbital of N to the  $sp^{1.19}$  hybrid Rydberg pair orbital of Ni and Cu(II)(salpn)-EDOT, the  $\sigma$ -donation involves the electron transfer from the  $sp^{0.35}$  hybrid anti-lone pair orbital of N to the  $sp^{0.67}$  hybrid Rydberg orbital of Cu. The  $\sigma$ -donation on Co, Ni and Cu is calculated to be 35.73, 35.75 and 14.80 kcal/mol, respectively and the  $\sigma$ -back-donation from Co, Ni and Cu to N is calculated to be 149.09, 36.42 and 15.04 kcal/mol (shown in table 11), respectively. From these phenomenon, the electron transfer of the functionalize of EDOT onto metals(salpn)

are better than metals(salpn). Therefore, the adsorption of NO onto metals(salpn)-EDOT complexes are better than NO adsorbed onto the metals(salpn) complexes too.

**Figure 24** Natural bond orbitals (NBOs) involved in the  $\sigma$ -donation (a, c, e) and the  $\sigma$ -back donation (b, d, f) for the NO adsorption on Co(II)(salpn)-EDOT (top), Ni(II)(salpn)-EDOT (middle) and Cu(II)(salpn)-EDOT (bottom)

### 3.2.3 Energy gap

It can be seen that the adsorption of the NO molecule onto the metal center results in a widening of the energy gap of the metal-salpn complexes (Figure 20). However, an emergence of unoccupied states between the HOMO and LUMO orbitals of the metal-salpn complexes upon the adsorption of NO could facilitate an electron hop along the metal-salpn complex, and hence enhance its electrical conductivity. These unoccupied states, which are mostly purely contributed from the NO molecule, act as electron accepting sites, and as the same they can function as an electron donor. The variation energy gap of Co(II), Ni(II) and Cu(II)(salpn)-EDOT are 1.357, 1.468 and 1.349eV., respectively as compare with isolate metal(II)(salon).

These sensors showed the advantages on the selectivity more than sensitivity. Due to the fact that Co(II) and Ni(II)(salpn)-EDOT have a good selectivity (adsorption energy are about -13.33 and -10.56 kcal/mol, respectively). Cu(II)(salpn)-EDOT has a poor selectivity (adsorption energy are about -5.39 kcal/mol), although it has a good sensitivity.

The results from the density functional theory calculation show that the modified EDOT into metal(II)(salpn), we found that all of metal(II)(salpn)-EDOT/NO is better than the metal(II)(salpn)/NO. Such as the adsorption energy and energy gap of metal(II)(salpn)-EDOT/NO are increase. However, the adsorption energy of Cu(II)(salpn)-EDOT/NO is more poorly than the Co(II) and Ni(II)(salpn)/NO, although, the energy gap of Cu(II)(salpn)-EDOT/NO are in good as compare with Co(II) and Ni(II)(salpn)-EDOT/NO complexes (shown in Figure 25), because sensors are interested previously selectivity before sensitivity. This phenomenon could be useful in the design of Co(II)(salpn)-EDOT for NO-sensing applications.

**Figure 25** Frontier molecular orbitals of an isolated NO gas, metal(II)(salpn)-EDOT complexes, and their NO adsorption complexes, Energies are in eV.

#### 4. Metal(II)(salpn)-EDOT and metal(II)(salpn)-EDOT/CO, NO<sub>2</sub> and O<sub>2</sub> complexes

In this part, we be specific to the geometry, adsorption energy and energy gap because this properties of the metal-containing conductive polymer can promise property for being applied on chemical sensing device at molecular level.

##### 4.1 Geometry optimization of metal(II)(salpn)-EDOT/CO, NO<sub>2</sub> and O<sub>2</sub> complexes

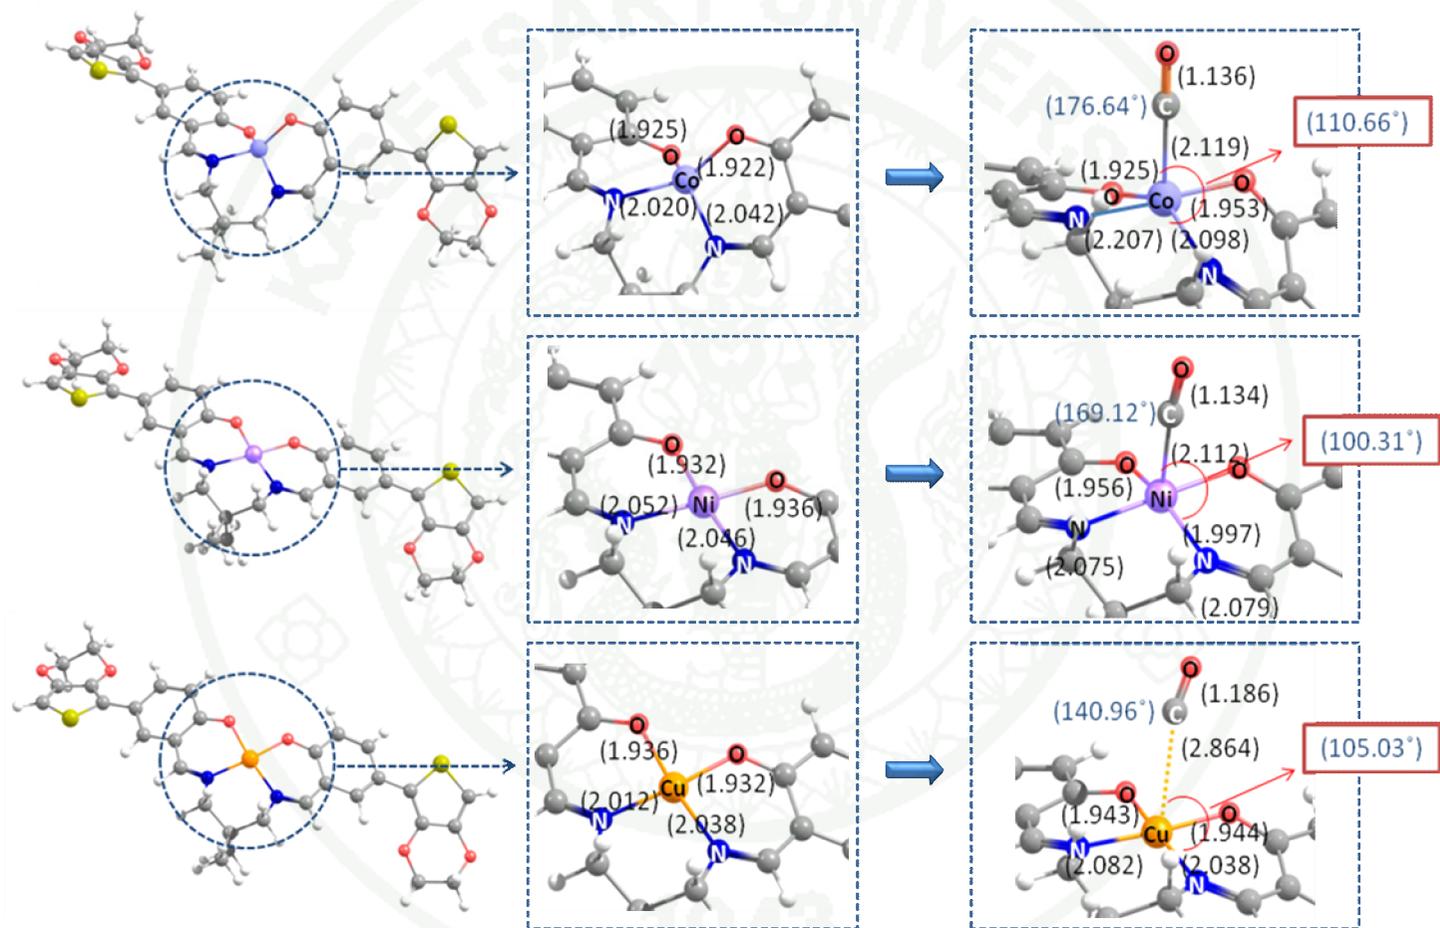

These results, were varied gas (such as CO, NO<sub>2</sub> and O<sub>2</sub>) onto metal(salpn)-EDOT. The local geometry of all metal(II)(salpn)-EDOT complexes are disturbed by gas molecules. To accommodate an adsorbing CO and O<sub>2</sub> molecules, the metal center adopts distort square pyramidal geometry, shown in Figure 26, 30. While the accommodate an adsorbing NO<sub>2</sub> molecule, the metal center adopts violent distorted square pyramidal geometry, shown in Figure 28.

##### 4.2 Electronic properties of metal(II)(salpn)-EDOT/CO, NO<sub>2</sub> and O<sub>2</sub> complexes

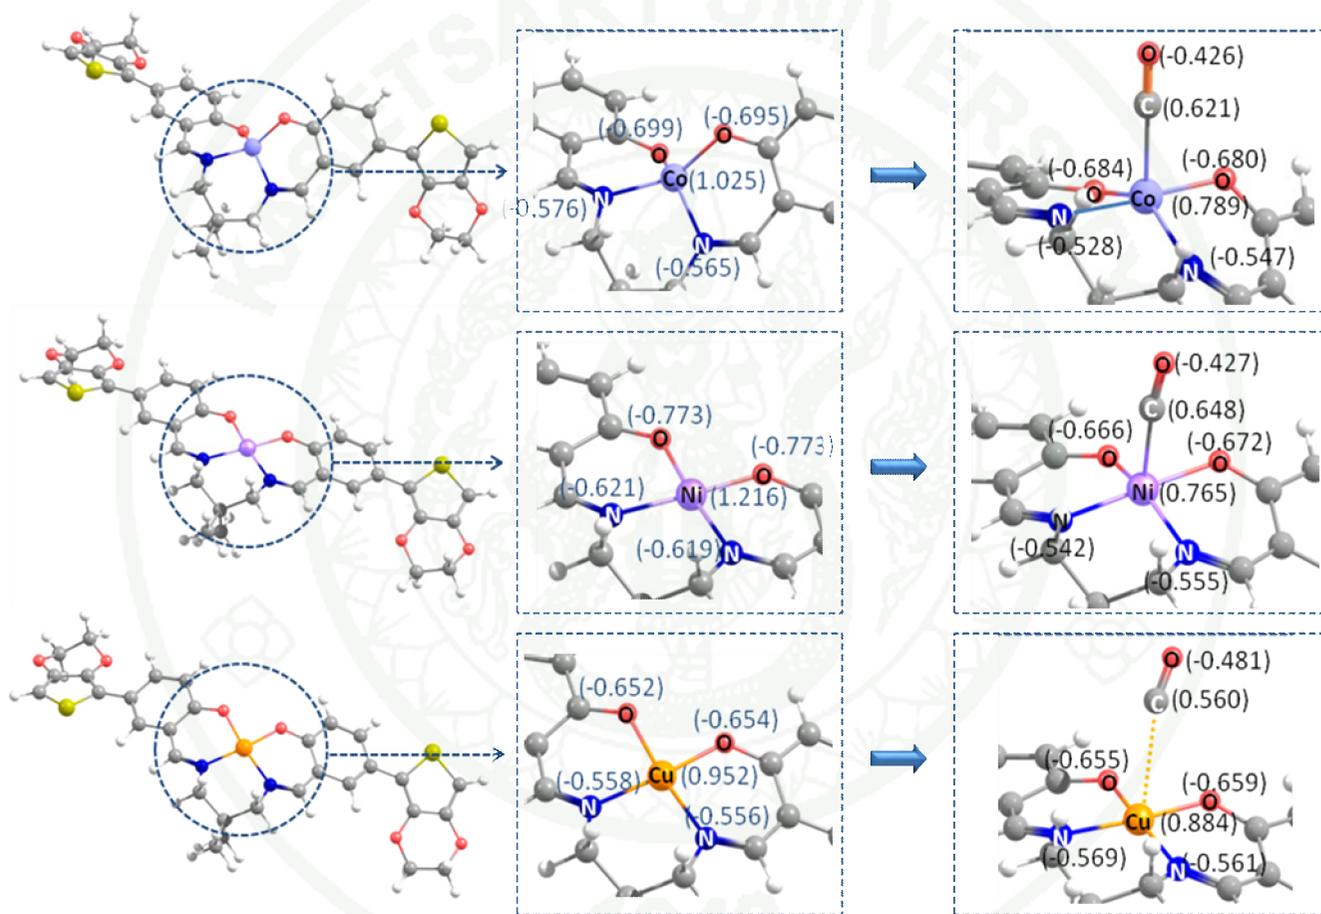

###### 4.2.1 Adsorption energy

The tip of the pyramid is engaged by the CO and O<sub>2</sub> molecule. From several directions of trial adsorption configuration, CO preferably adsorbs on the metal center with the C-bound configuration in a linear fashion with the O-C-M (where M = Co, Ni and Cu) bond angle of about 165-180° (see also Figure 26) and O<sub>2</sub> preferably adsorbs on the metal center with O-bound configuration in a bent fashion with the O-O-M bond angle of about 100-120° (see also Figure 30). While NO<sub>2</sub> preferably adsorbs on the metal center with the O-O bound configuration in a parallel fashion with the ONO-M (see also Figure 28).

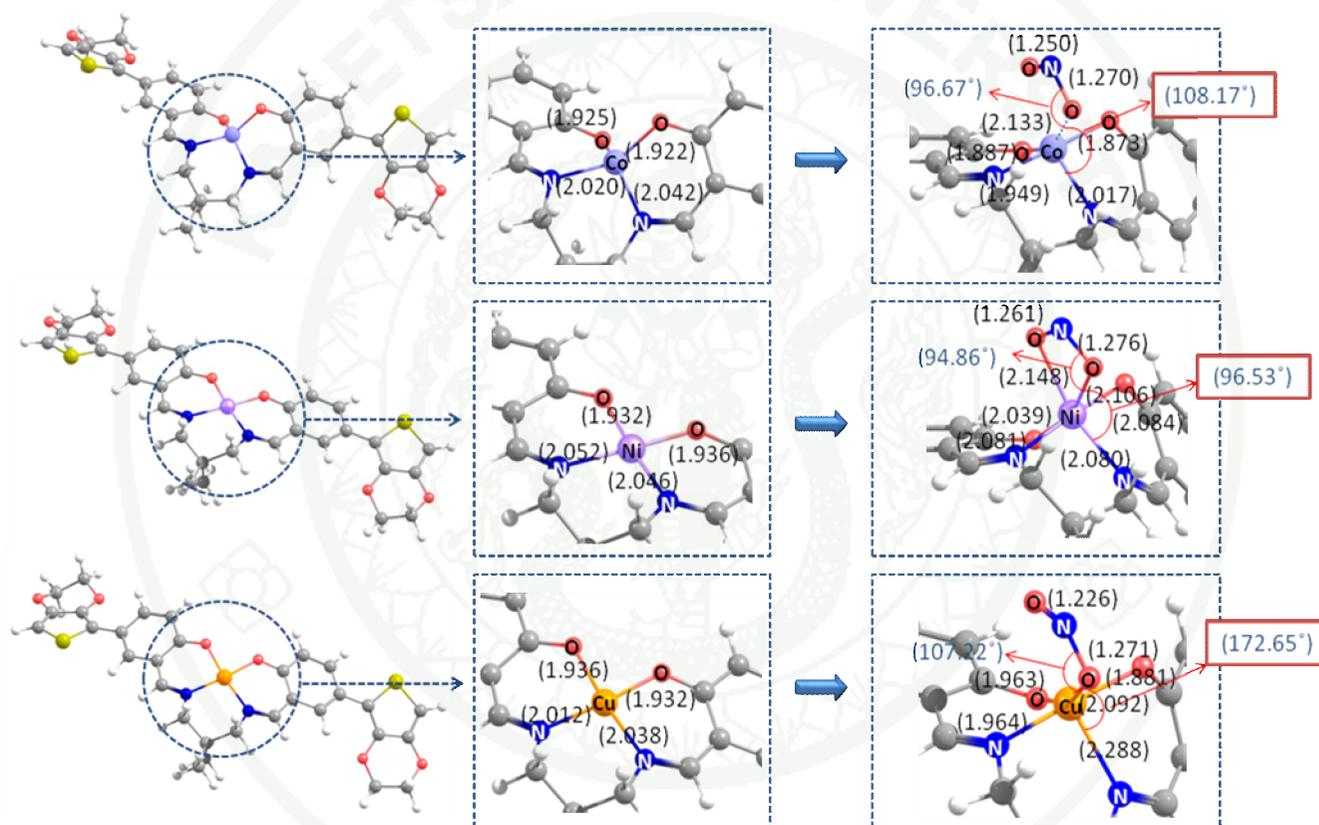

The atomic radii of Co, Ni and Cu are about the same value (Slater, J.C. et al. 1964), their interatomic distances with CO in the adsorption complex can be different. The C...Ni distance (2.112 Å) is slightly shorter than the C...Co distance (2.119 Å) and C...Cu distance (2.864 Å), respectively (shown in Figure 26). Their corresponding adsorption energies are -5.82, -4.88 and -3.67 kcal/mol for CO on Ni(II)(salpn), Co(II)(salpn) and Cu(II)(salpn) complexes, respectively). For NO<sub>2</sub> adsorption, The O...Cu distance average (2.092 Å) is slightly shorter than the O...Ni distance (2.106 Å) and O...Co distance (2.133 Å), respectively (shown in Figure 28). Their corresponding adsorption energies are -20.17, -19.76 and -14.13 kcal/mol for CO on Cu(II)(salpn), Ni(II)(salpn) and Co(II)(salpn) complexes, respectively). For O<sub>2</sub> adsorption, The O...Ni distance average (3.045 Å) is slightly shorter than the O...Cu distance (3.109 Å) and O...Co distance (2.149 Å), respectively (shown in Figure 30). Their corresponding adsorption energies are -4.57, -4.01 and -3.98 kcal/mol for CO on Ni(II)(salpn), Cu(II)(salpn) and Co(II)(salpn) complexes, respectively.

#### 4.2.2 Energy gap

To study the gas-selective properties of the metallopolymer, the sensitivity of the metal-salpn complexes is examined by evaluating the energy gap ( $E_g$ ) of the adsorption complexes at the frontier molecular orbitals. Figure 32, 33 and 34 shows frontier molecular orbitals of an isolated CO, NO<sub>2</sub>, and O<sub>2</sub> molecules, metal-salpn complex and the metal-salpn/NO<sub>2</sub> adsorption complex. The energy gaps are calculated from the energy difference between the lowest-unoccupied molecular orbital (LUMO) and the highest-occupied molecular orbital (HOMO). It can be seen that the adsorption of the NO molecule onto the metal center results in a widening of the energy gap of the metal-salpn complexes. However, an emergence of unoccupied states between the HOMO and LUMO orbitals of the metal-salpn complexes upon the adsorption of NO<sub>2</sub> could facilitate an electron hop along the metal-salpn complex, and hence enhance its electrical conductivity (shown in Figure 33). These unoccupied states, which are mostly purely contributed from the NO<sub>2</sub> molecule, act as electron accepting sites, and as the same they can function as an electron donor. While the metal-salpn/CO and O<sub>2</sub> adsorption complex, The energy gaps are calculated from the energy difference between the LUMO and the HOMO. It can be seen that the adsorption of the CO and O<sub>2</sub> molecule onto the metal center results in a widening of the energy gap of the metal-salpn complexes. However, an emergence of unoccupied states between the HOMO and LUMO orbitals of the metal-salpn complexes upon the adsorption of CO and O<sub>2</sub> could not facilitate an electron hop along the metal-salpn complex, and not hence enhance its electrical conductivity (shown in Figure 32, 34, respectively).

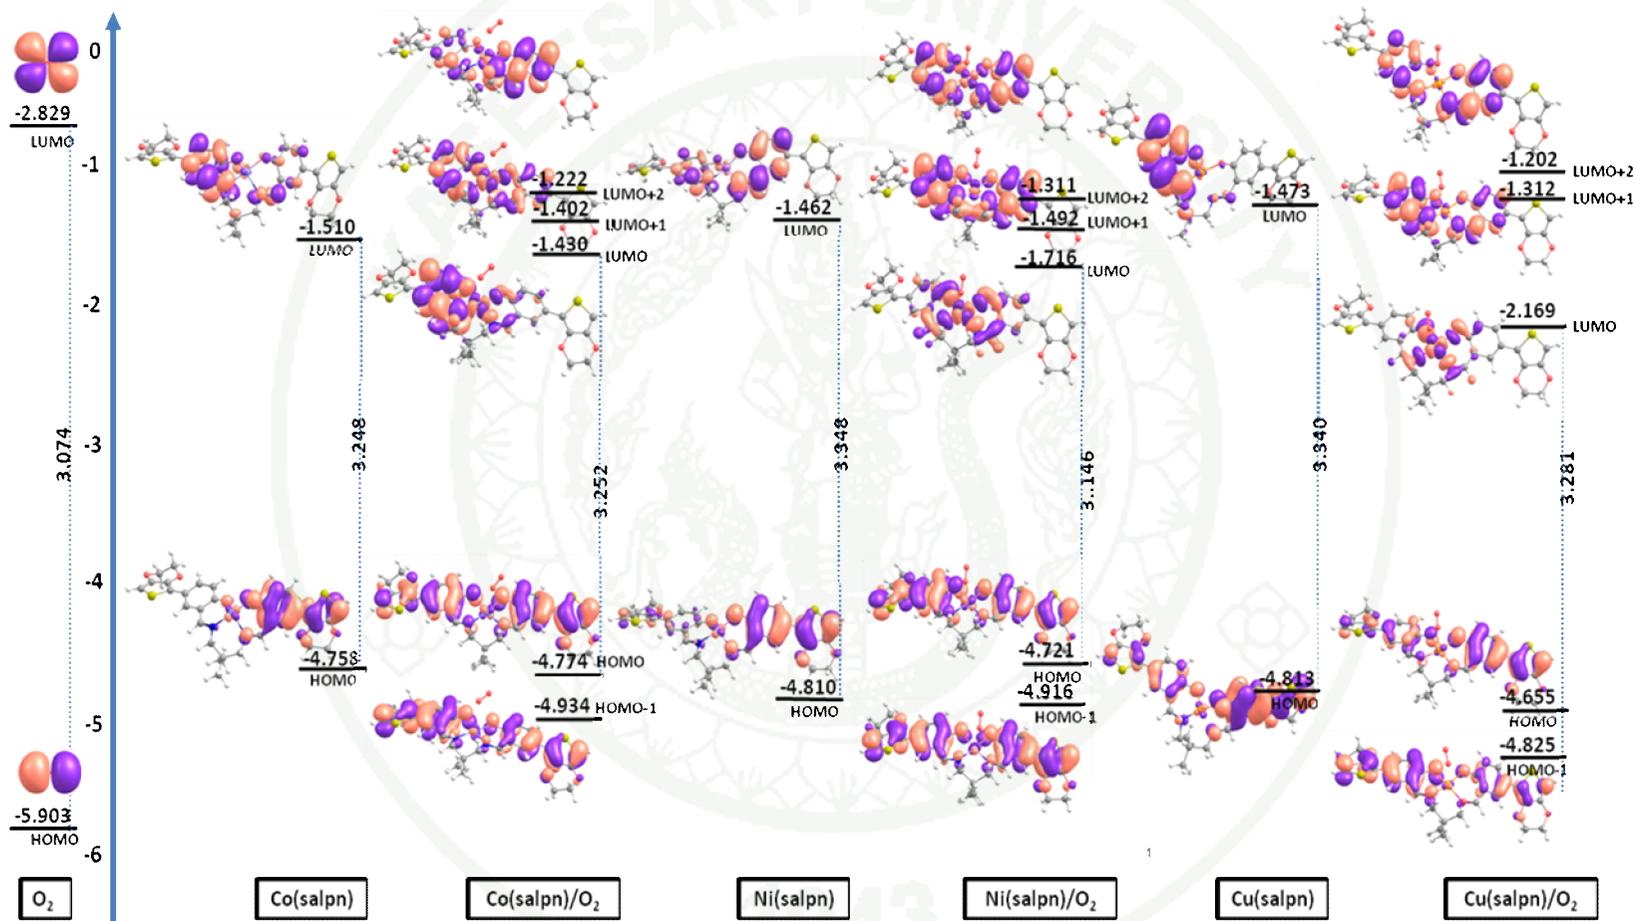

In this part for NO<sub>2</sub> adsorption, results show that the NO<sub>2</sub> gas molecule can reasonably adsorb onto the metal center of the Co(II)(salpn), Ni(II)(salpn) and Cu(II)(salpn) complexes, an adsorption center model of the metallopolymer. The emergence of unoccupied states in the frontier region upon the adsorption of NO<sub>2</sub> could enhance an electrical conductivity along the chain of metallopolymer.

## CONCLUSION

Density functional theory calculations were performed to study the structure and electronic properties of metallopolymer, metal(II)(salpn), the coordination of metal center on 2N2O-plane of salpn were examined. For Co(II)(salpn), the most stable geometry is a distorted square planar conformation. The local geometry of Co(II)(salpn) complex is disturbed by NO adsorption. The adsorption energies for NO on Co(II)(salpn) and Ni(II)(salpn) are the same (-10.47 and -10.43 kcal/mol). The NO was found to weakly bound on the Cu(II)(salpn) with an adsorption energy of -4.28 kcal/mol. For EDOT-modification on Metal(II)(salpn), the adsorption energy of NO onto Co(II)(salpn) is increased to -13.33 kcal/mol. The modification on Ni(II)(salpn) and Cu(II)(salpn) is insensible to the gas capture capability. The emergence of unoccupied states in the frontier region upon the adsorption of NO could enhance an electrical conductivity along the chain of metallopolymer. Upon the interaction of NO on metal active site, the energy gap of Co(II)(salpn)-EDOT is significantly reduced from 3.248 eV to 1.891 eV. Even though, Cu(II)(salpn)-EDOT has the most conductive response to the NO molecule, but the NO is barely adsorbed to the active site. In addition, for CO, NO<sub>2</sub> and O<sub>2</sub> molecule, I found that the CO and O<sub>2</sub> weakly adsorbed on metal(salpn)-EDOT ( $E_b$  -4.00 to -6.00 kcal/mol) and the energy gap of metal(salpn)-EDOT/CO, O<sub>2</sub> complexes have no variation, compare with the intrinsic metal(salpn)-EDOT complexes. For NO<sub>2</sub> molecule, the NO<sub>2</sub> has strong adsorption on Co, Ni, Cu(salpn)-EDOT ( $E_b$  -14.00 to -20.00 kcal/mol) and the energy gap of Co, Ni, Cu(salpn)-EDOT/NO<sub>2</sub> complexes is more variation (0.873, 2.642 and 2.163, respectively), compare with the intrinsic Co(II), Ni(II)(salpn)-EDOT complexes. Therefore, this work has theoretically demonstrated the effectiveness of the Co(II) and Ni(II)(salpn)-EDOT based sensor for being applied in gas sensing applications for NO and NO<sub>2</sub>.
