In this paper, we propose the modified template waveform based correlation receiver for interference suppression. The proposed waveform is the filtered Gaussian doublet pulse by using notch-filter to reject the narrowband interference (IEEE802.11a WLAN). Our simulation illustrates that the modified template waveform based correlation receiver allows significant performance improvement in the presence of the narrowband interference.

The organization of the paper is as follows. In Section II, the models of UWB time-hopping transmission and IEEE 802.11a interference are provided. The performance simulation and results will be given in Section III and the conclusion is given in Section IV.

II. SYSTEM MODELS

A. The UWB Transmitter Model

A common method for implementing the UWB signal is widely referred to as Impulse Radio (IR) [13]. Therefore, Gaussian doublet pulse shape is considered as a transmitted waveform and is given by

$$p(t) = A(1 - \frac{2t^2}{\xi^2}) \exp\left[-(t/\xi)^2\right], \quad (1)$$

where A is the maximum amplitude, ξ is the $1/e$ characteristic delay time. This waveform is the second derivative of the Gaussian pulse.

Modulation method for UWB time-hopping in the transmission are considered. The most common method of time-based techniques modulation is pulse position modulation (PPM) which may be expressed as

$$s_{\mathrm{PPM}}(t) = \sum_{n=-\infty}^{+\infty} p(t - nT_f - T_{c_n} - T_{p_n} - \tau_k), \quad (2)$$

where T_f represents the time duration of the frame, $p(t)$ is the Gaussian doublet pulse, T_f denotes the pulse repetition time, T_{c_n} is the time shift related to the PN code sequence, T_{p_n} represents the time shift from the pulse position modulation scheme and τ_k is the time delay.

Another common method of modulation is to invert the pulse. This is known as bi-phase modulation (BPM) and is

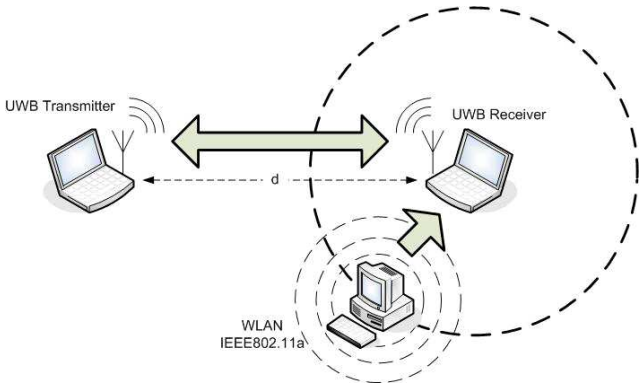

Fig. 1. Model of UWB transmission in the presence of the IEEE 802.11a interference.

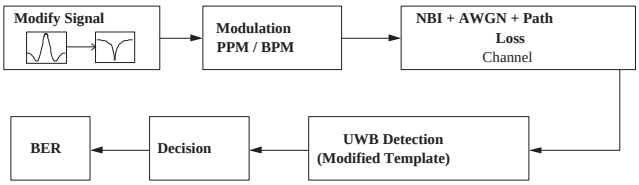

Fig. 2. The block diagram of the NBI suppression technique based on modified template waveform.

given by

$$s_{\mathrm{BPM}}(t) = \alpha_k \sum_{n=-\infty}^{+\infty} p(t - nT_f - T_{c_n} - \tau_k), \qquad (3)$$

where α_k represents the modulation symbol sequence for BPM ($[-1, 1]$).

B. IEEE 802.11a NBI and Path Loss Model

The NBI transmitted signal can be represented as [9]

$$s_{\mathrm{NBI}}(t) = w_T(t) \cdot \Re\left\{ \sum_{k=-N_{ST}/2}^{k=N_{ST}/2-1} c_k e^{j2\pi k \Delta F (t-T_G)} e^{j2\pi f_c t} \right\}, \qquad (4)$$

where N_{ST} is the total number of subcarrier, c_k is the set of coefficients transmitted, T_G is the guard time and ΔF represents the subcarrier frequency spacing, $w_T(t)$ is a time-windowing function that defines the boundaries of the subframe which assume a rectangular $w_T(t)$ with unit amplitude.

In order to calculate the SINR of the UWB system in the presence of the IEEE 802.11a interference, the empirical path loss model is employed. Therefore, the SINR at the UWB receiver is given by

$$SINR_{\mathrm{UWB}} = P_R(d) - 10\log(NBI_{802.11a} + N_{\mathrm{UWB}}), \qquad (5)$$

where $NBI_{802.11a}$ and N_{UWB} are interference and noise power at the UWB receiver, respectively. The propagation path loss model may be expressed as

$$PL(d) = PL(d_0) + 10n\log_{10}\left(\frac{d}{d_0}\right);\ d \geq d_0, \qquad (6)$$

where n is the path loss exponent which indicates the rate of the path loss increases with distance and d represents the T-R separation distance. Fig. 1 illustrates the UWB time-hopping system in the presence of IEEE 802.11a interference.

C. The Modified Template Waveform

Due to the UWB transmitted signal occupies an ultrawide bandwidth which cover the IEEE802.11a wireless LAN system operation. From [14], the IEEE802.11a wireless LAN can affect the performance of the UWB time-hopping system. Therefore, the interference suppression technique is required. We propose the modified template waveform technique which is simple and low complexity structure. This suppression technique involves the filtered UWB transmitted signal $p(t)$ by using the notch filter for reject bandwidth of the IEEE802.11a wireless LAN. Moreover, we consider the modified template waveform use to transmit and detect signal in the UWB system as shown in Fig. 2. The modified transmitted waveform is given by

$$u(t) = \sum_{w=-W}^{+W} \alpha_w p(t - wT_c). \qquad (7)$$

Therefore, the modified template waveform is given by

$$M(t) = u(t) - u(t - \delta), \qquad (8)$$

where T_c is one sample per bin period, the coefficients of the filter are $\{\alpha_w\}$ for $w = [-W, ..., W]$ and the number of taps on each side of the notch filter is W.

Fig. 3 shows the template waveform for the UWB correlation receiver. A left side pulse in the figure is the original template waveform, while the modified template waveform is shown in the right figure.

D. The UWB Receiver Model

A transmitted signal passes through the wireless channel including the transmitter and receiver antennas. Therefore,

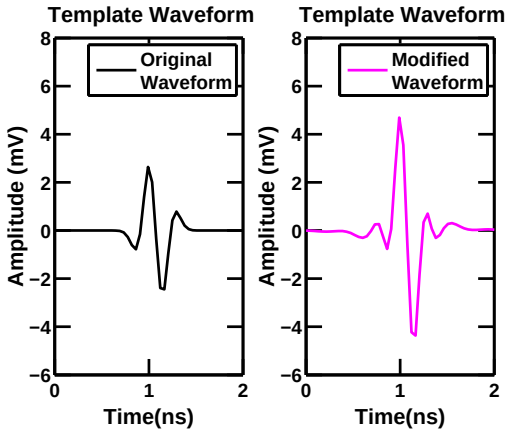

Fig. 3. The template signal waveform based correlation receiver. The left figure is the original template waveform and the right figure is the modified template waveform.

the total received signal for UWB PPM transmitter can be expressed as

$$r_{\mathrm{PPM}}(t) = \sum_{n=-\infty}^{+\infty} p(t - nT_f - T_{c_n} - T_{p_n} - \tau_k) + s_{\mathrm{NBI}}(t) + n(t), \quad (9)$$

and for UWB BPM transmitter,

$$r_{\mathrm{BPM}}(t) = \alpha_k \sum_{n=-\infty}^{+\infty} p(t - nT_f - T_{c_n} - \tau_k) + s_{\mathrm{NBI}}(t) + n(t), \quad (10)$$

where $s_{NBI}(t)$ represents the IEEE 802.11a interference and $n(t)$ is the additive white Gaussian noise.

The receiver considers the received signal $r(t)$ and decide based on an observation of the received signal for the decided bit, it uses correlation receiver signal with the template signal. Therefore, the received signal with the PPM transmission may be expressed as

$$r_{\mathrm{PPM,k}} = \sum_{n=-\infty}^{+\infty} \int_{\tau_k+nT_f}^{\tau_k+(j+1)T_f} r_{\mathrm{PPM}}(t) \cdot v(t - nT_f - T_{c_n} - T_{p_n} - \tau_k)dt, \quad (11)$$

and for the BPM transmission

$$r_{\mathrm{BPM,k}} = \sum_{n=-\infty}^{+\infty} \int_{\tau_k+nT_f}^{\tau_k+(j+1)T_f} r_{\mathrm{BPM}}(t) \cdot v(t - nT_f - T_{c_n} - \tau_k)dt, \quad (12)$$

where $v(t) = p(t) - p(t - \delta)$ represents the template signal. Therefore, in the case of the modified template waveform based correlation receiver, $v(t)$ is replaced by $M(t)$.

III. Performance Simulation and Results

The effects of NBI on the UWB time-hopping system, the IEEE 802.11a wireless LAN physical layer [15] with the operating frequency bands of 5.15-5.25 GHz, 5.25-5.35 GHz, and 5.725-5.825 GHz were generated by the computer simulation. The empirical path loss exponent in equation (6), n equals to 1.73 [16]. Consequently, the UWB transmitted power (EIRP) was set to be -41.3 dBm/MHz based on the FCC requirements [1]. The Gaussian doublet pulse width of 0.28 ns was assumed for the transmitting waveform. The pulse repetition time $T_f = 5$ ns, therefore, the transmission rate equals to 200 Mbps. Antennas are assumed to be omni-directional radiation pattern. Suppose that the transmitter and the receiver are perfectly synchronized. Therefore, the correlation receiver can be obtained for detecting the PPM and BPM symbols. The UWB and the NBI simulation parameters are listed in Table I.

Referring to the model of the UWB time-hopping in the presence of the IEEE 802.11a interference as shown in Fig. 1. The influence of the NBI increases as the T-R separation distance increases. Therefore, three observation points at 1, 5 and 10 meter are investigated to verify the performance of the modified template waveform for the UWB time-hopping system. However, the BER performance of the UWB system depends on the T-R separation distance between UWB transmitter and receiver. Moreover, it also depends on the separation between UWB receiver and wireless LAN interferer. The separation distance between the UWB receiver and the NBI depends on the SINR. Hence, the continuous transmission of the interferer was assumed for entire simulation time for the considered UWB system.

TABLE I
UWB AND NBI SIMULATION PARAMETERS.

Quantity	Values
UWB data rate	200 Mbps
UWB transmitter power	-41.3 dBm/MHz
UWB bandwidth	7.5 GHz
UWB center frequency	6.85 GHz
T-R separation	1, 5, and 10 m
Pulse width	0.28 ns
Pulse repetition time	5 ns
PPM time shift	0.188 ns
NBI frequency bands	5.15-5.25 GHz
	5.25-5.35 GHz
	5.725-5.825 GHz
NBI data rate	54 Mbps
Path loss exponent	1.73

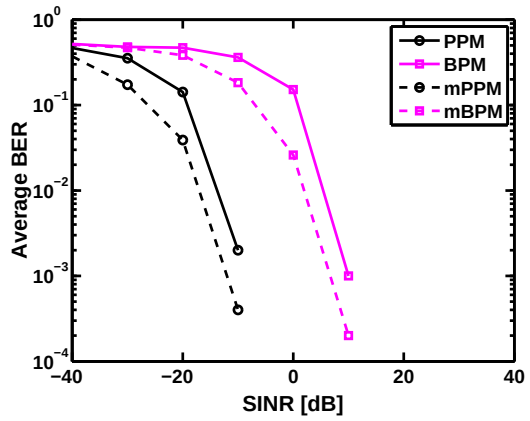
Fig. 4 shows the UWB performance of the original template waveform and the modified template waveform on the influence of the IEEE 802.11a wireless LAN interferer. The BER performance of the UWB-PPM without modified template (PPM), the UWB-BPM without modified template (BPM), the UWB-PPM modified template waveform (mPPM) and the UWB-BPM modified template waveform (mBPM) are illustrated by the cycle solid line, the square solid line, the cycle dot line and the square dot line, respectively, for the transmission rate of 200 Mbps at the three different observation points.

Fig. 4(a)-(c) show the comparison of BER performances for the observation points at 1, 5, and 10 meter, respectively. As predicted, it can be seen that the UWB correlation receiver with the modified template waveform (mBPM, mPPM) always outperform the UWB-PPM and UWB-BPM that without the modified template (BPM, PPM).

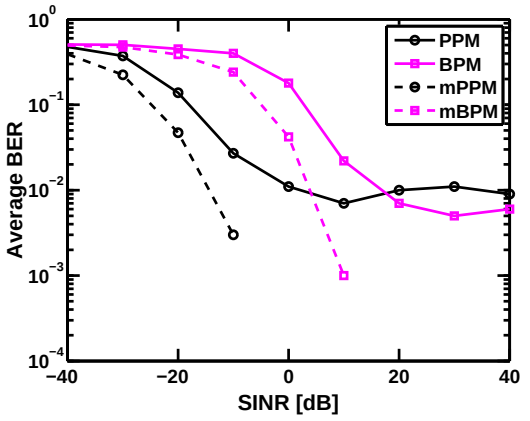
From these results, it is found that the modified template waveform performs better than the original template waveform. Therefore, this NBI suppression technique can improve the performance of UWB system. In addition, it is clearly observed that the involvement of the T-R separation distance with the average BER performance are direct variation.

IV. Conclusion

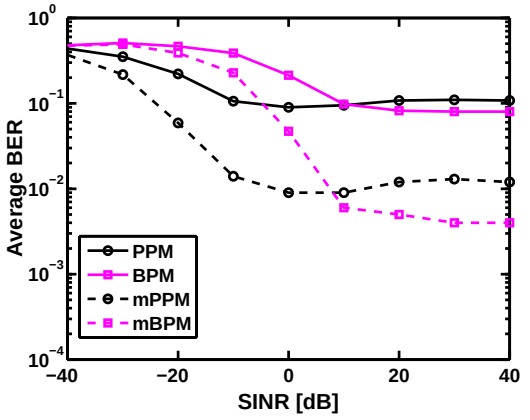
In this paper, the narrowband interference suppression technique for UWB-TH system based on modified template waveform is investigated. The system performance was characterized in term of the bit error rate. Simulation results show that the modified template waveform outperforms the original



(a) 1 m.



(b) 5 m.



(c) 10 m.

Fig. 4. Average BER vs SINR for UWB correlation receiver with the original and modified templates waveform. The T-R separation distance was set to be 1, 5, and 10 meter, respectively.

one. In addition, it is found that the BER performances of the PPM are better than the BPM in the presence of the NBI for the entire range of the SINR. Moreover, the NBI can significantly affect to the UWB correlation receiver depended on the probability of signal overlap and the T-R separation distance of the IEEE 802.11a interferer to the UWB receiver.

A Survey on Non-Coherent QAM receiver structure in Noisy Channel

Shahab Asoodeh, Alireza Rezazade
Dept. of electrical and Computer Engineering
Shahid Behehsti University
Asoodehshahab@gmail.com

Abstract- **In wireless receiver, carrier's phase derivation and mismatching of I/Q are so considerable. Recently Independent Component Analysis (ICA) has been proposed that does not need to phase estimation. But the noise of channel leads to break down of performance. In this paper, the structure of QAM receiver based on Noisy ICA is proposed with assumption of presence of channel noise. Simulations result high Signal to Interference Rejection Ratio (SIRR) especially in low Signal to Noise Ratio (SNR).**

I. INTRODUCTION

For demodulation of QAM signal, receiver needs synchronized sinusoidal with received signal. Synchronization of local oscillator can be accomplished by Phase Locked Loop (PLL) and nonlinear analog method [1] that need more number of signal's period otherwise the performance will be broken down. Also mismatching of used signals' amplitudes of demodulation in QAM receiver can lead to go down the performance [10]. In order to solve these problems Independent Component Analysis (ICA) has been applied when frequency of local oscillator and received signal are the same [3]. On the other hand, the error of ICA method will be increased when the noise of channel are assumed [7-9]. In order to reduce the effect of noise, methods have been introduced such as time signal filtering and Primary Component Analysis (PCA) [5]. Since these methods can not totally omit that, Noisy ICA (NICA) have been considered [4,5]. In this paper, the performance of NICA-based QAM receiver with the presence of noise has been studied.

II. QAM RECEIVER MODEL

The general form of received QAM signal in the time interval $kT < t < (k+1)T$ has been shown in (1).

$$r(t) = A_{mc}(k) g_T(t) \cos(w_c t) + A_{ms}(k) g_T(t) \sin(w_c t) + n(t) \quad (1)$$

Where $\{A_{mc}(k)\}$ and $\{A_{ms}(k)\}$ are the sets of used amplitudes for n-bit sequence mapping, $g_T(t)$ and w_c are the frequency response of shaping filter and angle frequency of carrier signal, respectively and finally $n(t)$ is symbol of AWGN in channel.

Received signal is summation of two PAM signals having 90° phase difference plus additive noise to both signals. Demodulator divides QAM received signal to $y(k) = [y_1(k) \quad y_2(k)]^T$ at which $y_1(k)$ and $y_2(k)$ are the estimated value of $A_{mc}(k)$ and $A_{ms}(k)$ in the time interval $kT < t < (k+1)T$. A QAM demodulator has been shown in Fig.1 [1].

For ideal *I/Q* separation in receiver, phase and frequency of local oscillator and carrier signal must be the same. Local oscillator signals in Fig.1 are considered as (2) and (3).

$$v_1 = A\cos(w_c t + \alpha) \quad (2)$$

$$v_2 = B\cos(w_s t + \beta) \quad (3)$$

Where α and β show the phase differences between received signals and local oscillator signals. Suppose that noise in (1) can be represented as (4).

$$n(t) = n_{wc}(k)\cos(w_c t) + n_{rem}(t) \quad (4)$$

Where $n_{wc}(k)$ and $n_{rem}(t)$ are the noise elements in w_c frequency and other frequencies in time interval $kT < t < (k+1)T$ .in this case $s_i(t)$ in Fig.1 can be obtained as (5).

$$\begin{aligned} s_i(t) &= \frac{1}{2} A g_T(t) A_{mc}(k)[\cos(2w_c t + \alpha) + \cos(\alpha)] \\ &+ \frac{1}{2} A g_T(t) A_{ms}(k)[\sin(2w_c t + \alpha) - \sin(\alpha)] \\ &+ \frac{1}{2} A g_T(t) n_{wc}(k)[\cos(2w_c t + \alpha) + \cos(\alpha)] \\ &+ n_{rem}(k) A g_T(t)\cos(w_c t + \alpha) \end{aligned} \quad (5)$$

Subsequently, the output of LPF can be shown as (6).

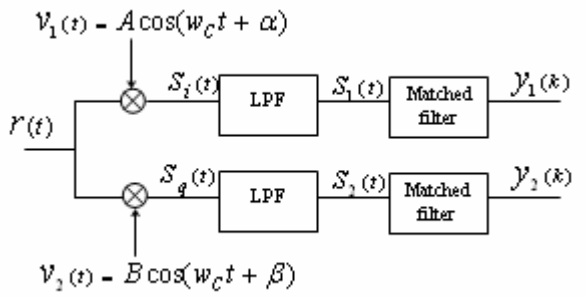

Fig. 1. Block diagram of a QAM demodulator

$$s_1(t) = \frac{1}{2}Ag_T(t)A_{mc}(k)\cos(\alpha) - \frac{1}{2}Ag_T(t)A_{ms}(k)\sin(\alpha) + \frac{1}{2}Ag_T(t)n_{wc}(k)\cos(\alpha) \quad (6)$$

And finally the sampled output of matched filter is written as (7).

$$y_1(k) = \frac{1}{2}AA_{mc}(k)E_g\cos(\alpha) - \frac{1}{2}AA_{ms}(k)E_g\sin(\alpha) + n_1(k) \quad (7)$$

Where $E_g = \int_0^T g_T^2(t)dt$ is the energy of shaping filter's frequency response and $n_1(k)$ is defined as $n_l(k) = \frac{1}{2}An_{wc}(k)E_g\cos(\alpha)$. After doing same steps for *Q*-branch and combination of both results, the output can be finally presented as follow.

$$y(k) = Ma(k) + n(k) \quad (8)$$

Where $a(k)$, $y(k)$, $n(k)$ and M are the transmitted symbols vector, match filter's output signals vector, noise vector in k[th] signaling time interval and linear transmission matrix or mixer matrix, respectively which are formulated as follow.

$$a(k) = [A_{mc}(k) \quad A_{ms}(k)]^T \quad (9)$$

$$y(k) = [y_1(k) \quad y_2(k)]^T \quad (10)$$

$$n(k) = [n_1(k) \quad n_2(k)]^T \quad (11)$$

$$M = \begin{pmatrix} A\cos(\alpha) & -A\sin(\alpha) \\ B\sin(\beta) & B\cos(\beta) \end{pmatrix} \quad (12)$$

In the above formulation for ease of calculation we suppose $E_g = 2$. These formulations show that channel noise appears in linear manner in QAM receiver and does not have any affect on mixer matrix and due to this characteristic, ICA can be used in the presence of noise [4].

III. NOISY ICA IN QAM RECEIVER

The general ICA-based structure for QAM signaling has been described in [3]. In this paper, we use the NICA (Noisy ICA) method [4] for *I/Q* separation in QAM receiver. According to (8) it can be readily shown that outputs $y_1(k)$ and $y_2(k)$ appear linearly in terms of symbol vectors and noise in the QAM receiver.

The main target of NICA process for QAM signaling is to determine the matrix W in (13) in order that $A_{mc}(k)$ and $A_{ms}(k)$ can be estimated with use of $y_1(k)$ and $y_2(k)$.

$$\hat{a}(k) = Wy(k) \quad (13)$$

Where $\hat{a}(k)$ and W are the estimated vector of $a(k)$ and estimated of reverse matrix of *A*, respectively. On the other hand, the amplitude of separated signals can not be determined in the ICA algorithm because the value of $a(k)$ and M are not definite [5,6]. This problem can be solved with the assumption of unit variance for separated signals [5]. In other words we determine the elements of matrix W in order that variances of estimated signals become unit. For QAM signaling, variances of transmitted symbols are determined in *I* and *Q* braches. This is because the QAM signals can be considered as two PAM signals modulated with orthogonal phases. If the amplitude of these signals be symmetric, variance of PAM signals will be as follow. [1]

$$\sigma_{PAM}^2 = \frac{M^2 - 1}{3} \quad (14)$$

Where M is the number of signals' amplitudes. Hence, the amplitudes of detected signals must be multiplied by $\sqrt{(M^2-1)/3}$ gained from (14). Also in order to decrease the volume of computations, it can be estimated just one row of matrix *W* or coefficient vector and another coefficient vector can be gained with augmenting 90° to first vector's phase.

To determine the NICA algorithm for QAM receiver, it has been assumed in [4] that the covariance matrix of noise is definite. Moreover, $n(k)$ in output of match filter will be white [1] and therefore its covariance matrix can be obtained from multiplication of unit matrix by noise variance which can be estimated by primitive transmitted data.

NICA algorithm includes two steps pre-process and main process. In the former, initially the average of received signals is forced to become zero and received signals are made quasi-white as follow [4].

$$\hat{y}(k) = (C - \Sigma)^{-\frac{1}{2}}y(k) \quad (15)$$

Where $C = E(yy^T)$ and $\Sigma = E(nn^T)$ are the covariance matrix of input signal and noise, respectively. According to (8), (15) can be rewritten as follow.

$$\hat{y}(k) = \boldsymbol{B}a(k) + n(k) \quad (16)$$

$$\boldsymbol{B} = (C - \Sigma)^{-\frac{1}{2}}M \quad (17)$$

In the main process, an initial *2*1*dimension vector *w* (one of the columns of matrix W^T) are placed in (18) [4] and this procedure will be done iteratively in order to reach the constant value for *w*.

$$w_{new} \leftarrow E(\hat{y}(w^T \hat{y})^3) - 3(I + \hat{\Sigma})wE((w^T \hat{y})^2) \quad (18)$$

Where

$$\hat{\Sigma} = (C - \Sigma)^{-\frac{1}{2}} \Sigma (C - \Sigma)^{-\frac{1}{2}} \quad (19)$$

As it was said, the next row of matrix *W* can be gained from addition 90° to phase of first row. Hence the transmitted symbols are estimated using (13). The NICA algorithm can be presented as Fig.2.

IV. SIMULATION AND RESULTS

In this section the performance of 16-QAM receiver based on NICA is simulated according to presented method in [3]. In this method for measurement of systems performance, Signal to Interference Rejection Ratio *(SIRR)* has been introduced which is defined as follow.

$$SIRR = \frac{1}{2}\left[\left|20\log(\frac{h_{11}}{h_{12}})\right| + \left|20\log(\frac{h_{21}}{h_{22}})\right|\right] \quad (20)$$

Where h_{ij}s are the elements of matrix $\boldsymbol{H}$ defined as follow.

$$\boldsymbol{H} = \boldsymbol{WB} \quad (21)$$

In ideal state, $\boldsymbol{B}$ will be the reverse of $\boldsymbol{W}$ and therefore $\boldsymbol{H}$ will become unit matrix, in this case *SIRR* will be indefinite. In this section, results are presented based on 1000 independent experiments and calculation of average *SIRR*. In any iteration α is the value with uniform distribution in $\left[0 \quad 2\pi\right]$ and $\beta = \alpha + \varphi$. The values of *A* and *B* are assumed 1 and $A(1-\Delta)$. Indeed, φ represent the phase difference between received signal and receiver local oscillator signals and Δ is the symbol of amplitude mismatch of *I* and *Q* branches. Results show that use of proposed NICA instead of SICA [3], *SIRR* will be increased and therefore the error due to noise will be decreased. The values of average *SIRR* are shown in the table 1 for both NICA and SICA [3]. From the results derived in *SNR=2dB* it is clear that the values of average *SIRR* for the different values of φ and Δ are constant approximately, this point shows that NICA algorithm is so robust rather phase and amplitude variety as well as SICA. In other words, receiver has the same performance for different values of phase difference between received signal and local oscillator signals. The values of *SIRR* for different *SNR* and 2000 symbols are depicted in fig.3. In simulations Δ and φ are supposed to be 0.1 and 10, respectively. From fig.3 it is evident that for a constant *SNR* the average value of *SIRR* for NICA is higher than SICA, so with use of NICA in the QAM receiver, estimated signals are much similar to transmitted signals. The average values of SIRR in terms of the number of symbols are illustrated in Fig.4. It is readily seen that the average values of *SIRR* is increased with the increase of number symbols and proposed NICA algorithm has the higher values of *SIRR* for most number of symbols. Consequently, the errors derived from the channel noise will be decreased with use of proposed NICA algorithm in non-coherent QAM receiver.

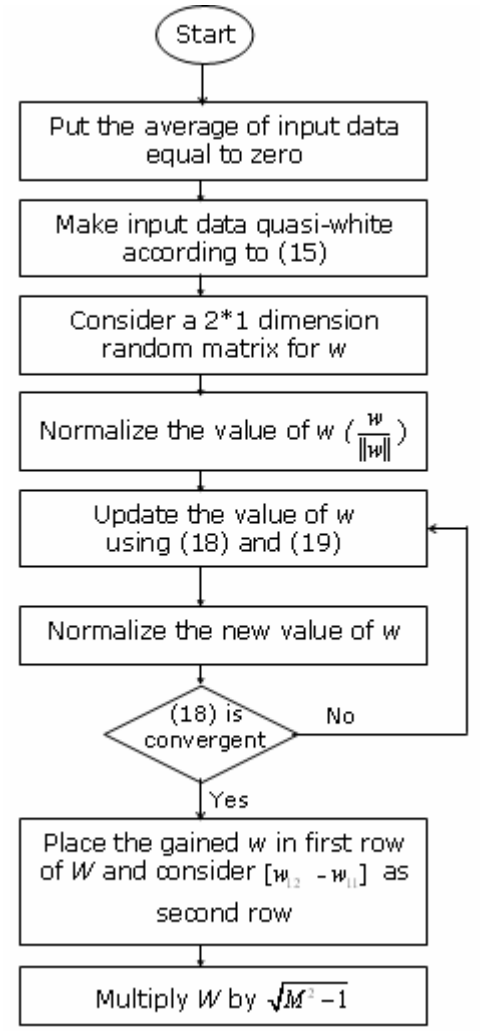

Fig. 2. Proposed NICA algorithm form QAM receiver

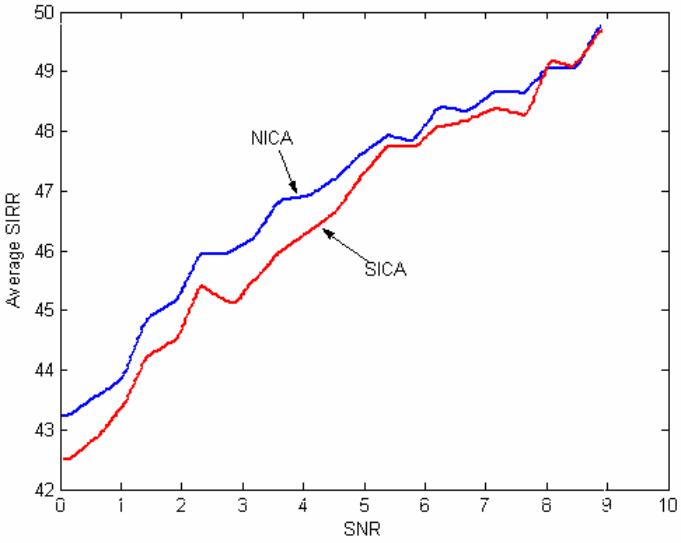

Fig.3. The average value of *SIRR* in terms of *SNR* for 2000 symbols

V. CONCLUSION

In this paper, we showed that in case of presence of channel noise in QAM receiver, the output of demodulator is the linear combination of transmitted symbols and noise. An ICA based non-coherent receiver was introduced which leads to higher values of *SIRR* especially for low *SNR* and hence is so robust against channel noise.

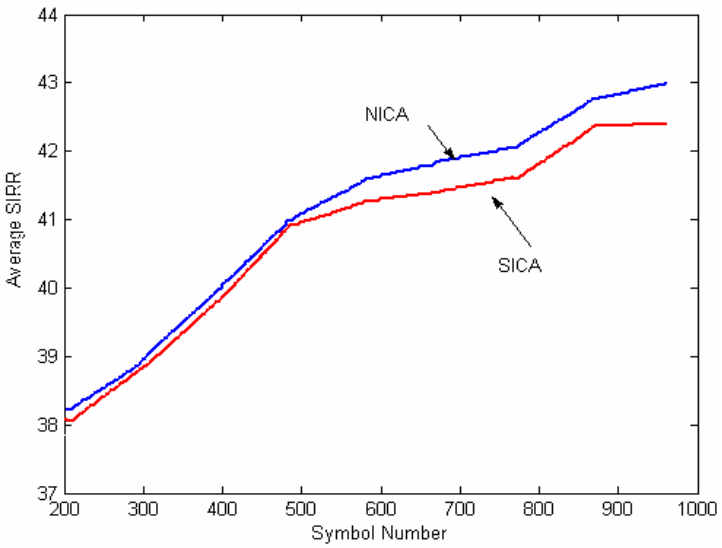

Fig.4. The average value of *SIRR* in terms of number of symbols in SNR=2dB

***Abstract*- In this paper, we propose a new transformation for orthogonal frequency division multiplexing (OFDM) systems with Harmonic transform. The main idea of our research is to improve performance of estimating a small frequency offset in a signal with a large carrier frequency. The most appealing feature of OFDM is the simplicity of the receiver design due to the efficiency of frequency offset. OFDM can cope with the effects of frequency-selective multipath channels. OFDM is more sensitive to carrier frequency offset than the one of single-carrier systems. To solve those problems, the Harmonic transform can be applied. In this paper, we evaluate the performance of our proposed system in the terms of the accuracy of estimation and computational complexity. Finally, we show the improvement of our purposed system comparing with the conventional fast-Fourier transform (FFT).**

***Keywords*-OFDM, Fourier transform, Harmonic transform**

I. INTRODUCTION

Use of wireless access to the Internet has exploded in recent years with appearance of mobile Internet access services such as wireless LAN (WLAN) systems. In the near future people will demand much higher data rate in wide coverage to transfer large data files or enjoy high quality video streaming anytime anywhere.

OFDM is well known for its sensitivity to the time and frequency offset [1], [2]. There have been several papers on the subject of synchronization for OFDM in recent year. Moose gives the maximum likelihood estimator for the carrier frequency offset which is calculated in the frequency domain after taking the FFT [3], [4], [5], [6].

In the problem of frequency offset estimation, there have been proposed in [7], [8], [9] for warped discrete Fourier transform (WDFT). It is efficient to resolve closely spaced sinusoids. Harmonic transform (HT) [10] is a new method of spectrum analysis. This paper, we use this method to transform the signal.

The rest of the paper is organized as follows. We consider the OFDM system model and problem definition in section II, while section III illustrates main idea of Harmonic transform. We develop the Harmonic transform based on OFDM in section IV. In selection V, we discuss on results for computation complexity of proposed receivers, with Fourier transform and Harmonic transform. Finally, in section VI, some conclusions are drawn.

II. OFDM SYTEM MODEL AND PROBLEM DEFINITION

A. OFDM System Model.

Firstly, we introduce some basic of OFDM : Orthogonal Frequency Division Multiplexing). The "orthogonal" part of the OFDM name indicates that there is a precise mathematical relationship between the frequencies of the carriers in the system. Fig. 1 shows the spectrum of an OFDM. The conventional OFDM signal is generated at baseband by taking the inverse fast Fourier transform (IFFT) of quadrature amplitude modulated (QAM) or phase-shift keyed (PSK). In the fig. 2, an OFDM symbol has a useful period T and proceeding each symbol is a cyclic prefix of length T_g, which is longer than the channel impulse response so that there will be no intersymbol interference (ISI) [11]. The frequencies of the complex exponentials are $f_k = k/T$,and the useful part for $2N+1$ subcarriers is given by

$$u(t) = \sum_{k=-N}^{N} c_k e^{j 2\pi f_k t} \quad , 0 \le t \le T \qquad (1)$$

A carrier frequency offset of Δf causes a phase rotation of $2\pi t\Delta f$. The carrier frequency offset is not correct a rotation of the constellation and a spread of the constellation points similar to additive white Gaussian noise (AWGN) [2].

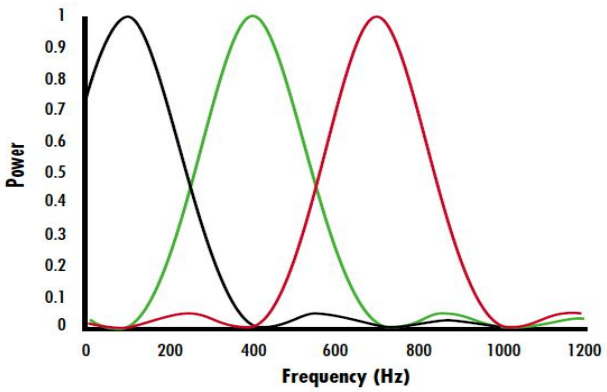

Figure 1. Spectrum frequency domain of OFDM.

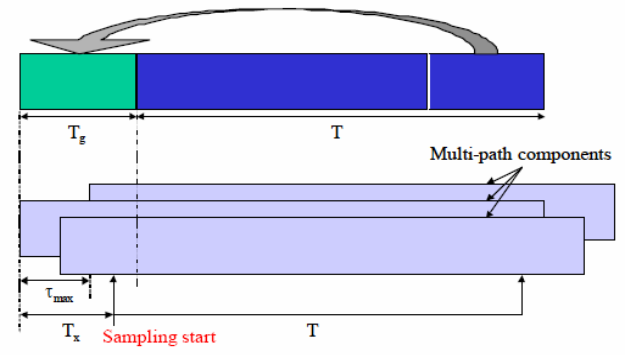

Figure 2. Multipath fading of OFDM

Figure 3 illustrates a general system overview of OFDM. At the transmitter, the signal is defined in the frequency domain. It is a sampled digital signal, and it is defined such that the discrete Fourier spectrum exists only at discrete frequencies. Each OFDM carrier corresponds to one element of discrete Fourier spectrum. The amplitudes and phases of the carriers depend on the data that is transmitted. The data transmissions are synchronized at the carriers, and can be processed together, symbol by symbol.

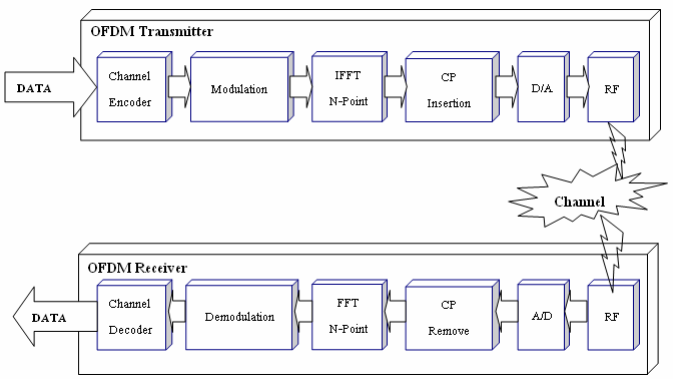

Figure 3. General system overview of OFDM.

B. Problem definition.

The main problem with reception of radio signals is fading caused by multipath propagation. Also, there are intersymbol interference (ISI), shadowing, interference. This makes link vary. As a result of the multipath propagation, there are many reflected signals, which arrive at the receiver at different time. Delayed signals are the result of reflections from terrain features such as trees, hills or mountains, or objects such as people, vehicles or buildings as shown in Fig. 2. These echoes cause ISI. The time delay of each OFDM symbol is the time-shifting property in signals, which indicates that a shift of a function in time corresponds to multiplication of the harmonic function by a complex function of harmonic number k [12]. Therefore, we use Harmonic transform to analysis the signals in OFDM symbol caused by multipath propagation.

III. HARMONIC TRANSFORM

Harmonic is a new method of spectrum analysis, which is proposed to provide an impulse-train spectrum for signals that are comprised of time-varying harmonics.

The Fourier transform (FT) represents signal $f(t)$ in term of sinusoids of various frequencies, that is defined as

$$F(\omega) = \int_{-\infty}^{+\infty} f(t) e^{-j\omega t} dt \qquad (2)$$

The original signal is recovered by the inverse Fourier transform (IFT)

$$f(t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} F(\omega) e^{-j\omega t} d\omega \qquad (3)$$

For signals consisting of fixed frequency components, the FT effectively reveals their frequency contents and is generally able to represent the signals with an acceptable resolution within a narrow band of spectra. However, this capability deteriorates quickly when the frequency components are time-varying as shown in Fig. 4

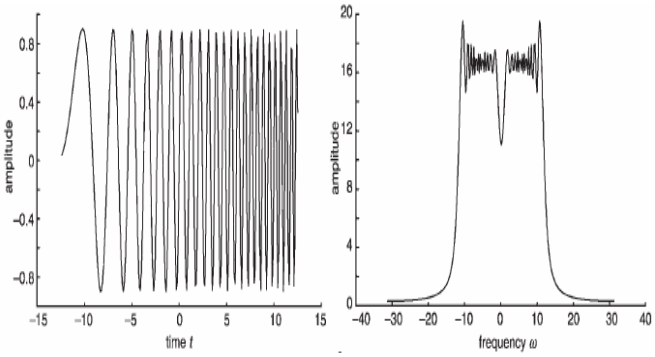

Figure 4. Fourier transforms of signals
Left: Waveforms Right: Corresponding spectra

One solution to avoid the deterioration is the warped Fourier transform, in which the signal is warped in time before calculation of the spectrum. Harmonic transform has a built-in warping function.

The time-varying harmonic signal generally contains harmonics whose nominal instantaneous frequencies are expressed by

$$c_k(t) = (k+1)c_0(t), \quad k = 1, 2, 3, \ldots \qquad (4)$$

where $c_0(t)$ is the frequency of the fundamental and $c_k(t)$ is the frequency of the kth harmonic component.

Now let us consider a time-varying harmonic signal in the time-frequency plane. For simplicity, only the nominal instantaneous frequency of the fundamental and the first two harmonics are given in Fig. 5(b). The Fourier transform of the signal, as shown in Fig. 5(c), can be treated as the linear

integration of the signal along the time axis in the time-frequency plane, which fails to distinguish the harmonic components. A better solution is to integrate the signal along the nominal instantaneous frequency of every component, rather than along the time axis, to obtain an impulse-train spectrum, as shown in Fig. 5(a). This is the basic concept of the harmonic transform (HT).

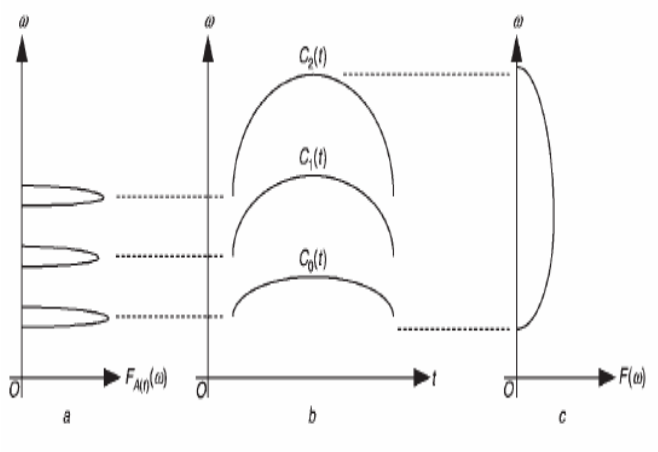

Figure 5. Concept of harmonic transform
a: Harmonic transform
b: Time-frequency representation
c: Fourier transform

The Harmonic transform of $f(t)$ is defined by

$$F_{\varphi_{u(t)}}(\omega) = \int_{-\infty}^{+\infty} f(t)\varphi_u'(t)e^{-j\omega\varphi_u t}\,dt \qquad (5)$$

where $\phi_u(t)$ is the unit phase function, which is the phase function of the fundamental divided by its nominal instantaneous frequency and $\phi'_u(t)$ is the first-order derivative of $\phi_u(t)$. The requirement for $\phi_u(t)$ is that it should be differentiable and invertible on $(-\infty, +\infty)$. HT of the signal will be scaled if the nominal instantaneous frequency of any harmonic is used. The inverse harmonic transform (IHT) is

$$F(t) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} F_{\varphi u(t)}(\omega)e^{-j\omega\varphi_u(t)}\,d\omega \qquad (6)$$

It is noted that the Harmonic transform becomes the Fourier transform when $\phi_u(t) = t$. Fig. 6 shows FT and HT of speech. Clear peaks representing the fundamental and harmonics are seen in the HT, while the same observation cannot be made from the FT.

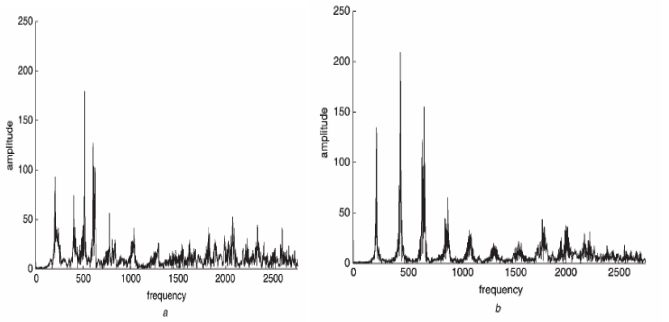

Figure 6. Transform of speech.

IV. HARMONIC TRANSFORM BASED ON OFDM

A basic diagram of an OFDM system under proposed scheme is shown in Fig.7. We consider the transformation of an OFDM system. We substitute IHT and HT into IFFT and FFT, respectively.

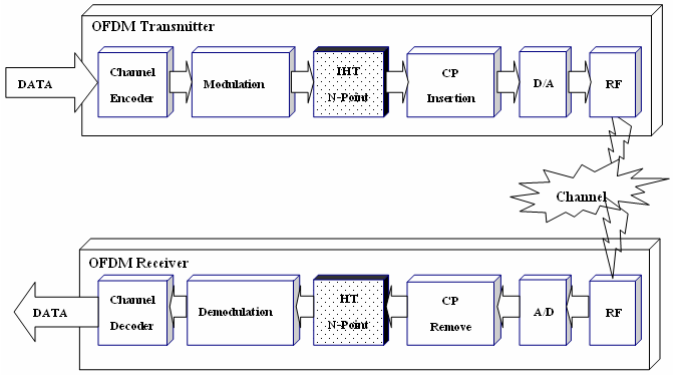

Figure 7. OFDM system based on HT.

In figure 8, we present the block diagram of channel estimation based on Harmonic transform using same pilot sequences [13] that to measure the number of multipath (NoM). While signal to interference plus noise power ratio (SINR) is used to calculate interference plus noise level (I+N level). The most important issue is that the receiver should know the number of multipath and interference plus noise level for each subcarrier to setup parameter of Harmonic transform.

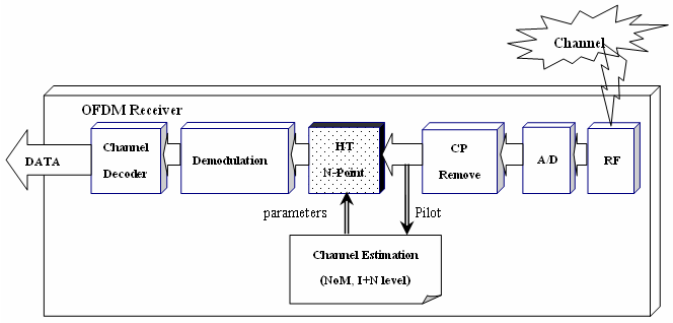

Figure 8. Block diagram of channel estimation based on HT .

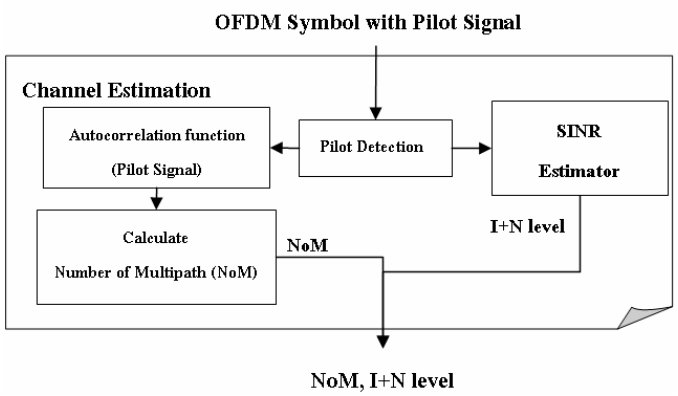

Figure 9. Procedure of channel estimation for HT.

The I+N level for each subcarrier is estimated by calculating vector error of the received symbols from the reference symbols. SINR estimator takes the average values of vector error over adjacent sub carriers.

In order to estimate channel multipath delay desired locations and interfering channels, same pilot symbols are received OFDM symbol signals from the transmitters. The Pilot detection will prepare pilot signals for next function.

First part of the algorithm is estimating number of multipath. In this method, Autocorrelation function will be used. We can calculate number of multipath by peak of pilot signals counting. The NoM will be used in Harmonic transform as a number of harmonic.

Second part of the algorithm is SINR Estimator, which estimate SINR for calculate I+N level of each subcarrier. The I+N level will be used in Harmonic transform for setup parameter of each subcarrier.

V. DISCUSSIONS

We now compare the performance of the HT with FT based on OFDM systems. The use of Fourier transform in conventional OFDM is not flexible and very sensitive to carrier frequency offset, which is much more affected by carrier frequency errors. A small frequency offset at the receiver compromises the orthogonally between the sub channels, causes a degradation in a system performance. The channel estimation after taking FFT has been researched and more complexity cause of no more information from FFT.

In the case of HT based on OFDM is the best way to achieve flexibility. It can adapt on condition of environments, when signals are very strong echoes. In bad environments, the HT will be adapted and have more efficiency. But it has more computational complexity. In other hand, good environments, the computational complexity of our proposed system similar as the conventional OFDM. Therefore, the conventional transmitter can use for our proposed scheme. It does not design any more for transmitter. However, we can reduce design and computational complexity of channel estimation after taking FFT in the conventional OFDM.

Harmonic transform based on OFDM especially in the multipath propagation, interference and fading environment is a promising technique for digital communications including mobile multimedia.

VI. CONCLUSIONS

We propose a new signal transformation using Harmonic transform based on OFDM. The main idea of our research is to improve performance of frequency offset estimation. Therefore, the receiver can reduce computational complexity after take FFT. Our proposed system is flexibility and computes on condition of environments. However, transmitter can process with the conventional OFDM. The computational complexities of transformation in receiver depend on environments. But it still has an accuracy frequency offset.

***Abstract*— The location estimation technique for UWB wireless network is very importance issue in mobility management. In this paper, the estimation accuracy based on TOA measurement for direct-calculation method is improved by using CLEAN algorithm. The performance criterias such as TOA and distance estimation errors are compared. As the simulation results, the CLEAN algorithm can increase the estimation accuracy, especially for low SNR region, more than conventional TOA measurement.**

I. INTRODUCTION

Ultra-wideband (UWB) technology has been seen as one promising solution for future short-range indoor radio communication systems. The technology offers many advantages over conventional narrowband and wide-band systems (CNWS) such as high bit rate services, low power consumption, very large capacity and accuracy positioning capabilities [1]. Because of the advantages of this technology, therefore, it was considered as the suitable wireless transmission media for IEEE WPAN working groups [2]. The Federal Communication Commission (FCC) [3] specifies that UWB has a frequency spectrum ranging from 3.1 to 10.6 GHz. The FCC defined the UWB signal as those which have a fractional bandwidth is greater than 0.20 or occupied bandwidth is equal to or greater than 500 MHz.

The radio signal is used as the key for several location estimated techniques. Time of arrival (TOA) measurement, angle of arrival (AOA) and signal strength can be used for the location estimation. The most popular method for estimating location is directly solve a set of simultaneous equations based on the time difference of arrival (TDOA). For accurate solution, this method must be obtained for x-y plane locating with 3 sensors and 2 TDOA measurements, and x-y-z plane locating with four sensors [4]. In the case of undecided system, to avoid the convergence problems, the double maximum likelihood [5] and the spherical interpolation techniques have been proposed [6]. However, the DFP quasi-Newton algorithm [7] was employed in the UWB precision assets location system [8]. The CLEAN algorithm initial used to improve radio-astronomical maps of the sky [9]. Also, it has been used in more narrow-band communication channel characterization problems [10]. Based on the advantage of the CLEAN algorithm, it can eliminate unwanted signal, such as interference and noise. In the communication system, the signal to noise ratio is reduced by several factors such as the multipath component, the long T-R separation between transmitter and receiver, and so on. These impairments lead to the higher location estimation error. Therefore, several methods are introduced to improve the estimated accuracy. Although the CLEAN algorithm is proposed for radio-astronomical maps, for the position estimation, the CLEAN algorithm can be used to eliminate unwanted signal from TOA measurements. Due to the TOA estimation error of each array sensor is not possible to completely remove the unwanted signal. Therefore, the CLEAN algorithm is involved for reducing noise in TOA measurements.

In this paper, the modified TOA measurement by using the CLEAN algorithm for position estimation based on the direct-calculation method is investigated. The channel measurements are examined in the indoor environment for the frequency ranging from 3.0 GHz to 11 GHz. The rest of paper is organized as follows. Section II presents the measurement method, measurement equipment and model under investigated. Section III briefly examines the direct-calculation method, Signal to noise ratio and summary step of the CLEAN algorithm. Section IV describes the simulation results of the modified TOA measurement by using the CLEAN algorithm, probability of TOA and distance errors and finally, the conclusion.

II. TOA MEASUREMENT METHOD

The UWB channel characterizations can be achieved by performing measurements in time domain or in frequency domain. The real-time channel measurement can only be obtained in time domain. Unfortunately, receiver noise, jitter, and synchronization are mainly degrade factors for the TOA measurement. On the other hand, when the vector network analyzer (VNA) is used, the TOAs can be obtained by performing the inverse discrete Fourier transform (IDFT) of the measured channel frequency responses.

A. Measurement Equipment

The vector network analyzer (VNA) is used as the frequency domain channel sounder. Then, the transmit and receive antennas are connected to the VNA with the double-shielded low-loss cables. The experiments were made while the transmit antenna was located in a fixed position, and the receive antenna was moved within the precisely measurement grids of 8×8

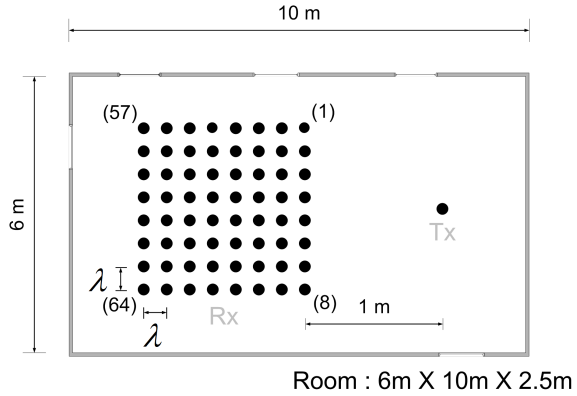

Fig. 1. Measurement model.

TABLE I
EXPERIMENT PARAMETERS.

Parameter setting	Value
Frequency Range	3.0∼11.0 GHz
Frequency Resolution	1601 points
Tx Antenna Height	1 m
Rx Antenna Height	1 m
Polarization	Vertical
T-R Separation	1∼1.3065 m

positions. The linear inter-distance of the synthesized array antenna is set to λ at the center frequency of 6.85 GHz. The 30 dB ultra-wideband and low-noise amplifier is used to compensate the loss in the cables. The biconical antennas are used to measure the UWB channel for presenting the channel characterizations with omni-directional propagation. The dynamic range for the VNA (HP 8510C) is exceeded 80 dB. Table I lists the main parameters of the experiments.

B. Measurement Location

In this experiment, the real indoor environment is investigated. Fig. 1 shows the measurement plane of the 8×8 grids of the receive antenna. The distance of the first array sensor plane and the transmitter site about 1 m. The measurement room, 10 m long, 6 m wide, and 2.5 m high, is used. The walls of the room are made of autoclaved aerated concrete internationally known as AAC, which is lighter weight than the conventional one. The ceiling and floor are made of chipboard and wood, respectively.

III. SIMULATION MODELS

In this paper, the modified UWB channel measurements in indoor environment are used to estimate the TOA and distance by using the CLEAN algorithm based on direct-calculation method. Therefore, the performance criterias such as TOA and position estimations for direct-calculation method are analyzed.

A. Direct Calculation Method

The direct-calculation method is algorithm for basic position estimation method. This method do not require knowledge of variance or distribution of the TOA estimation error and the direct-calculation method also do not require an accurate initial position estimation as described and derived in [11],

$$\sqrt{(x-x_i)^2+(y-y_i)^2} = c(t_i - t_0), \tag{1}$$

where c is the speed of light, t_i is the TOA at sensor i, t_0 is the transmit time, x, y and x_i, y_i are the coordinates of the tag and the sensor, respectively.

B. CLEAN Algorithm

Generally, CLEAN algorithm is introduced for evaluating the receiver signal of the more narrow-band communication channel. On the other hand, it also provides the advantage of array response from the actual signal for UWB communication. In this algorithm, the actual signal is called dirty signal. The steps in the CLEAN algorithm are as follows [13]:

1. Generate the dirty spectrum to the input data over a window spectrum in time.
2. Search the spectrum output window over time for the peak response.
3. Determine and store the amplitude and time of peak response.
4. Estimate the signal corresponding to the peak response and store waveform.
5. Generate the spectrum response to this estimated waveform.
6. Update the spectrum response by subtracting a gain factor of the response to the estimated signal from the previous spectrum response.

$$\mathbf{C}_n(t) = \mathbf{C}_{n-1}(t) - \gamma \widehat{\mathbf{C}}_{k,n-1}(t), \tag{2}$$

where k is an index of the largest response in $\mathbf{C}_{n-1}(t)$, $\mathbf{C}_n(t)$ is the beamformer response at the nth interation, and $\widehat{\mathbf{C}}_{k,n-1}(t)$ is the estimated response to the kth impulse at time $n-1$.

7. Add the current signal amplitude, scaled by gain factor, to the appropriate place in a list of signal location.
8. If a stopping criterion (a threshold on the signal level or residual energy) is not met, go to step 2.
9. Generate a list of the signals found, including amplitude and the time of arrival.
10. Form the CLEAN map by convolving the list of signals with delta functions.

C. SNR Calculation

The signal to noise ratio (SNR) compares the level of a desired signal (such as peak response) to the level of background noise for measuring the clarity of the signal in a transmission channel. The SNR of each array is defined as magnitude of signal between the first arrival of the channel impulse response and the average noise floor. Therefore, the SNR is given by

$$\mathbf{SNR}_{(k)}[dB] = 20\log_{10}[\frac{A(i)_k}{A_{ave}(n)_k}], \tag{3}$$

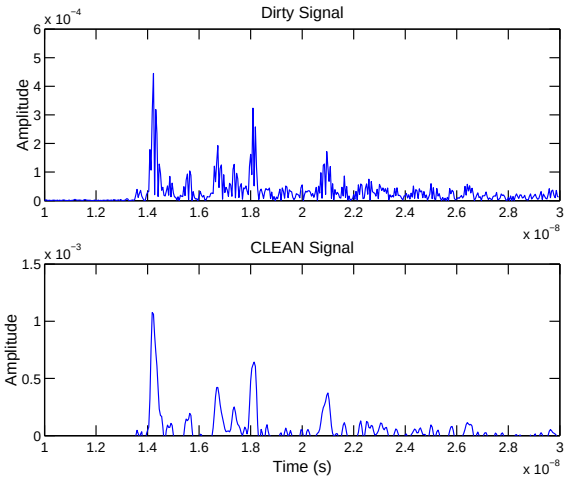

Fig. 2. The channel responses of the conventional and modified TOA measuremnts.

where $A(i)$ is the magnitude of the first arrival at the kth array, $A_{ave}(n)$ is the average noise floor at the kth array

IV. Numerical Results

The results of the channel impulse responses for the conventional and modified TOA measurements by using CLEAN algorithm are shown in Fig. 2. Consequently, the results of the SNR improvement are listed in Table. II. From Fig. 2, the impulse responses of the modified TOA measurement with the CLEAN algorithm are smoother than conventional measurement. Therefore, the TOA can simply to find more than without the CLEAN algorithm. From Table. II, shows the SNR of all arrays. The SNR of the improved TOA measurement arrays by using CLEAN algorithm are higher than the conventional one, for example the SNR at the 30th array is 33.37 dB and 38.36 dB, respectively.

For location estimation based on direct-calculation method, the distance estimated errors with and without CLEAN algorithm are shown in Fig.3. From the results, the distance error trends to increase as the distance between the transmitter and the receiver increase, both for with and without the CLEAN algorithm. For example, the distance error at the 12th array is 3.227 meter and 3.2407 meter and at the 61th array is 3.3225 meter and 3.3361 meter, respectively. The TOA and the distance errors with the CLEAN algorithm are lower than the conventional measurement.

Fig. 4 shows the distance error versus SNR (dB) for the location estimation. The SNR of the position estimation with the CLEAN algorithm is higher than without the CLEAN algorithm for all arrays. Moreover, the distance error for the location estimation with the CLEAN algorithm at the low SNR is lower than without the CLEAN algorithm. Because at the long distance, the CLEAN algorithm can improve the SNR by eliminating the unwanted signal.

V. CONCLUSIONS

In this paper, the modified TOA measurement for location estimation based on the direct-calculation method in ultra-wideband network is proposed. The CLEAN algorithm is introduced as the effective approach to eliminate the unwanted signal. The numerical results show that the TOA and distance errors trend to be linear. Therefore, the CLEAN algorithm is used to improve the estimated accuracy of the TOA estimation based on direct-calculation method. In addition, the CLEAN algorithm also provides the SNR improvement for location estimation in low SNR region.

***Abstract*— The focusing resolution is very important performance for ultra wideband (UWB) imaging system. In this paper, the accuracy of focusing resolution with time-reversal (TR) electromagnetic (EM) pulse propagation is analyzed. The TR EM pulse propagation is done via the numerical simulation of finite difference time domain (FDTD) method. The modulated Gaussian pulse is used as the UWB EM pulse. The directional error of focusing resolution at specific locations is shown. The results are discussed in the conclusion.**

I. Introduction

Recently, ultra wideband (UWB) radio technology based on the transmission of short duration pulses has gained much interest because of its low cost and low power consumption potentials [1]-[3]. Federal Communications Commission (FCC) [4] defined the UWB signal as those, which have a fractional bandwidth equal or greater than 0.20, or occupied bandwidth equal or greater than 500 MHz. The fractional and occupied bandwidth are defined as

$$\text{Fractional bandwidth} = \frac{2(f_{\mathrm{H}} - f_{\mathrm{L}})}{f_{\mathrm{H}} + f_{\mathrm{L}}}, \quad (1)$$

$$\text{Occupied bandwidth} = f_{\mathrm{H}} - f_{\mathrm{L}}, \quad (2)$$

where f_{L} and f_{H} are the lowest and highest frequencies at the -10 dB point, respectively.

The FCC established different technical standards and operating restrictions for three types of UWB devices based on their potential to cause interference. These three types of UWB devices are 1) imaging systems, 2) vehicular radar systems and 3) communications and measurement systems. The applications of UWB imaging systems include ground penetrating radar (GPR), wall, through-wall, surveillance and medical imaging systems. Furthermore, the UWB imaging systems are designated as three classes, which are low-frequency, mid-frequency and high-frequency imaging systems. The FCC spectral masks of these UWB imaging systems are shown in Fig. 1. In this paper, we focus on only high-frequency imaging system.

The focusing resolution is important performance of imaging system. There are many focusing techniques for imaging systems, such as depth-focused echo imaging [5], aperture focusing technique [6], [7] and auto-focusing algorithm [8]. The time reversal (TR) algorithm is widely used for UWB imaging system because its simplicity and high focusing resolution [9]. This TR algorithm can be directly performed by using the FDTD method [10], [11]. The use of FDTD method for TR is purposed in [12]. Although, the focusing resolution of TM ER pulse propagation is proposed [13], there is no considered about its accuracy.

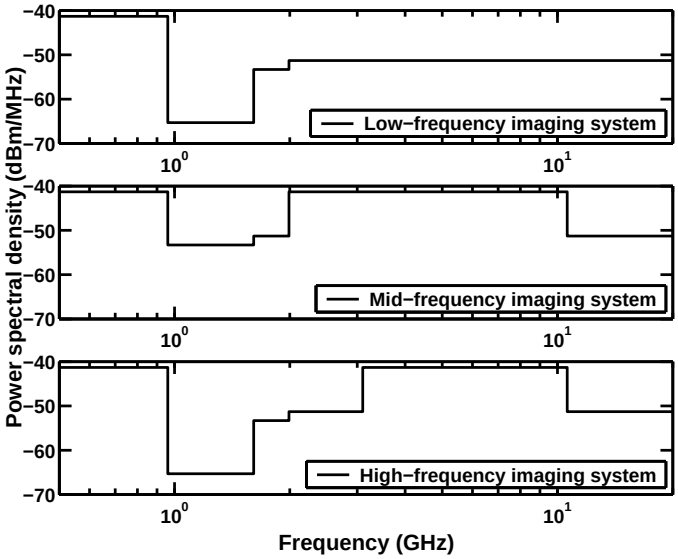

Fig. 1. FCC Spectral masks of UWB imaging systems [4]

In this paper, the accuracy of focusing resolution with TR electromagnetic (EM) pulse propagation is analyzed. The TR EM pulse propagation is done via the numerical simulation of two-dimensional (2-D) transverse magnetic (TM) mode finite difference time domain (FDTD) method. The modulated Gaussian pulse is used as the UWB EM pulse. The directional error of focusing resolution at specific locations is shown. The results are discussed in the conclusion.

The rest of this paper is organized as follows. Section 2, the FDTD method used in this paper is described. Next, the results of accuracy analysis are demonstrated in Sec. 3. Finally, the conclusions are discussed in Sec. 4.

II. FDTD METHOD

A. Conventional FDTD Algorithm

The 2-D TM mode finite difference equations are directly derived from Maxwell's curl equations in time domain. Maxwell's curl equation can be written as [14]

$$\mu\frac{\partial\vec{H}}{\partial t} = -\nabla\times\vec{E}, \tag{3}$$

$$\varepsilon\frac{\partial\vec{E}}{\partial t} = \nabla\times\vec{H}, \tag{4}$$

where H is the magnetic field, E is the electric field, μ is the magnetic permeability and ε is the electric permittivity.

To obtain discrete approximation of the continuous partial differential equations, the centered difference approximation is used on both the time and space first-order partial differences. The entire computation domain is the collection of all the unit cells. The dimensions of the unit cell along x and y directions are Δx and Δy, respectively. The node with subscript indices i and j corresponds to node number in x and y directions. The time step is indicated with the superscript index n. The time interval of each time step is Δt. After simple arrangement, the 2-D TM mode of finite difference equations are described as [10], [11]

$$H_x|_{i,j}^{n+\frac{1}{2}} = H_x|_{i,j}^{n-1/2} + \left(\frac{\Delta t}{\mu_{i,j}}\right)\left(\frac{E_z|_{i,j-\frac{1}{2}}^{n} - E_z|_{i,j+\frac{1}{2}}^{n}}{\Delta y}\right), \tag{5}$$

$$H_y|_{i,j}^{n+\frac{1}{2}} = H_y|_{i,j}^{n-1/2} + \left(\frac{\Delta t}{\mu_{i,j}}\right)\left(\frac{E_z|_{i+\frac{1}{2},j}^{n} - E_z|_{i-\frac{1}{2},j}^{n}}{\Delta x}\right), \tag{6}$$

$$E_z|_{i,j}^{n+1} = C_{\mathrm{a}}|_{i,j}E_z|_{i,j}^{n} + C_{\mathrm{b}}|_{i,j}\left(\frac{H_y|_{i+\frac{1}{2},j}^{n+\frac{1}{2}} - H_y|_{i-\frac{1}{2},j}^{n+\frac{1}{2}}}{\Delta x} + \frac{H_x|_{i,j-\frac{1}{2}}^{n+\frac{1}{2}} - H_x|_{i,j+\frac{1}{2}}^{n+\frac{1}{2}}}{\Delta y}\right), \tag{7}$$

with the electric field updating coefficients at node (i,j) are given by

$$C_{\mathrm{a}}|_{i,j} = \left(1-\frac{\sigma_{i,j}\Delta t}{2\varepsilon_{i,j}}\right)\Big/\left(1+\frac{\sigma_{i,j}\Delta t}{2\varepsilon_{i,j}}\right), \tag{8}$$

$$C_{\mathrm{b}}|_{i,j} = \left(\frac{\Delta t}{\varepsilon_{i,j}}\right)\Big/\left(1+\frac{\sigma_{i,j}\Delta t}{2\varepsilon_{i,j}}\right), \tag{9}$$

where the parameter σ is the electric conductivity.

B. TR FDTD Algorithm

To reversing the time direction, the time sequence of conventional FDTD algorithm is reversed. The EM waves, E^n and $H^{n-1/2}$, are computed form $H^{n+1/2}$ and E^n, respectively. Therefore, the 2-D TM mode of time reversal FDTD can be written as [12]

$$E_z|_{i,j}^{n} = C_{\mathrm{a}}|_{i,j}E_z|_{i,j}^{n+1} - C_{\mathrm{b}}|_{i,j}\left(\frac{H_y|_{i+\frac{1}{2},j}^{n+\frac{1}{2}} - H_y|_{i-\frac{1}{2},j}^{n+\frac{1}{2}}}{\Delta x} + \frac{H_x|_{i,j-\frac{1}{2}}^{n+\frac{1}{2}} - H_x|_{i,j+\frac{1}{2}}^{n+\frac{1}{2}}}{\Delta y}\right), \tag{10}$$

$$H_y|_{i,j}^{n-\frac{1}{2}} = H_y|_{i,j}^{n+1/2} - \left(\frac{\Delta t}{\mu_{i,j}}\right)\left(\frac{E_z|_{i+\frac{1}{2},j}^{n} - E_z|_{i-\frac{1}{2},j}^{n}}{\Delta x}\right), \tag{11}$$

$$H_x|_{i,j}^{n-\frac{1}{2}} = H_x|_{i,j}^{n+1/2} - \left(\frac{\Delta t}{\mu_{i,j}}\right)\left(\frac{E_z|_{i,j-\frac{1}{2}}^{n} - E_z|_{i,j+\frac{1}{2}}^{n}}{\Delta y}\right), \tag{12}$$

C. Numerical Stability Condition

The maximum time step is limited by the stability restriction of the finite difference equation. The numerical stability condition of 2-D FDTD is specified as [15]

$$\Delta t \le \frac{1}{c\sqrt{\frac{1}{\Delta x^2}+\frac{1}{\Delta y^2}}}, \tag{13}$$

where c is the velocity of light in free space.

In this paper, the magic time step condition is used to obtain the minimum numerical error. The magic time step condition is defined as

$$\Delta t = \frac{1}{c\sqrt{\frac{1}{\Delta x^2}+\frac{1}{\Delta y^2}}}. \tag{14}$$

D. Excitation of UWB EM Wave

The modulated Gaussian pulse is used as the UWB EM wave excitation V_{S}. The expression of this pulse is

$$V_{\mathrm{S}}|^n = Ae^{-[(n-n_0)\Delta t/d]^2}\sin[2\pi f_{\mathrm{c}}(n-n_0)\Delta t], \tag{15}$$

where A is the maximum amplitude of the envelope signal, f_{c} is the carrier frequency, d is the $1/e$ characteristic decay time and n_0 is the delayed time step.

E. PML ABC Treatment

The tangential field components on the four mesh walls must be specified in such a way that outgoing waves are not reflected. The FDTD simulation in this paper uses the perfectly matched layer adsorbing boundary condition (PML ABC) [16]. The PML ABC can effectively absorb propagation wave by using nonphysical lossy media adjacent to the outer-grid boundaries backed by perfectly conducting walls. The field components are

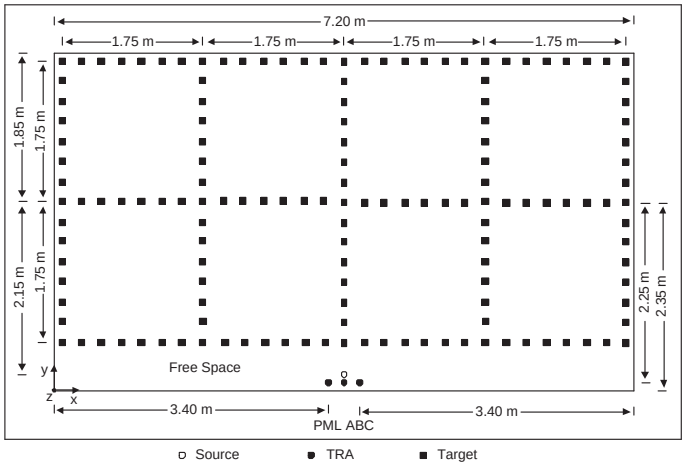

Fig. 2. Dimensions of simulation model and locations of target

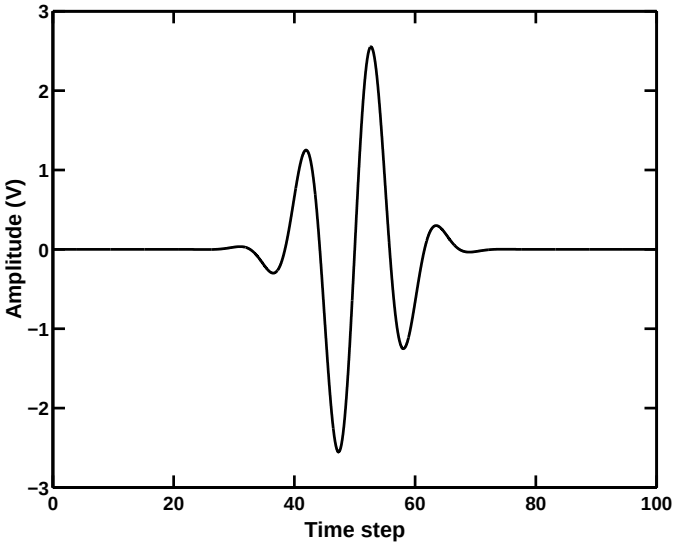

Fig. 3. Time domain waveform of UWB EM wave excitation.

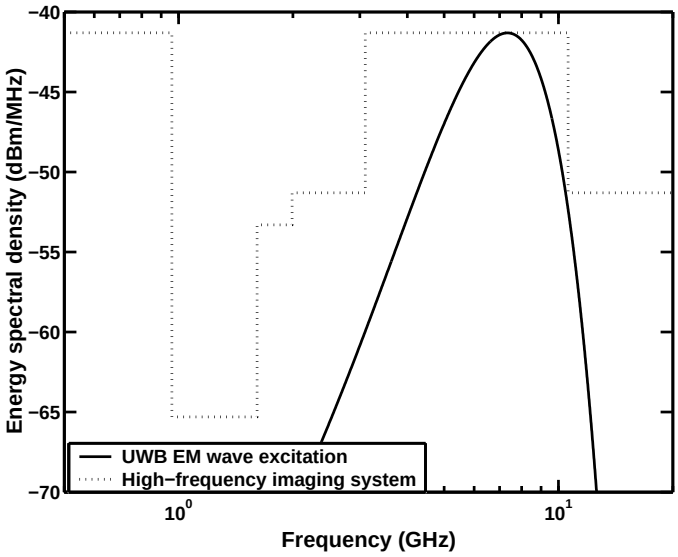

Fig. 4. Energy spectral density of UWB EM wave excitation compared with FCC spectral mask of high-frequency imaging system.

split into two subcomponents. The electric and magnetic losses, $\sigma_{\rm e}$ and $\sigma_{\rm h}$, inside the PML medium are specified by satisfying the PML impedance-matching condition

$$\frac{\sigma_{\rm e}}{\varepsilon} = \frac{\sigma_{\rm h}}{\mu}. \tag{16}$$

After the specification of electric and magnetic losses, EM waves inside the PML medium is rapidly attenuated. The explicit exponentially difference field-updating equations [11] are used to replace the conventional FDTD algorithm.

The electric loss inside the PML legion is assumed to increase with depth from zero at $\rho = 0$ to a maximum value of $\sigma_{\max}$ at $\rho = \delta$ by the quadratic ramping

$$\sigma_{\rm e}(\rho) = \sigma_{\max}\left(\frac{\rho}{\delta}\right)^2, \tag{17}$$

where $\sigma_{\max}$ is chosen to bound the PML reflection coefficient. The PML reflection coefficient at normal incident has the following expression,

$$R(0) = e^{-2\sigma_{\max}\delta/(3\varepsilon c)}. \tag{18}$$

III. Accuracy Analysis Results

The simulation model is done in free space medium with three transceivers as the TR array (TRA) and one source point. The accuracy of focusing resolution is analyzed along both horizontal and vertical axes. The dimensions of simulation model and locations of targets are shown in Fig. 2. All targets are perfect conductors and the increment of each target location along the horizontal and vertical axes is 0.25 m.

Subsequently, the 2-D TM mode of FDTD simulation is used to model this structure. The cell sizes in x and y directions are $\Delta x = \Delta y = 0.005$ m. The PML ABC with 16 layers is used to reduce the reflection error at the edges of the simulation boundaries. The dimension of total lattice is $872 \times 1,472$ cells. The time interval of each time step is $\Delta t = 11.79$ ps which is satisfied the numerical stability condition. The total time steps of this simulation is $n = 2,500$. For the UWB EM wave excitation, the parameters of modulated Gaussian pulse are $f_{\rm c} = 7.34$ GHz, $d = 0.11$ ns, $A = 2.79$ V, and $n_0 = 50$. The time domain waveform of UWB EM wave excitation and its energy spectral density are shown in Figs. 3 and 4, respectively. This waveform is well satisfied the FCC spectral mask of high-frequency imaging system.

First, the UWB EM wave source is excited by using the 2-D TM mode of conventional FDTD algorithm. The UWB EM wave propagates to each target and reflects back to the TRA. Then, each element of TRA is recorded the reflected UWB EM waves, and the directed UWB EM wave from source is eliminated. Next, the reflected UWB EM wave of each target is separated and performed the TR algorithm. The TR EM wave of each TRA element is transmitted by using the 2-D TM mode of TR FDTD algorithm. The TR EM waves focus back to each

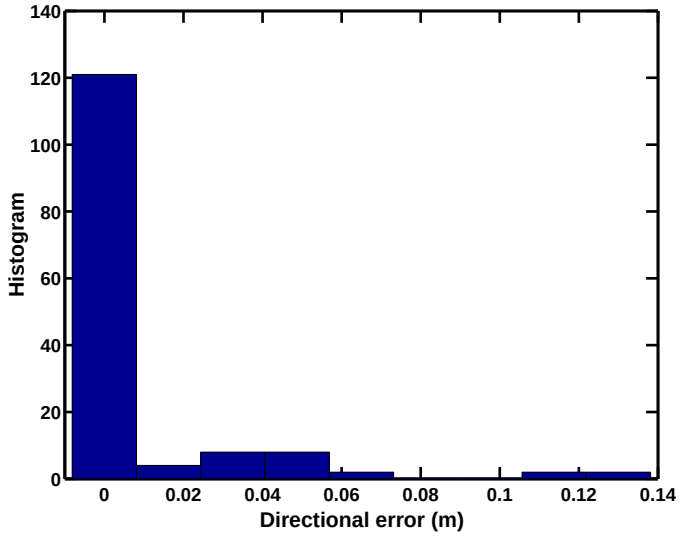

Fig. 5. Histogram of directional error.

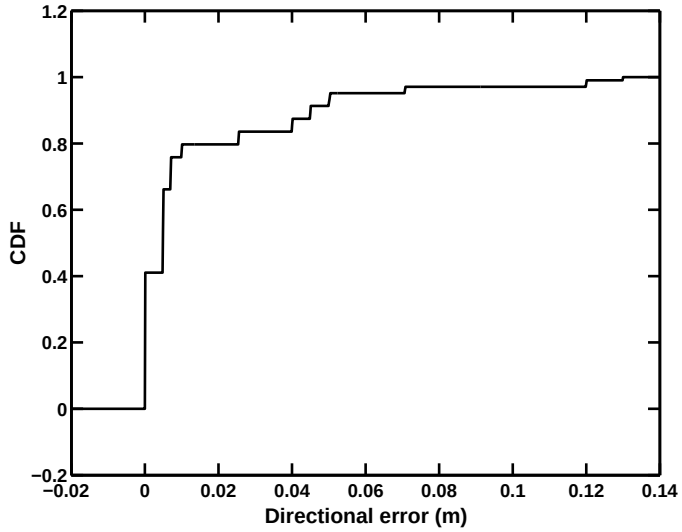

Fig. 6. CDF of directional error.

target. The accuracy of focusing resolution is considered in the terms of directional error.

The directional error e indicates the resolution accuracy of TR EM waves that focus back to the target and it can be written as

$$e = \sqrt{e_{\mathrm{x}}^2 + e_{\mathrm{y}}^2}, \tag{19}$$

where e_{x} and e_{y} are the directional error of TR EM waves that focus back to the target along the x and y directions, respectively.

The histogram and cumulative distribution function (CDF) of directional error are shown in Figs. 5 and 6 respectively. There are 26 error targets from all 147 targets, which is about 17.69 %. All directional errors are less than 0.13 m. The mean and standard deviation of directional error are only 0.01 m and 0.02 m, respectively.

IV. Conclusion

In this paper, the accuracy of focusing resolution with TR EM pulse propagation is analyzed. The TR EM pulse propagation is done via the numerical simulation of FDTD method. The directional error of all target is evaluated. The histogram and CDF of directional error are shown. From the result, there are error targets about 17.69 %. The average and standard deviation of directional error are 0.01 m and 0.02 m, respectively. In future work, the improvement of directional error by increasing the elements of TRA is investigated.

***Abstract*— An ultra wideband impulse radio (UWB-IR) is applied for short-range system such as wireless local area network (WLAN) and wireless personal area network (WPAN) on office and home networking. The characteristics of indoor propagation channel are very complicated and difficult to predict. Therefore, the performances of transmission signal shall be considered. In this paper, we discuss the performance of UWB-IR transmission signal. The template signal receiver is considered at receiver side to maximize the signal-to-noise ratio (SNR) for evaluation. The experiment results are used to evaluate the transmission signal waveform based on Friis' transmission formula. This technique gives very accurate results and is useful to design and evaluate the UWB-IR systems, especially for the performance evaluations of waveform distortion.**

I. Introduction

Today the wireless personal area networks (WPANs) are required to have high data rate, low power consumption and low cost. The ultra wideband impulse radio (UWB-IR) technology is an ideal candidate focusing on WPAN.

Federal Communications Commission (FCC) is currently working on setting emission limits that would allow UWB-IR communication systems to be deployed on an unlicensed band following the part 15 rules for radiated emissions of intentional radiators [1].The frequency range of UWB-IR signal for wireless communications is from 3.1 GHz to 10.6 GHz. The UWB-IR transmitter sends pulses with ultra high bandwidth and the UWB-IR receiver collects the power of received signal for rebuilding the pulses. Since the power spectral density (PSD) level of UWB-IR signal may be below the noise level of other systems, UWB-IR technology can exist with other RF technology without interference.

The antennas of UWB-IR communication systems are significantly pulse-shaping filters. Any distortion of the signal in the frequency domain causes the distortion of the transmitting pulse shape. Consequently, this will increase the complexity of the detection mechanism at the receiver [2]. Moreover, low cost, geometrically small and still efficient structures are required for typical wireless applications. Therefore, the antenna design for UWB-IR signal radiation is the one of main challenges [3].

Even if the channel is in line-of-sight (LOS), Friis' transmission formula cannot be directly applied to the UWB-IR system as the bandwidth of the pulse is extremely wide. Furthermore, simple comparison between the waveforms of transmitter and receiver is not significant because of the distortion of the waveform caused by the frequency response of the antenna.

In this paper, we discuss the free space transmission waveform evaluation scheme for UWB-IR systems. This scheme is based on the Friis' transmission formula, adapted for UWB-IR. The transmitted waveform and the receiver template waveform are keys for the extension of Friis' transmission formula to UWB system. An experiment is carried out using two types of broadband antennas for UWB operation in an indoor environment.

II. Ultra Wideband Thoery

In this study, we focus on the performance evaluation for UWB-IR system in free space.

A. Extension of Friis' Transmission Formula for UWB transmission System

UWB-IR transmission systems have attracted a great deal of attention because of its potential applications on short-range, high-speed, and low-power wireless communications. In order to minimize the interference with existing systems, UWB is expected to be mainly used in indoor wideband environments.

In narrowband systems, the link budget of the free space propagation loss is usually estimated by using Friis' transmission formula [4]. However, it is not directly applicable to the UWB impulse radio transmission system, as the formula is expressed as a function of the frequency. Moreover, the waveform may be distorted due to the frequency characteristics of the antenna. [5] treats the special cases of the constant gain and the constant aperture, but no general discussion had been made although it suggested the use of the time-domain antenna effective length.

The Friis' transmission formula has been widely used, and can be applied to the calculation of these LOS channels.

$$G_{\text{Friis}}(f) = \frac{P_{\text{r}}(f)}{P_{\text{t}}(f)} = G_{\text{f}}(f) G_{\text{r}}(f) G_{\text{t}}(f), \tag{1}$$

where G_{r} and G_{t} are Rx and Tx antenna gain,

$$G_{\text{f}}(f) = \left(\frac{\lambda}{4\pi d}\right)^2 \tag{2}$$

is the free space propagation gain (less than unity in practice), $\lambda = \frac{c}{f}$ is the wavelength, c is the velocity of the light, f

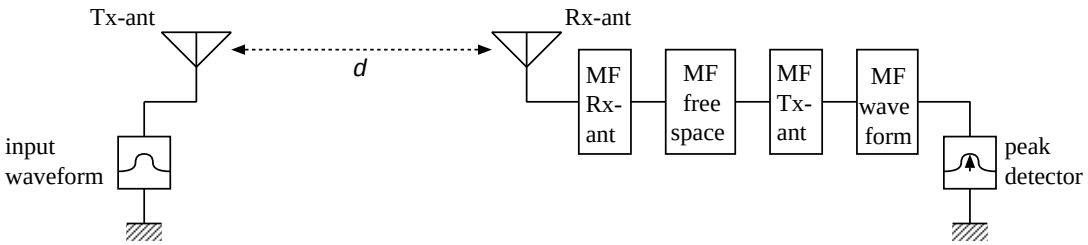

Fig. 1. Block diagram of transmission system for UWB-IR signal.

is the operating frequency, and d is the separation between transmitter and receiver antennas.

It is noted, however, that Eq. (1) is satisfied only at some certain frequency, and is not directly applicable to UWB systems. The Friis' transmission formula shall be extended to take into account the transmission signal waveform and its distortion as well [6], [7].

Input signal $v_{\rm i}(t)$ at the transmitter port is expressed as the convolution of an impulse input and the pulse shaping filter $h_{\rm i}(t)$ as

$$v_{\rm i}(t) = E_{\rm i}\delta(t) * h_{\rm i}(t), \tag{3}$$

where

$$\int_{-\infty}^{\infty} h_{\rm i}^2(t){\rm d}t = \int_{-\infty}^{\infty} |H_{\rm i}(f)|^2\,{\rm d}f = 1. \tag{4}$$

Friis' formula is extended taking into account the transmission waveform as

$$H_{\text{e-Friis}}(f) = \frac{V_{\rm r}(f)}{E_{\rm i}} = H_{\rm f}H_{\rm i}\mathbf{H}_{\rm r}\cdot\mathbf{H}_{\rm t}, \tag{5}$$

where

$$\begin{aligned}\mathbf{H}_a &= \mathbf{H}_a(\theta_a,\ \varphi_a,\ f)\\ &= \hat{\boldsymbol{\theta}}_a H_{a\theta}(\theta_a,\ \varphi_a,\ f) + \hat{\boldsymbol{\varphi}}_a H_{a\varphi}(\theta_a,\ \varphi_a,\ f), \quad (6)\\ a &= \text{r } \textit{or } \text{t},\end{aligned}$$

is a complex transfer function vector of the antenna relative to the isotropic antenna,

$$H_{\rm f} = \frac{\lambda}{4\pi d}\exp(-{\rm j}kd), \tag{7}$$

is the free space transfer function where

$$k = \frac{2\pi}{\lambda}, \tag{8}$$

is the propagation constant. Unit vectors $\hat{\boldsymbol{\theta}}_{\rm a}$, $\hat{\boldsymbol{\varphi}}_{\rm a}$ express the polarization and are defined with respect to the local polar coordinates of each of the antennas. The following relations can be easily derived.

$$\hat{\boldsymbol{\theta}}_{\rm r} = \hat{\boldsymbol{\theta}}_{\rm t}, \tag{9}$$

$$\hat{\boldsymbol{\varphi}}_{\rm r} = -\hat{\boldsymbol{\varphi}}_{\rm t}. \tag{10}$$

At the receiver, the matched filter $H_{\rm MF}(f)$ is introduced to maximize the signal-to-noise ratio (SNR) of the receiver output, as shown in Figure 1.

$$H_{\rm MF}(f) = \frac{H^*_{\text{e-Friis}}(f)}{\sqrt{\displaystyle\int_{-\infty}^{\infty} |H_{\text{e-Friis}}(f)|^2\,{\rm d}f}}, \tag{11}$$

which satisfies the following constant noise output power condition

$$\int_{-\infty}^{\infty} |H_{\rm MF}(f)|^2\,{\rm d}f = 1. \tag{12}$$

In this case, the output waveform when $E_{\rm i} = 1$, and the spectrum of the receiver output are $h_{\text{e-Friis}}(t)$ and $H_{\text{e-Friis}}(f)$, respectively. The waveform of the output from the matched filter $v_{\rm MF}(t)$ and the spectrum of the output from the matched filter $V_{\rm MF}(f)$ are

$$\begin{aligned}v_{\rm MF}(t) &= h_{\text{e-Friis}}(t) * h_{\rm MF}(t)\\ &= \frac{h_{\text{e-Friis}}(t) * h_{\text{e-Friis}}(-t)}{\sqrt{\displaystyle\int_{-\infty}^{\infty} h^2_{\text{e-Friis}}(t){\rm d}t}}, \quad (13)\end{aligned}$$

$$\begin{aligned}V_{\rm MF}(f) &= H_{\text{e-Friis}}(f)H_{\rm MF}(f)\\ &= \frac{|H_{\text{e-Friis}}(f)|^2}{\sqrt{\displaystyle\int_{-\infty}^{\infty} |H_{\text{e-Friis}}(f)|^2\,{\rm d}f}}, \quad (14)\end{aligned}$$

taking its maximum as

$$\begin{aligned}\max_t v_{\rm MF}(t) &= \int_{-\infty}^{\infty} V_{\rm MF}(f){\rm d}f\\ &= \sqrt{\int_{-\infty}^{\infty} |H_{\text{e-Friis}}(f)|^2\,{\rm d}f}. \quad (15)\end{aligned}$$

Equation (15) is the UWB extension of Friis' transmission formula. It includes three elements, namely the frequency characteristics of the antennas, the frequency characteristics of free space propagation, and the spectrum of the transmit signal. It is clear from Eq. (15) that the transmission gain of the UWB signal can not be defined as the product of gains of antennas and a free space channel as Friis' formula (1). Instead, the total transmission gain including the effect of the waveform can be obtained as Eq. (15). For the normalization, the reference isotropic antenna with $H_{\rm Iso}(f) = 1$ is considered. The UWB transmission gain can be defined as

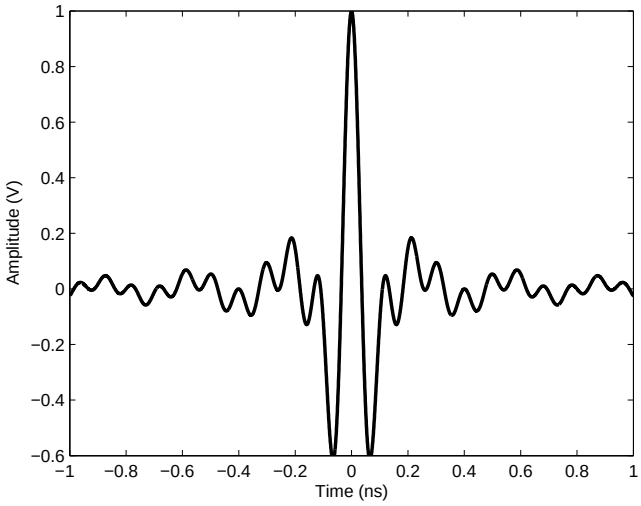

Fig. 2. The transmission waveform of UWB-IR signal.

$$G_{\mathrm{UWB}} = \max_{t} v_{\mathrm{MF}}(t) / \max_{t} v_{\mathrm{MF,Iso}}(t). \qquad (16)$$

III. Measurement Systems

A. UWB Signal Model

The rectangular density spectral waveform covering the FCC band [8], i.e., that is 3.1 GHz $\backsim$ 10.6 GHz is used to test the distortion of the received UWB waveform.The UWB transmission signal is set in the full UWB spectrum bandwidth. The minimum and maximum frequencies are $f_{\min}$ = 3.1 GHz and $f_{\max}$ = 10.6 GHz, respectively. The spectral bandwidth is f_{b} = 7.5 GHz and equation is

$$v_{\mathrm{t}}(t) = \frac{1}{\mathrm{f_b}}[f_{\max}\mathrm{sinc}(2f_{\max}t) - f_{\min}\mathrm{sinc}(2f_{\min}t)] \qquad (17)$$

where $f_{\min}$ = 3.1 GHz, $f_{\max}$ = 10.6 GHz, f_{b} = $f_{\max} - f_{\min}$ and $\mathrm{sinc(x)} = \sin(\pi x)/(\pi x)$. This signal waveform in time domain is shown in Fig. 2.

B. Experimental Setup and Measurement Model

The vector network analyzer (VNA) was operated in the response measurement mode, where Port-1 was the transmitter port (Tx) and Port-2 was the receiver port (Rx), respectively. The Tx antenna is a Biconical antennas with the maximum diameter of 65.3 mm and the length of 37 mm used as the standard antennas [9]. The Rx antenna is a commerial, small-size , low profile antenna developed by Skycross Lnc.,(USA) [10] used as the AUT. The measurement was done in the meeting room at Department of Information Engineering (KMITL). Tx and Rx antenna are fixed on labtop computer at the height of 1.40 m from ground. Rx antenna is separated at a distance of 1.43 m.

It is noted that the calibration is done at the connectors of the cables to be connected to the antennas. Therefore, all the impairments of the antenna characteristics are included in the measured results. The setup is sketched in Fig. 3.

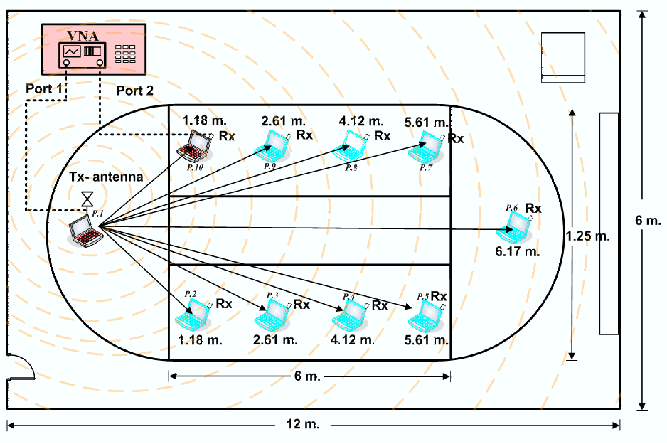

Fig. 3. The measurement model setup.

TABLE I
Experimental Setup Parameters.

Parameter	Value
Frequency range	3 GHz to 11 GHz
Number of frequency points	801
Dynamic power range	80 dB
Tx antenna height	1.40 m
Rx antenna height	1.40 m
Distance between Tx and Rx	1.18 to 6.17 m

C. Parameters of Experiment and Calibration Techniques

The important parameters for the experiments are listed in Table I.

IV. Results and Discussion

From the results of experiment by using the VNA. The data measured shows that BER of signal will be considered in two part are effect from opening and closing laptop computer.

Fig.4. shows BER performance of correlation receiver for UWB-IR with laptop computer (open). The transmitted rate has increasing BER when SNR has risen in every points of observation. Moreover, in the 2^{nd} position (P.2) has the minimum BER because of the distance that is too close (1 m). However, in the 6^{th} position (P.6) has the maximum BER because the received antenna is too far (6.17 m).

Fig.5. shows BER performance of correlation receiver for UWB-IR with laptop computer (closed). From analytical result, transmitted rate has decreasing BER when SNR has risen in every points of observation. Moreover, in the 2^{nd} position (P.2) has the minimum BER and the 6^{th} position (P.6) has the maximum BER, respectively. In the same way of laptop computer (open) case.

V. Conclusion

In this paper, we discuss the performance evaluation of free space transmission gain with laptop computer for UWB-IR, which comparison between opening and closing laptop

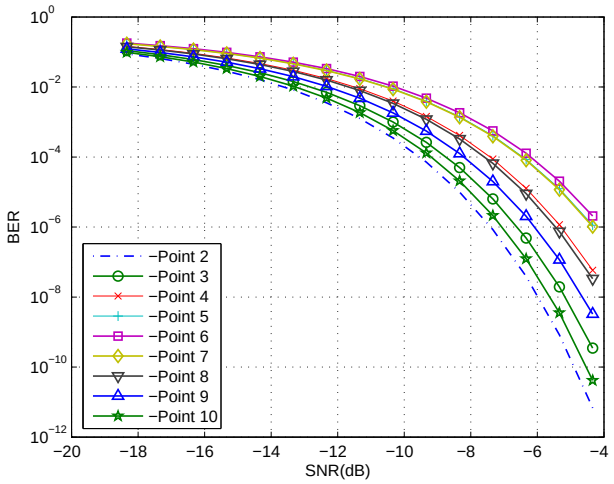

Fig. 4. BER performance of correlation receiver for UWB impulse radio with laptop computer : open.

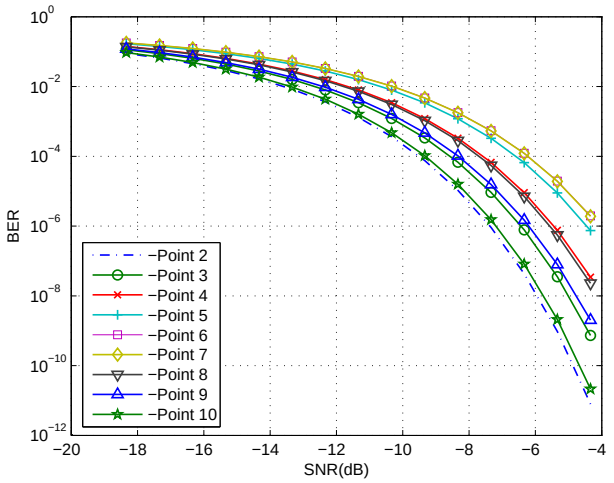

Fig. 5. BER performance of correlation receiver for UWB impulse radio with laptop computer : closed.

computer. Every points of investigation express a BER of an opening part is more increasing than close one. Obviously, BER varies to distance between transmitted and received antenna and setting position of antenna.

Abstract- **In this paper, we present a new Coplanar Waveguide-fed elliptical loop slot antenna for ultra-wideband applications. This antenna consists of a 50 Ω coplanar waveguide feeding line. Proper parametric results of an optimal structure with a bandwidth of 146.26 % are thus achieved. Experimental investigations are also presented and the obtained results confirm high antenna performances.**

I. INTRODUCTION

Ultra-wideband technology has experienced a blooming growth in the past few years and has become the most promising candidate for future short rang high-speed indoor data communications. In 2002, the U.S. Federal Communication commission officially allocated the spectrum from 3.1-10.6 GHz for unlicensed UWB communication application, which meets the 802.15.3 protocal requirements. The interest of the Coplanar Waveguide (CPW)-fed slot antennas has been increasingly studied in recent years. CPW-fed antennas also have many attractive features including low radiation loss, less dispersion, easy integration for monolithic microwave integrated circuits (MMIC) and simple configuration with a single metallic layer, since no backside processing (via holes) is required for integration of devices, thus the designs of these antennas have recently become more and more attractive. One of the main issues with CPW-fed slot antennas is to provide an easy impedance matching to the CPW line. In order to obtain broadband CPW-fed slot antennas, several impedance tuning techniques have been reported in literatures based on a change of slot dimensions in bow-tie slot [1]-[3], a square slot fed by a CPW [4]-[5] and CPW-fed equilateral hexagonal slot [6]. However, up to now the CPW-fed slot antenas designed by using these techniques have impedance bandwidths generally less than 60-110 %. In this paper, an alternative method for proposed radiator is an Ultra-wideband CPW-fed elliptical loop slot antenna that requires an additional stub for input impedance matching and offers more wide bandwidth. The antenna consists of a circular CPW stub surrounded by a slot elliptical loop. For designing, a widened tuning stub is used, and the parameters of the location and size of the tuning stub can control the coupling between the CPW-fed line and the radiating loop slot leading to large bandwidth of 146.26 %. In this study several designs are experimentally investigated, and the characteristics of input impedance radiation pattern are analyzed and discussed.

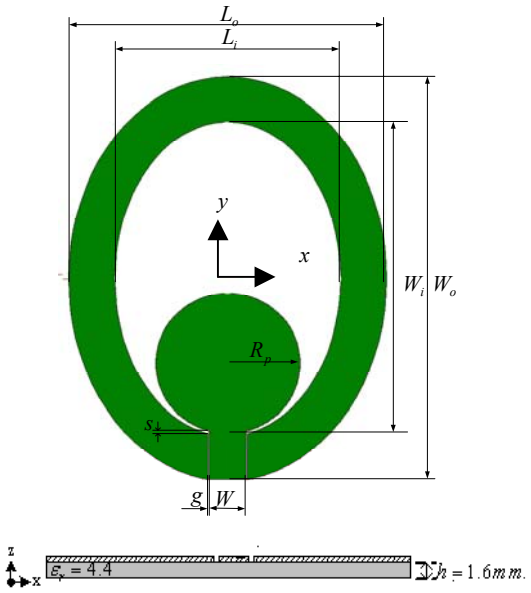

Figure 1. Geometry of the proposed CPW-fed elliptical loop slot antenna.

II. ANTENNA DESCRIPTION

The geometry of the propose CPW-fed elliptical loop slot antenna is shown in Fig. 1. The proposed antenna is farbricated on an inexpensive FR-4 substrate with thickness (h) of 1.6 mm and relatively permittivity (ε_r) of 4.4. The printed elliptical loop radiating slot has a side width of W_o, W_i and a length of L_o, L_i. A 50Ω CPW has a signal strip of width W and a gap of the spacing g between the signal strip and the coplanar ground plane. The widened tuning stub with circular tuning stub in the elliptical loop slot has a side radius of R_p. The spacing between the tuning stub and edge of the ground plane is S. The antenna geometric parameters are designed and optimized using IE3D resulting in W_o = 72 mm, W_i = 56 mm, L_o = 55 mm, L_i = 39 mm, W = 6.37 mm and g = 0.5 mm. Thus, six parameters of adjusting include W_o, W_i, L_o, L_i, R_p and S. The overall antenna size is thus 72 × 55 mm^2, therefore, the details of the design, simulation and measurement will be described in following sections.

III. PARAMETER STUDY AND IMPLEMENTATION

A. *Elliptical loop slot*

First, a CPW–fed line is designed with the strip width W = 6.37 mm and gap with g of 0.5 mm, corresponding to the characteristic impedance of 50 Ω. Simulation has been carried out by using IE3D. The proposed design can be futher enchanced by adjusting parameters of elliptical loop slot width (W_o, W_i) and (L_o, L_i) Fig. 2 shows the simulated return losses for different elliptical slots (W_o = 72,79,89,93 and 100 mm).

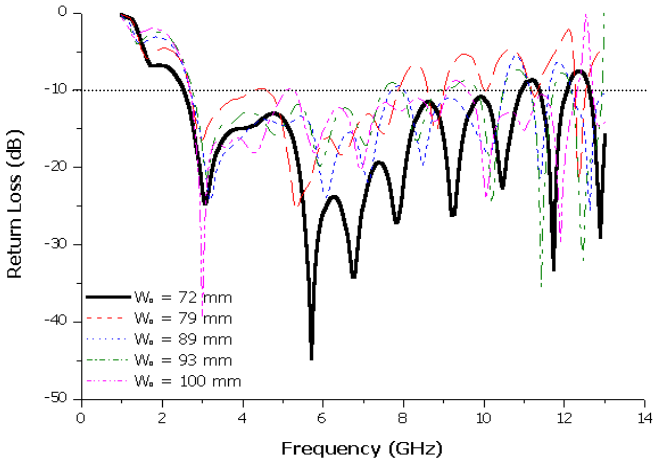

Figure 2. Simulated return losses for the different width (W_o) elliptical slot with W_i = 56 mm, L_o = 55 mm, L_i = 39mm, W = 6.37 mm, R_p = 12.5 mm and S = 0.5 mm.

The results, when W_o is chosen in a rang of about 72 to 100 mm, obtain much enhanced impedance bandwidth (also see Table 1). It can be observed that the return losses for the case of W_o =72 to 100 mm, all frequencies between and in the much higher resonant modes have a return loss larger than 10 dB. The maximum impedance bandwidth is obtained to be as large as 10.67 GHz or about 140.21 % of the center frequency, which is at 7.61 GHz. Fig. 3 shows the simulated return losses for different elliptical slots (W_i = 56,57,58,59 and 60 mm).

Table 1 : Performance of the proposed CPW-fed elliptical loop with various tuning W_o

	W_o (mm)	f_c (MHz)	BW (%,GHz)
Antenna1	72	7.61	140.21,10.67
Antenna2	79	3.41/6.25	41.28,1.41/51.68,3.23
Antenna3	89	5.17	95.74,4.95
Antenna4	93	3.58/6.46	52.23,1.87/36.06,2.33
Antenna5	100	3.88/7.15	59.27,2.30/53.00,3.79

It can be seen that the maximum impedance bandwidth (also see Table 2) is as large as 10.67 GHz or about 67.2 % of the center frequency, which is at about 7.61GHz. The optimized antenna dimension of W_o = 72 mm and W_i = 56 mm.

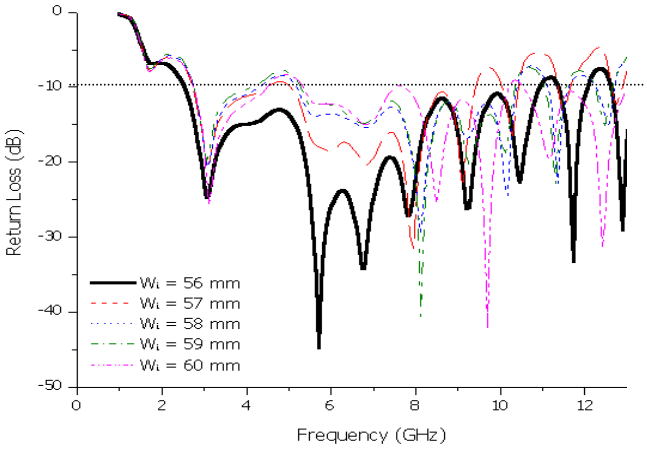

Figure 3. Simulated return losses for the different width (W_i) elliptical slot with W_o = 72 mm, L_o = 55 mm, L_i = 39 mm, W = 6.37 mm, R_p = 12.5 mm and S = 0.5 mm.

Fig. 4 Shows the simulated return losses for different elliptical slots (L_o = 55,62,69,76 and 83 mm). The results, when L_o is chosen in the rang of about 55 to 83 mm, obtain much enchanced impedance bandwidth (also see Table 3). Fig. 5 shows the simulated return losses for different elliptical slots (L_i = 39,40,41,42 and 43 mm). It can be seen that the maximum bandwidth (also see Table 4) is as large as 10.67 GHz.

Table 2 : Performance of the proposed CPW-fed elliptical loop with various tuning W_i

	W_i (mm)	f_c (MHz)	BW (%,GHz)
Antenna1	56	7.61	140.21,10.67

Antenna5	83	3.29	45.28,1.49

B. Circular tuning stub

The simulated return losses for various tuning stub radius shown in Fig. 6. In this case, the optimal tuning stub is obtained by varying R_p. Many prototypes (antennas 1 to 5) have been simulated and their designed parameters and performances are listed in Table 5 for comparision.

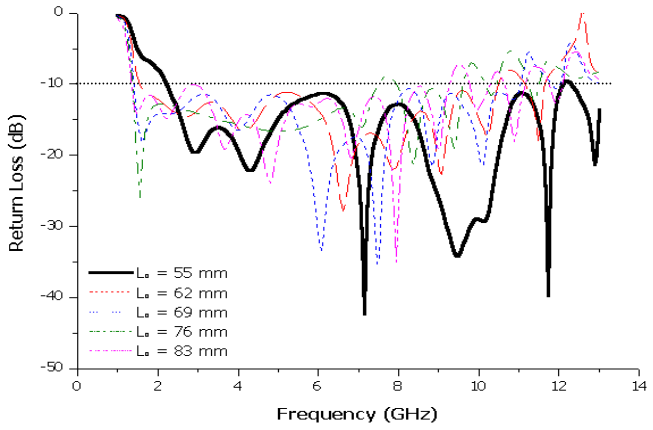

Figure 4. Simulated return losses for the different width (L_o) elliptical slot with W_o = 72 mm, W_i = 56 mm, L_i = 39 mm, W = 6.37mm, R_p =12.5 mm and S= 0.5 mm.

Table 4: Performance of the proposed CPW-fed elliptical loop with various tuning L_i

	L_i (mm)	f_c (MHz)	BW (%,GHz)
Antenna1	39	7.64	140.21,10.67
Antenna2	40	3.64/4.28	48.90,1.74/99.06,4.24
Antenna3	41	3.42/7.19	49.58,1.80/69.49,5.40
Antenna4	42	3.44/7.00	48.75,1.76/60.85,4.43
Antenna5	43	3.29	112.87,6.84

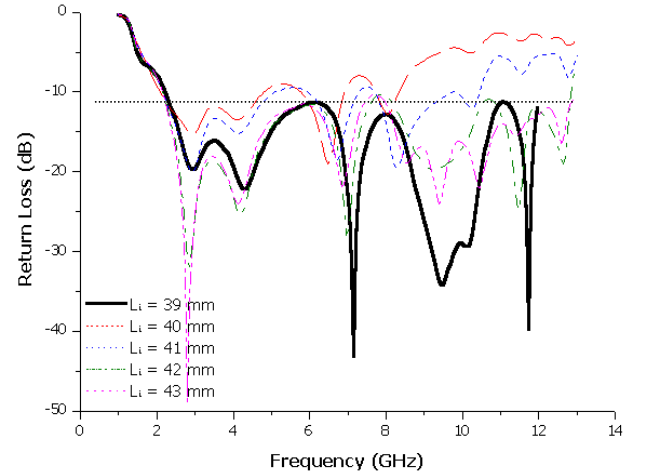

Figure 5. Simulated return losses for the different width (L_i) elliptical slot with W_o = 72 mm, W_i = 56 mm, L_o = 55 mm, W = 6.37 mm, R_p = 12.5 mm and S = 0.5 mm.

The width of W_o is fixed to be 72 mm, W_i = 56 mm and S = 0.5 mm. and the length of L_o is fixed to be 55 mm, L_i = 39 mm and S = 0.5 mm for antenna 1 to 6 in Table 5, which R_p is varied to be 10.5,11.5,12.5,13.5 and 14.5 mm. It is noted that an impedance bandwidth larger than 111 % can be obtained when R_p is chosen in a rang from 11.5 to 13.5 mm. The results also show that the radius of R_p has a significant effect on the impedance bandwidth of a CPW. When a radius of stub is selected, this new resonant mode (higher frequency) can be shifted. Finally, The proposed antenna has been constructed as shown in Fig. 7, and then tested using a calibrated vector network analyzer. Measured result of S_{11} compared with simulation is shown in Fig. 8. We can see a very good agreement of the measurement and simulation results.

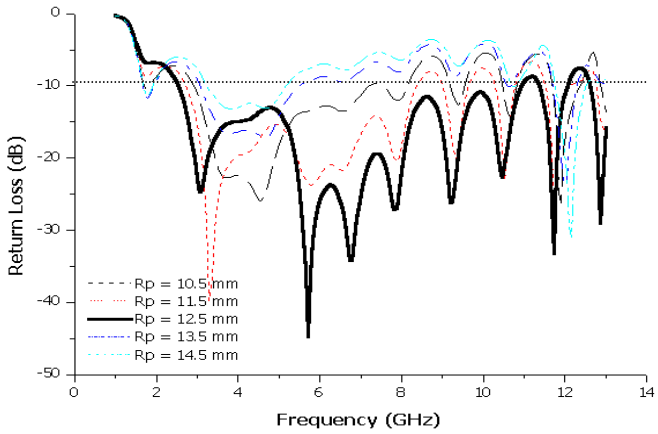

Figure 6. Simulated return losses for the different width (R_p) elliptical slot with W_o = 72 mm, W_i = 56 mm, L_o = 55 mm, W = 6.37 mm, L_i = 39 mm and S = 0.5mm.

Far-field radiation patterns of the proposed antenna with the largest operating bandwidth using the designed parameters of W_o = 72 mm, W_i = 56 mm, L_o = 55mm, L_i = 55 mm W = 6.37 mm, R_p = 12.5 mm and S = 0.5 mm have been then measured.

Table 5: Performance of the proposed CPW-fed elliptical loop with various tuning R_p

	R_p (mm)	f_c (MHz)	BW (%,GHz)
Antenna1	10.5	6.29	111.44,7.01
Antenna2	11.5	6.69	118.53,7.93
Antenna3	12.5	7.61	140.21,10.67
Antenna4	13.5	6.04	114.40,6.91
Antenna5	14.5	7.21	86.82,6.26

Fig. 9 shows the plots of pattern measured in x-z and y-z planes at frequencies of 3.4 GHz, 6.8 GHz, and 8.9 GHz. From the results,

it demonstrates that all the operating frequencies have the similar radiation pattern. It is also noted that all design exhibit an omnidirectional profile in lower frequencies for the x-z plane and bidirectional for the y-z plane. As the frequency increases, Antenna 3 radiates either with strong side lobes (3.4 GHz) and multiple lobes (6.8 GHz).

Figure 7. The constructed antenna.

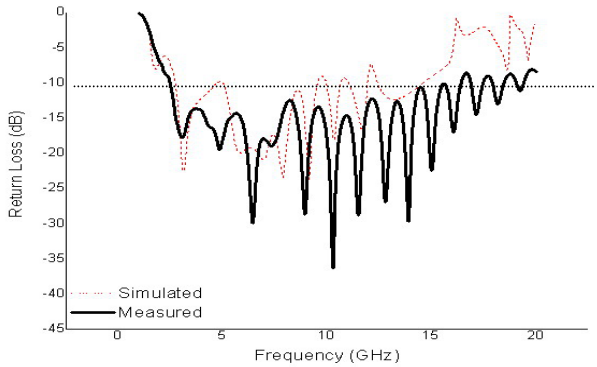

Figure 8. Measured and Simulated return losses for W_o = 72 mm, W_i = 56 mm, L_o = 55mm, L_i = 39 mm W = 6.37 mm, S and g= 0.5 mm.

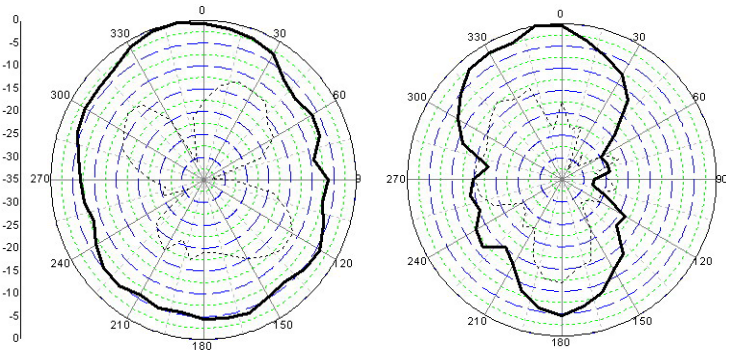

(a)

IV. CONCLUSION

This paper presents study and design of an ultra-wideband CPW-fed elliptical loop slot antenna. It is seen that the antenna has a bandwidth of 2.56 – 16.57 GHz or about 146.26 % at return loss higher 10 dB. The constructed elliptical loop slot antenna has been compared with CPW square slot antenna. It is found the proposed antenna has a wider bandwidth than CPW-fed square slot antenna.

***Abstract*- In this paper, a novel microstrip antenna using log-periodic and series-fed techniques is proposed to increase operation frequency. This is modification of quasi-Yagi with log-periodic as driver and series-fed to get wider bandwidth and same pattern as end-fire pattern. The prototype antenna measurement shows more than 100 % bandwidth ($S_{11} \leq$ -10dB) and gain of 2-8 dBi. The enhanced performances have been confirmed by both simulation using IE3D and measurement.**

Keywords: Ultra wideband antenna, Log –Periodic arrays, Quasi-Yagi antenna

I. INTRODUCTION

The popularity of using wireless communication makes huge demand for high quality of every part of elements. The most important part of wireless communication systems is an antenna. Antenna is needed in a number of communication systems such as radar, civilian, and military systems. At present, antenna is modified to improve efficiency in various ways upon specialists of each system including microstrip antenna. Microstrip antennas have been extensively studied due to their low profile, low-cost, light-weight, and ease of fabrication. However, microstrip antennas also have some limitations such as narrow bandwidth [1], lower gain, and poor end-fire radiator except tapered slot antennas.

This paper proposes a new antenna using a combination of a quasi-Yagi antenna and a series-fed dipole array antenna in order to increase bandwidth. Normally, a quasi-Yagi microstrip antenna [2],[3] is modified from a classical Yagi-uda dipole. However, the microstrip has certainly uniplanar, therefore the second director or more added will perform as conducting reflectors which lift main lobe. Resolving this problem, series-fed dipole array technique [4] is used to combine them together. The result after combination could be a new antenna, which provides advantages of those characteristics. In addition to this work, it is also used log-periodic technique with driver element to increase operation bandwidth [5]. The proposed antenna could be able to increase up the efficiency ultra wideband operation.

The most interesting approach for this is a modified antenna using many techniques to obtain advantages of each technique. The proposed antenna is fabricated on FR-4 substrate and is demonstrated to achieve an ultra-wideband bandwidth (more than 100% for 10 dB return-loss), which is keeping end-fire pattern. The results will be confirmed by both of IE3D simulation and measurement.

II. DESIGN AND FABRICATION

The beginning ideas and theories of quasi-Yagi antenna have been developed by W. R. Deal, N. Kaneda [2]. In this paper, the quasi-Yagi had been modified to be a new structure. A design of ultra-wideband series-fed printed dipole antenna arrays with a log-periodic structure is conducted and simulated by IE3D (Zeland).

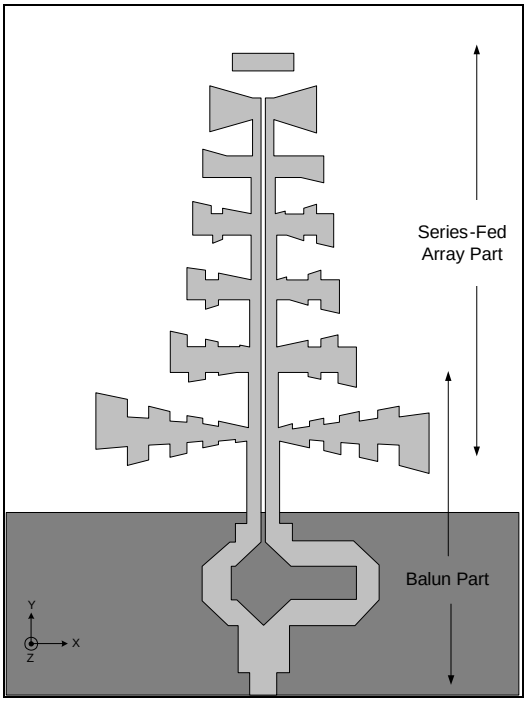

Figure 1. Schematic diagram of the Ultra Wideband Series-Fed Printed Dipole Antenna Arrays with a Log-periodic Structure on front and back side are depicted as shaded and black.

The UWB series-fed printed dipole antenna arrays with a log-periodic structure are fabricated on FR4 substrate, containing metallization on both sides. The top metallization consists of series-fed, which has pair of driver and 6 arrays and

a director fed by a broadband microstrip to coplanar strip transition. The microstrip arms are a balun used for introducing a half-wavelength delay (as center frequency). The bottom metallization is a truncated ground plane used as a reflector.

At last, the optimal new antenna is obtained in **Fig.1**. The new antenna consists of 3 main parts; the first one is microstrip-to-coplanar strips (CPS) balun part [7]. Secondly, it is series-fed dipole arrays part [4], and the last one is called a log-periodic part.

A. Design of balun

This research proposes an ultra-wideband microstrip antenna (3-12 GHz) based on quasi-Yagi antenna [7]. However, limitation of quasi-Yagi antenna requires high dielectric. Because of, the driver and director are placed on same place, then it would work for only broadband. However, balun is very interesting for end-fire antenna designing. Because of, it is major structure to increase band, reducing size, easy to fabricated and very sensitive. In addition to the ground plane, it will reduce the backside of the surface wave travelling which has the same direction as radiation.

The balun is designed for center frequency at 6 GHz. The others interesting structure are L_{dri} and S_{ref} because those values are designed for starting operation frequency point, therefore length of main driver (L_{dri}) and separation from truncated ground S_{ref} will cover starting frequency of 4GHz instead 6GHz (f_0) of quasi-Yagi concept. However, a balun is still designed at 6GHz (f_0) following to quasi-Yagi concept. The schematic diagram of balun part is shown as **Fig.2**.

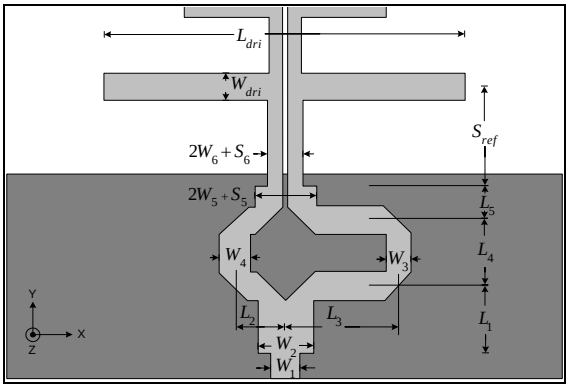

Figure 2. Schematic diagram of Balun part.

From **Fig. 2** The optimized dimensions of Balun part is *(unit:mm)* L_{dri}=38.6, L_1=7.208, L_2=5.424, L_3=12.124, L_4=7.332, L_5=3.5424, S_{ref} =11.2, S_5, S_6 =0.6, W_{dri}=3.016, W_1=3.016, W_2=5.832,W_3 =2.616, W_4=3.216, W_5=3.016 *and* W_6=1.608.

B. Design of a series-fed part

Next, we use a series-fed technique [7], which the operation bandwidth is restricted by lengths of the longest and the shortest dipole elements. Therefore, dipoles are placed on the front side of substrate by using a directing connection CPS between dipoles for resolving "conducting reflector problem". First structure is to replace the position of normally director. This is changing to general quasi-Yagi, the modified antenna is not called quasi-Yagi anymore.

The end of the series-fed is a parasitic director. Its dimension is designed for the end of operation frequency (11 GHz) instead 6GHz (f_0) following to quasi-Yagi concept. Because of The parasitic director element on the top plane simultaneously directs the antenna propagation toward the end-fire direction, and acts as an impedance matching element. **Fig.3** shows structure of the series-fed antenna.

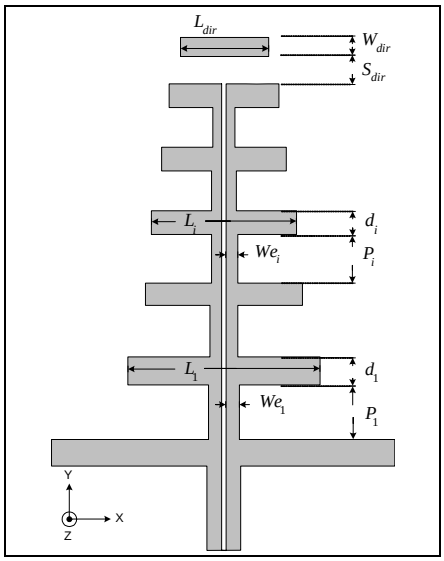

Figure 3. Schematic diagram of the element parts.

From **Fig.3** the dimensions after adjustment are (unit:mm) P_1=6.88, P_2=5.66, P_3=5.4, P_4=4.75, P_5=4.39, d_1 =3.0, d_2=2.71, d_3=2.52, d_4=2.51, d_5=2.71, L_1=21.4, L_2=17.8, L_3=16.2, L_4=14.2, L_5=12.2, L_{dir}=7.2, We_1=1.50, We_2=1.3, We_3=1.2, We_4=1.0, We_5=0.95, W_{dir}=2.216 and S_{dir}=3.284

C. Design of a Log-periodic part

Lately, we use a Log-periodic technique. The proposed log-periodic on quasi-Yagi antenna adopts new driver elements in order to achieve maximum bandwidth. This structure is replaced to the main driver and every series-fed dipole element. Every element is modified by same theory but difference scale. Designing of schematic diagrams of every log-periodic part are as follows:

If f_1 and f_2 are one period apart, they will be related to geometric ratio (τ) by [8]

$$\Delta=\ln(f_2)-\ln(f_1)=\ln\left(\frac{1}{\tau}\right) \quad (1)$$

Typical designs of Log-periodic dipole arrays have apex half angles (α)as [8]

$$10^\circ \le \alpha \le 45^\circ \text{ and } 0.95 \ge \tau \ge 0.7 \quad (2)$$

Maximum value of frequency span (Δ) is related with minimum value of τ, as 0.7. From **Fig.4** the dimensions of

log-periodic are defined by the inverse of the geometric ratio τ are [8]

$$\frac{1}{\tau} = \frac{l_{n+1}}{l_n} = \frac{R_{n+1}}{R_n} \quad (3)$$

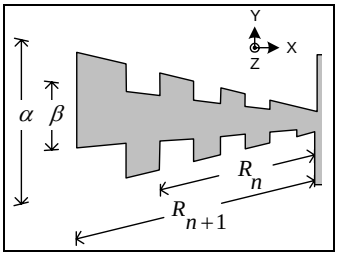

Figure 4.. Schematic diagram of the Log-periodic part.

Designing of log-periodic part has been described in [8] and hence it is not repeated here. From **Fig. 4** the dimensions after adjustment are τ = 0.7, the value of β is estimated as value of W_{dri} as 3.016 mm, and the other important value is α. Since the value of it is much, it is possible that the value interfere with truncated ground plane. Therefore 30° (9.834 mm) was used after adjustment.

III. MEASUREMENT AND RESULTS

Fig.5 shows the prototype of ultra-wideband series-fed printed dipole antenna arrays with a log-periodic structure. This prototype is fabricated on FR4 substrate with ε_r=4.4 and substrate thickness is 1.6 mm.

Figure 5. The antenna prototype (a) front-side and (b) back-side.

The HP8910C network analyzer was used for this measurement. **Fig.6** plots both simulation and measurement results for input return loss. The simulated and measured bandwidths (return loss ≤ 10 dB) that have consistent term are 118% and 121%, respectively that cover the Ultra wideband. Additionally, the gain of the antenna have been measured and its can be observed that the peak gains increase to more than 6 dBi at 7GHz and 11 GHz.

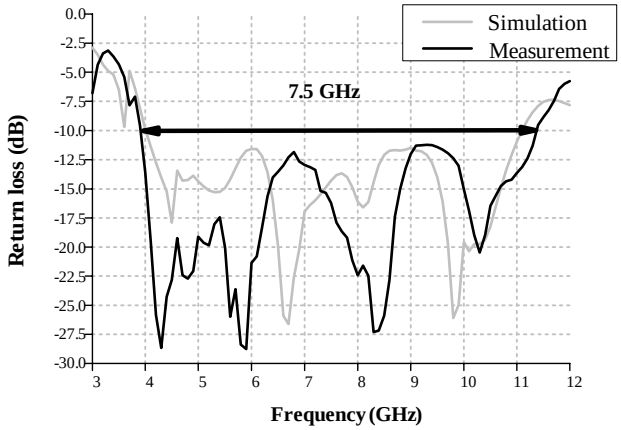

Figure 6. Measured and simulated return losses of the proposed antenna.

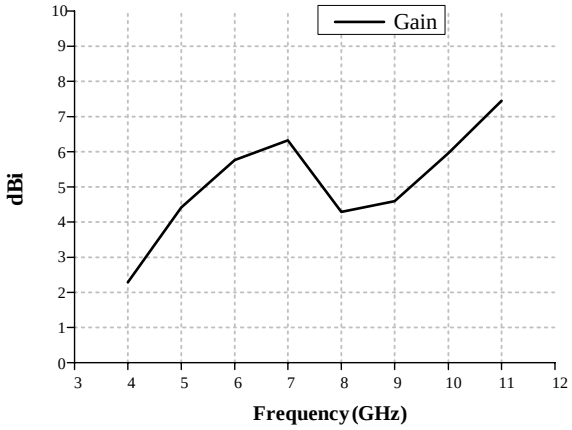

Figure 7.. Measured gain versus frequency.

IV. CONCLUSION

The ultra wideband series-fed printed dipole antenna arrays with log-periodic structure has been proposed and demonstrated. The antenna is based on a modified of the proposed techniques, which achieve ultra-wideband operation. A 100% bandwidth is obtained and it is also keeping end-fire pattern radiation. The antenna is compact and easy to fabricate, and it achieves extremely wide bandwidth and good end-fire radiation characteristics.

***Abstract*— This paper studies about the presence of ultra wideband (UWB) system to performance of IEEE 802.11a (WLAN). From our study, it indicates that UWB interference can cause a significant increase in the bit error rate (BER) of IEEE 802.11a. Then, we purpose a model to evaluate bit error rate by using Binary Phase Shift Keying modulation (BPSK). The model has purpose to investigate that the distance can increase the bit error rate of IEEE 802.11a when it operates simultaneously with UWB.**

I. INTRODUCTION

Recently, Ultra Wideband (UWB) [1] technology has attracted a lot of interest in the research community. UWB offers the potential for high data rates, low-power transmissions, low cost, robustness to multipath fading, and excellent geolocation capabilities. Given these superior capabilities, it is expected that UWB will quickly become a critical and integral part of the future home and office environments. As specified by the FCC [2], UWB can operate in the frequency range of 3.1 GHz ~10.6 GHz with an indoor emission limit of -41 dBm/MHz. IEEE 802.11a [3] wireless systems also operate in the 5 GHz U-NII bands, which overlaps the allowed UWB band, and will most likely co-exist with UWB technology that shown in Fig. 1. Therefore, UWB radio technology can induce interference and degrade the throughput of IEEE 802.11a system. This system studies the coexistence of UWB system and IEEE 802.11a in both Line of sight (LOS) and Non Line of sight NLOS propagation scenarios. The results show that UWB interference can greatly impact the performence of the IEEE 802.11a receiver that present in Fig. 2.

In this paper, we analyze about effect of UWB interference occurring while it works with IEEE 802.11a system [4]. We use a BPSK modulation and keep watching BER to SNR in every bit rates operating. In order to measure any impact or interference of UWB transmission to IEEE 802.11a system. In section II, the model of IEEE 802.11a transmission and UWB interference are provided. The Experiment setup and result will be given in Section III and IV respectively and a brief conclusion is given in Section V.

II. THEORY

A. The IEEE 802.11a Transmitter Model

The IEEE 802.11a signal used to transmit can be represented as [5]

$$s_{BPSK}(t) = m(t)\sqrt{\frac{2E_b}{T_b}}\cos(2\pi_{f_c}t + \theta_c) \quad (1)$$

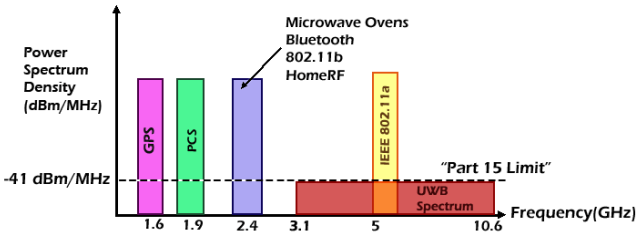

Fig. 1. Range of IEEE.802.11a frequency overlapping with UWB frequency.

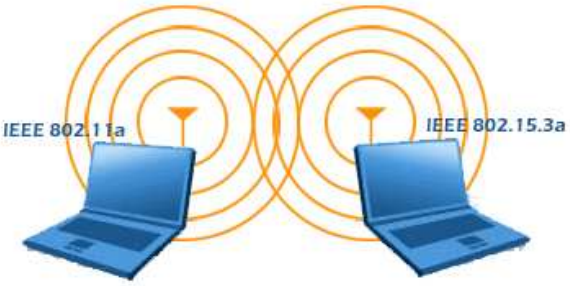

Fig. 2. Interference between IEEE.802.11a and UWB transmission.

where $\cos(2\pi_{\mathrm{f_c}}\mathrm{t})$ is applied as the carrier, and the data signal $\mathrm{m(t)}$ is applied as the modulating waveform.

B. The transmitted signal waveform of UWB and Path Loss Model

In this paper, we use BPSK modulation [6] method for UWB transmission incorporating Orthogonal Frequency Division Multiplexing (OFDM) [7]. BPSK modulation is a common method to invert the pulse. This is Eq. (2) and (3).

$$v_t(t) = \frac{1}{\mathrm{f_b}}[\mathrm{f_H}sinc(2\mathrm{f_H}t) - \mathrm{f_L}sinc(2\mathrm{f_L}t)] \quad (2)$$

$$V_t(f) = \begin{cases} \frac{1}{2f_b} & ||f| - f_c| \le \frac{f_b}{2} \\ 0 & ||f| - f_c| \ge \frac{f_b}{2} \end{cases} \quad (3)$$

where t represents the time duration, f is a frequency, $\mathrm{f_c}$ is a center frequency, $\mathrm{f_b}$ is a bandwidth frequency, $\mathrm{f_L} = \mathrm{f_c} - \frac{\mathrm{f_b}}{2}$ is minimized frequency, $\mathrm{f_L} = \mathrm{f_c} + \frac{\mathrm{f_b}}{2}$ is maximum frequency, and $\arcsin \mathrm{x} = \frac{\sin(\pi_{\mathrm{x}})}{\pi_{\mathrm{x}}}$ is waveform that has maximum magnitude equal to 1 at $\mathrm{t} = 1$. Fig.. 3 and 4 illustrate block diagram

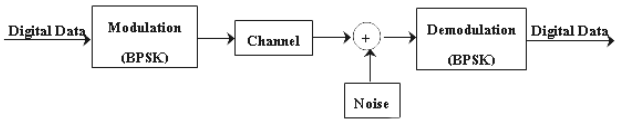

Fig. 3. Diagram of only IEEE 802.11a transmission.

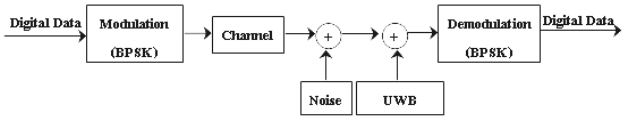

Fig. 4. Diagram of IEEE 802.11a transmission with presence of UWB transmission

about IEEE 802.11a transmission and with a presence of UWB transmission. The propagation path loss model may be expressed as

$$PL(d)[\mathrm{dB}] = 20\log\left[\frac{\max|\mathrm{v_t(t)}|}{\max|(\mathrm{v_r(t)}|}\right] \quad (4)$$

C. The IEEE 802.11a Receiver Model

A transmitted signal pass through the wireless channel including the transmitter and receiver antennas. Therefore, the total received signal from BPSK transmitter can be expressed as

$$r_{BPSK}(t) = m(t)\sqrt{\frac{2E_b}{T_b}}\cos^2(2\pi_{f_c}t + \theta_c) + V_t(f) + n_(t) \quad (5)$$

where $\mathrm{V_t(f)}$ represents UWB interference [8] and $\mathrm{n(t)}$ is additive white Gaussian noise.

D. The UWB Receiver Model

A received waveform of UWB transmission that works with IEEE 802.11a is $\mathrm{v(t)}$ that can be present as Eq. 6.

$$v(t) = \frac{h(t) * h(-t)}{\sqrt{\int_{-\infty}^{\infty} h^2(t)dt}} \quad (6)$$

For the spectrum of output from UWB transmission is $\mathrm{V(f)}$ present in Eq. 7.

$$V(f) = \frac{|H(f)|^2}{\sqrt{\int_{-\infty}^{\infty} |H(f)|^2 df}} \quad (7)$$

TABLE I
EXPERIMENTAL SETUP PARAMETERS

Parameter	Value
Frequency range	3 GHz ∼ 11 GHz
Number of frequency points	801
Tx antenna height	2.2 m
Rx antenna height	1.8-2.05 m
Antenna type	Biconical

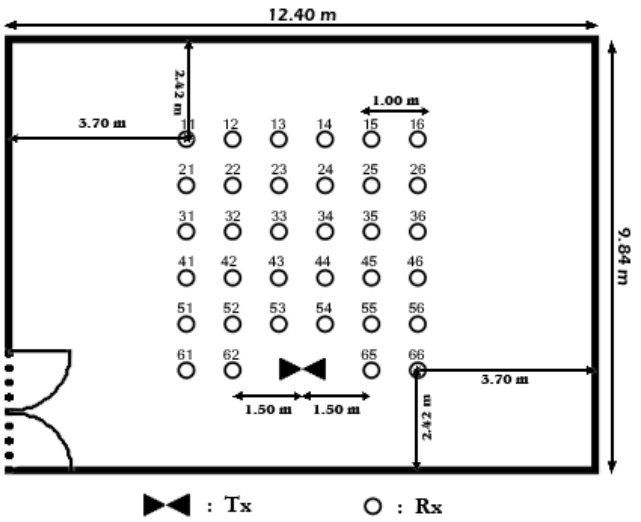

Fig. 5. Model 1 arranged antennas in horizontal view.

III. EXPERIMENTAL SETUP

In our analysis of interference of UWB working together with IEEE 802.11a, we propose a model to notice the characteristics of UWB interference which affects to IEEE 802.11a system [9]. Simulating a UWB signal at a frequency range of 3 GHz ∼ 11 GHz and IEEE 802.11a signal at 5.2 GHz that is performed in an anechoic chamber. The Vector Network Analyzer (VNA) generates transmitted signal and translates received signal. We use a biconical antenna to send and receive the signal. For all of detail about parameter is present in table 1. About transmitted bit rate, we define at 6 and 9 Mbps and pick 4 points from 64 points to compare BER to SNR in different angle. Our model aims to investigate the characteristics of horizontal UWB interference to IEEE 802.11a system by setting the antennas as Fig. 5 without changing in height of antennas.

IV. RESULT AND DISCUSSION

From the result, when we transmit only the IEEE 802.11a signal or UWB signal, the result shows that in a higher bit rate has more BER value than lower bit rate. About the SNR value, it has arisen when the bit rate are incresed. However, in every bit rates, raising SNR makes the BER decrease. Fig. 6 and 7 depict BER to SNR in only IEEE 802.11a transmission and UWB transmission respectively. From that graph, we can learn we should send the signal in lower rate because it provides better SNR than in higher rate. Moreover, when UWB and IEEE 802.11a signal perform in the same time, the BER will be risen more than only IEEE 802.11a transmission. Similarly, when SNR have arisen, they cause BER deplete. Fig. 8 and 9 illustrate the comparison between IEEE 802.11a transmission and IEEE 802.11a transmission with presence of UWB transmission at 6 Mbps and 9 Mbps respectively.

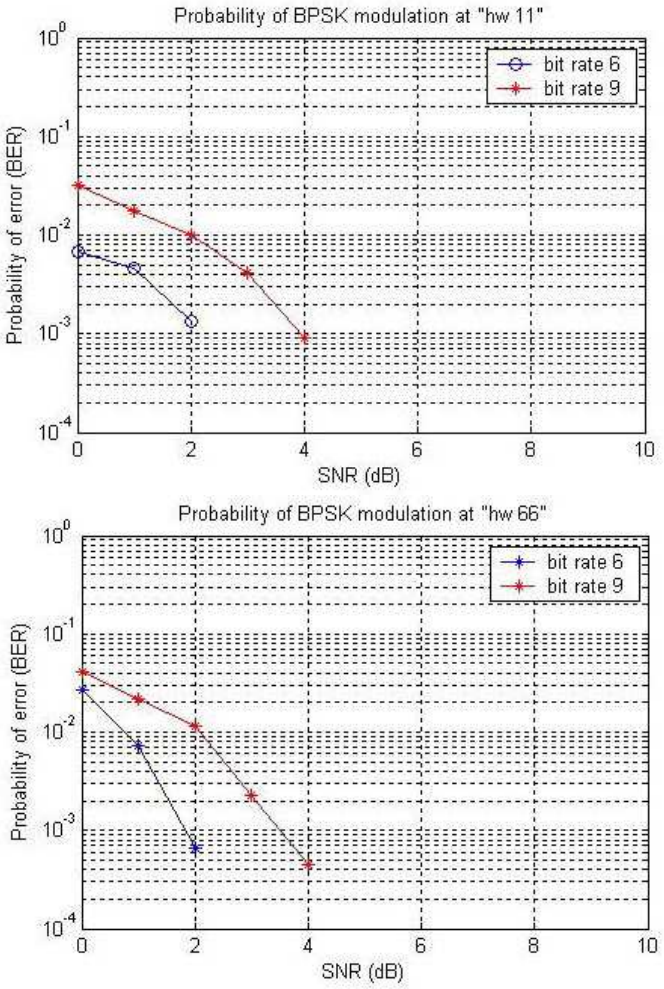

Fig. 6. BER to SNR in only IEEE 802.11a transmission.

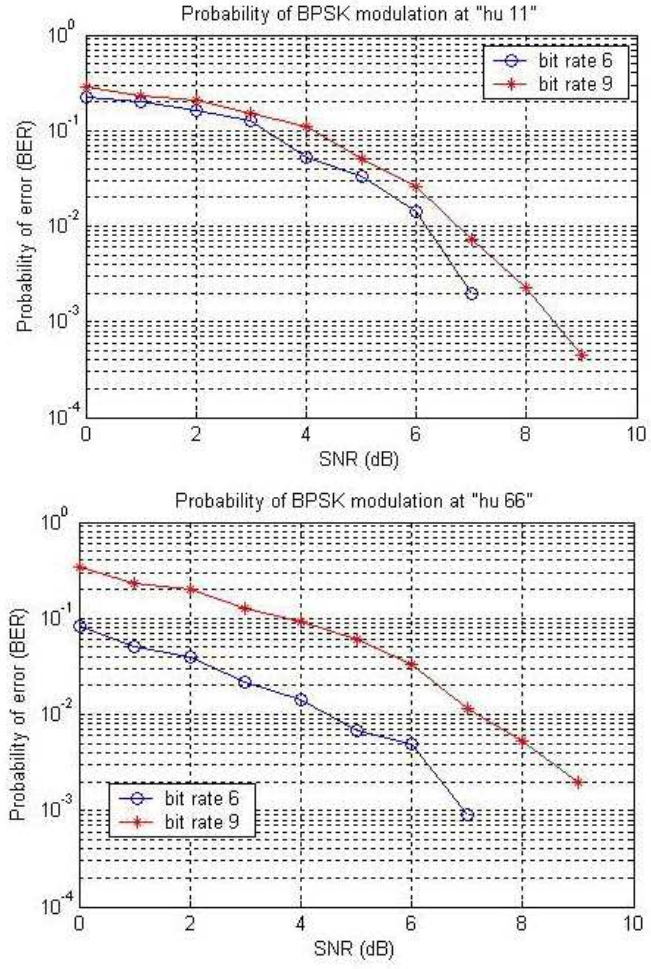

Fig. 7. BER to SNR in only UWB transmission.

V. Conclusions

In this paper, it purposes effect of UWB signal to IEEE 802.11a performance. We use a model to investigate its effect. From IEEE 802.11a transmission, UWB transmission, and IEEE 802.11a transmission with the coexistence of UWB, the result arriving from the model shows that when we send in higher bit rates, they always result in increasing BER. Especially, IEEE 802.11a transmission with the coexistence of UWB has higher BER more than IEEE 802.11a or UWB transmission themselves. Then we can conclude that UWB transmission makes interference to IEEE 802.11a transmission in every single bit rates and especially, in higher bit rate, it can notice obviously.

***Abstract*- This paper investigated wideband coplanar waveguide (CPW) fed rectangular slot antenna with rectangular planar patch and slot tuning. A rectangular slot antenna is excited by a 50 ohm CPW with slot tuning on rectangular planar patch for wireless applications. By adjusting size of rectangular planar patch and of slot tuning on rectangular planar patch, can easily achieve a wideband. The proposed antenna is designed to operate from 1.38 to 6.04 GHz which is suitable for applications in WLAN (Wireless Local Area Network) according to IEEE 802.11 a/b/g standards and covered the WiMAX (Worldwide Interoperability for Microwave Access, IEEE 802.16e). The characteristics of antenna are proposed and analyzed for bandwidth, return loss, input impedance and VSWR. The simulation results are analyzed by IE3D Zeland software.**

I. INTRODUCTION

Recently, there is growing research activity on multi-frequency and broadband and wideband antennas for various wireless communication applications such as WLAN (Wireless Local Area Network) or WiMAX (Worldwide Interoperability for Microwave Access. In particular, a great interest in coplanar waveguide (CPW) fed slot antenna has been presented in the paper because the CPW fed slot antennas have the advantage of wide bandwidth, simplest structure and easy integration with active devices [1]. The CPW fed slot antennas have been designed for wideband applications by rectangular and square slot and enhance bandwidth by optimizing a tuning stub [2, 3, 4].

In this paper, we propose a CPW fed slot antenna for wideband application in WLAN communication and WiMAX. Owing to the slot tuning on rectangular planar patch inset around the side edge of the rectangular slot antenna, a new resonant frequencies can be excited and enhance the operating bandwidth of the wideband by adjusting parameter of slot tuning on rectangular planar patch, which simulation covers the bandwidth of 1.38 to 6.04 GHz is enough for wireless communication. Detail of the proposed CPW fed slot antenna designs are described, and simulation results for obtained wideband performance are presented by using IE3D Zeland software.

II. ANTENNA STRUCTURE

Figure 1, shows the structure of the proposed CPW-fed rectangular slot antenna with slot tuning on rectangular planar patch at designed frequency 1.5 GHz. The slot antenna is on FR4 substrate of dielectric constant 4.5 (ε_r) and substrate of thickness 1.6 mm (h). The dimension of dielectric substrate is 53x61.5 mm^2. The proposed antenna consists of rectangular slot has a length Lx = 44.8 mm and Ly = 25.5 mm. A 50 ohms coplanar waveguide with gap width S = 0.5 mm and centre conductor width Wc = 5.4 mm and the end of CPW feed line connected to rectangular planar patch of dimensions width Wx = 27.8 mm and Wy = 15.5 mm. The both slot tuning etched at the middle of rectangular planar patch, the spacing between rectangular planar patch and edge of the ground plane is G = 1.6 mm. The slot tuning consist of four parameters which three parameters of slot tuning: Lh, Lw and Ls, affect to wideband operation, the other one is Lv fixed to 2 mm. The characteristics of the proposed antenna and details of designing are discussed in the following section.

The guide wavelength is given by

$$\lambda_g = \frac{c/f}{\sqrt{\varepsilon_{eff}}} \tag{1}$$

Where ε_{eff} is an effective dielectric constant which can be computed by using the following equation.

$$\varepsilon_{eff} \approx \frac{\varepsilon_r + 1}{2} \tag{2}$$

In this case, ε_{eff} = 2.75 and λ_g = 120.6 mm, and dimension of rectangular slot antenna in length and width (Ly and Lx) is about $0.58\lambda_g$ ($Lx = 0.37\lambda_g$ and $Ly = 0.21\lambda_g$).

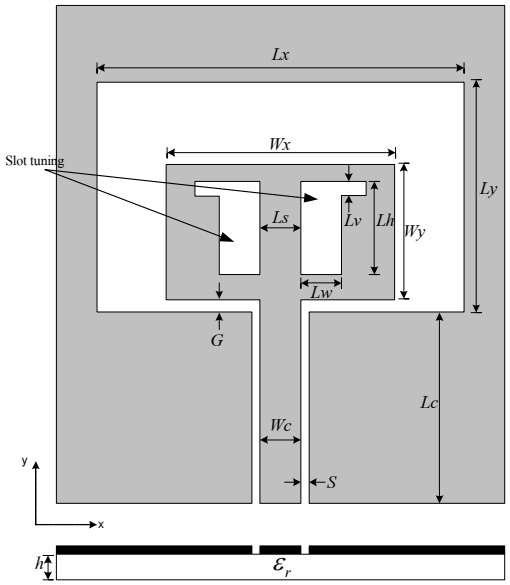

Figure 1. Structure of the proposed antenna.

III. SIMULATION RESULTS

The proposed antenna was designed and studied for bandwidth enhancement. The theoretical analysis was performed using the IE3D simulate software package of Zeland [5]. The CPW feed line is designed with the centre conductor width *Wc* = 5.4 mm, coplanar waveguide with gap width *S* = 0.5 mm, and length CPW feed line of *Lc* = 26 mm for match with 50 ohms characteristic impedance. There are three designs for show the enhancement of this antenna, the first is CPW fed rectangular slot antenna, second is rectangular planar patch inside of the slot, and third is slot tuning inside of the planar patch. The proposed design can be further enhanced by rectangular conductor patch and with slot tuning on rectangular planar patch. The main proposed of this paper is to show the effect of adjusting three parameters: *Lh*, *Lw* and *Ls* of slot tuning. The result of S11 in three designs is shown in Figure 2, which fixing value of the parameters: *Lx, Ly, Wx, Wy, G, Wc, S*, *Lv* and *Lc* as a first step. The initial value of three parameters of slot tuning of *Lh* = 11 mm, *Lw* = 2 mm and *Ls* = 5.4 mm are proposed for begin adjusting. From Figure 2, the bandwidth of proposed antenna will be increased when using conductor stub tuning (rectangular planar patch) and slot tuning. For more bandwidth enhancement from Figure 2, the adjusting of three parameters will be considered in next step.

A. Effect of Adjusting Lh of Slot Tuning

In this case, we fixed *Lw* = 2 mm, *Ls* = 5.4 mm and vary the length *Lh* of slot tuning to 11 mm, 11.3 mm, 11.5 mm and 12 mm, respectively. The effect on the resonant frequencies and bandwidth are investigated as shown in Figure 3. Its shown that the bandwidth at return loss -10 dB about 4 GHz, the lowest resonance frequency of each value of *Lh* is same but highest resonance frequency is shift down when *Lh* is increased. From Figure 3, the best matching for wideband is at *Lh* = 12 mm, which return loss is -50 dB at frequency 4.2GHz.

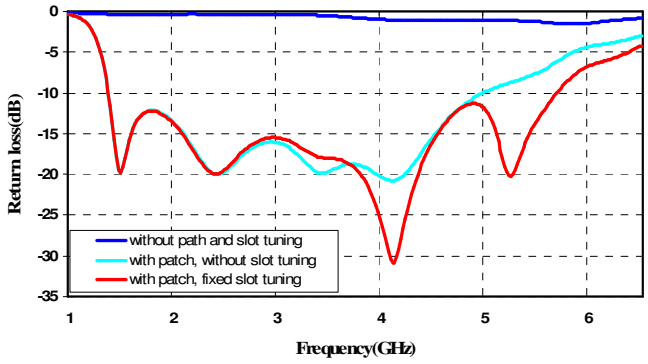

Figure 2. Comparison of return loss of three designs.

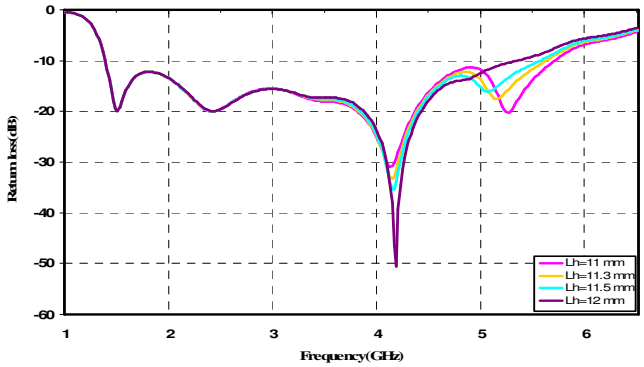

Figure 3. Simulation return loss for difference *Lh*.

B. Effect of Adjusting Lw of Slot Tuning

The effect of the width *Lw* of slot tuning on return loss is considered. Herein, the *Lw* is chosen to 3.7 mm, 4.2 mm, 4.7 mm and 5.7 mm, while *Lh* = 11.5 mm, *Ls* = 5.8 mm are fixed.

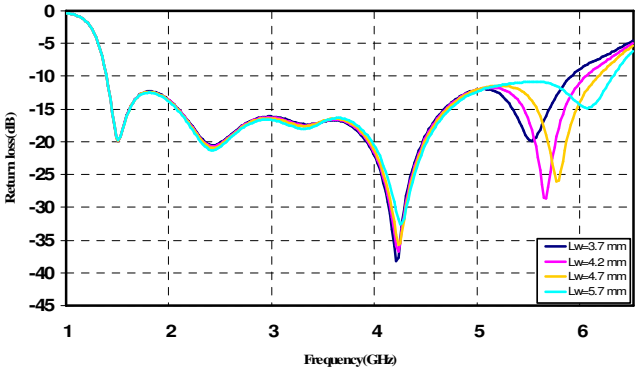

Figure 4. Simulation return loss for difference *Lw*.

The typical simulation results are shown in Figure 4, when we focus to the high resonance from 4 to 6 GHz, it can be found that the resonance frequency near 4 GHz is slightly

chanced but the resonance frequency near 6 GHz is shift up when value of *Lw* is increased and wider bandwidth.

C. Effect of Adjusting Ls of Slot Tuning

The effect of distance between both slot tuning (*Ls*) on the return loss is considered by vary values of *Ls*: 4.8 mm, 5.8 mm, 6.2 mm and 7 mm, respectively, while *Lh* = 11.5 mm and *Lw* = 4.2 mm, as shown in Figure 5. The resonance frequencies slightly changed and return loss is much changing.

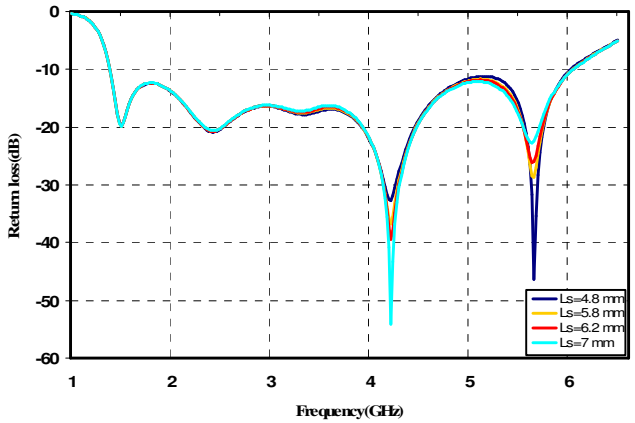

Figure 5. Simulated return loss for difference *Ls*.

D. Characteristic of Return Loss

We optimized and investigated the effect of adjusting three parameters of the antenna for enhance bandwidth covers IEEE 802.11a/b/g (2.4-2.4835GHz, 5.15-5.35GHz and 5.725-5.875GHz) WLAN applications and WiMAX (2-6 GHz). Finally, the dimension of slot tuning is *Lh* = 11.5 mm, *Lw* = 4.2 mm and *Ls* = 4.8 mm for sufficient choosing. Figure 6, shown the frequency band and maximum bandwidth coverage at 1.38 GHz to 6.04 GHz which all of parameters are shown in Table 1.

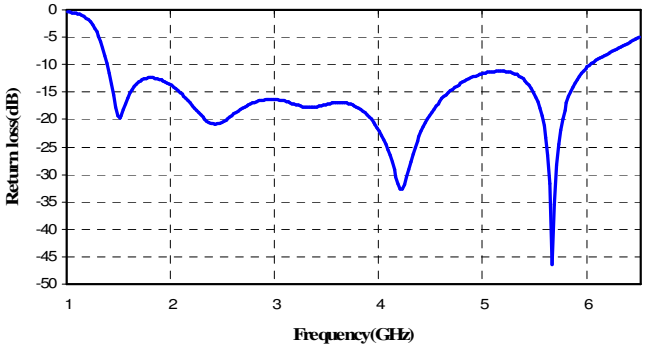

Figure 6. Simulated S_{11} of the proposed antenna.

E. Characteristic of Input Impedance

The input impedance Z_{in} is the complex number, which fined out by using the S_{11} parameter and characteristic impedance Z_o of transmission line. The characteristic of input impedance for this slot antenna is shown in Figure 7.

TABLE 1
Parameters of the proposed antenna designs.

	without patch and slot tuning (mm)	with patch, without slot tuning (mm)	with patch and slot tuning (mm)

IV. CONCLUSION

This paper presented the bandwidth enhancement of CPW fed slot antenna by rectangular conductor patch and slot tuning on rectangular planar patch. This slot antenna easy to fabrication and can achieved the wideband from frequency range 1.38 – 6.04 GHz coverage standard of IEEE 802.11 a/b/g (2.4-2.4835 GHz, 5.15-5.35GHz and 5.725-5.875GHz) for WLAN and WiMAX (IEEE 802.16e, 2-6 GHz).

***Abstract*—A rectangular slot excited by coplanar waveguide (CPW) with tuning stub is introduced to obtain a dual frequency operation. Prototype of the proposed antenna designed for WLAN operations in the 2.4 and 5.2 GHz bands. The antenna and CPW feed line are printed on the same side of a single conducting layer, thus simplifying the fabrication process. The characteristics of antenna are proposed and analyzed for instance input impedance, return loss, bandwidth, VSWR, and far field radiation patterns. The obtained impedance bandwidth for two operating bands can reach about 55.2% for the 2.4 GHz band and 12.97% for the 5.2 GHz band. Finite Difference Time Domain method (FDTD) is introduced to analyze this antenna. A verification of simulation procedure is confirmed by IE3D software which is based on the Method of Moments (MOM).**

I. INTRODUCTION

Recently, great advances have been made in wireless local area network (WLAN) communications, and in order to satisfy the IEEE 802.11 WLAN standards in the 2.4 GHz band (2.4 -2.484 GHz) and 5.2-GHz band (5.15-5.35 GHz), many wireless communication devices are now designed to be capable of dual-band operation in the 2.4 and 5.2-GHz bands. For this reason, dual-band antennas for WLAN operation are in demand accordingly.

Dual-frequency microstrip antennas are generally classified into two types: multiresonator antennas, such as multilayer patch antennas, and reactive loading antennas using etching slots on the patch and/or short circuit vias. Thus, the research for new microstrip configurations with wider bandwidth or dual band has been dominant feature of the research literature, and much effort continues to be expended [1]

The coplanar waveguide (CPW) fed antennas have been widely used for wireless communications owing to their many attractive features such as wide bandwidth, simplest structure of a single metallic layer, no soldering points, easy integration with MMICs, and broad bandwidth, etc [2]. Etching the slot and the feed line on the same side of the substrate eliminates the alignment problem needed for etching on both sides of the substrate. The coplanar waveguide (CPW) is such a transmission line that can achieve this. In addition, the CPW has lower loss than the microstrip line. For the available designs, the patch antenna fed by CPW reported in [1] is capable of dual band but two metallic layer are require for this antenna, the CPW-fed square slot antenna reported in [3] is capable of broad but single-band operation only, and some related designs applied for single metallic WLAN operations have been reported in [4-8] realize dual band operations. However, the lower mode has a narrow impedance bandwidth. In this paper, a novel and simple wideband dual-frequency, easy harmonic adjusting design of the rectangular slot fed by coplanar waveguide (CPW) with tuning stub is presented. The antenna and feed line structure are placed on the same single conductor side of the substrate, thus simplifying the fabrication process, it can be shown that this antenna is suitable for WLAN application, details of the antenna design are described and simulated results are presented and discussed.

II. FDTD METHOD

This software is a full wave electromagnetic simulation code for conventional three dimension (3D) passive structures, which are base on the FDTD algorithm that can predict and analysis of the electromagnetic responses of complex problems. The analytical space consists of $70\times249\times100$ cells with the cell dimension $\Delta x = 0.1575$ mm., $\Delta y = \Delta z = 0.25$ mm. The time step satisfies the following courant condition.

$$\Delta t \le \frac{1}{v_{\max}\sqrt{(1/\Delta x)^2 + (1/\Delta y)^2 + (1/\Delta z)^2}} \quad (1)$$

For source excitation of the antenna is input voltage $V(t)$ base on Gaussian pulse and express as

$$V(t) = e^{-\left(\frac{t-t_0}{T}\right)^2} \quad (2)$$

Where t_0 the center of the pulse, T is is the pulses width at its $1/e$ characteristic delay point.

III. ANTENNA DESIGN

The geometry of the proposed CPW-fed rectangular slot antenna with tuning stub for wideband and dual-frequency operations is shown in Figure 1. For the design studied here, the antenna is etched on the same side of RT/Duroid 5880 substrate with the dielectric constant of 2.2 (ε_r)and the substrate thickness of 1.575 mm (h), while the other side without any metallization. A CPW transmission line, which consists of a center conductor strip width of w_f and a gap distance of s between the conductor strip and the coplanar ground plane, is used for feeding the antenna. Two equal finite ground planes, each with dimensions of length L_{cpw} is situated symmetrically on each side of the CPW feed line. The basis of the antenna structure is a rectangular slot, which has the dimensions of length L and width W. To achieve the desired dual-frequency operations and for easy upper frequency control range, the feed line is connected with the tuning stub, which comprises both the horizontal and vertical sections with dimensions.

The guide wavelength is given by

$$\lambda_g = \frac{c/f}{\sqrt{\varepsilon_{eff}}} \tag{3}$$

Where ε_{eff} is an effective dielectric constant which can be computed by using the following equation.

$$\varepsilon_{eff} \approx \frac{\varepsilon_r + 1}{2} \tag{4}$$

To investigate the performance of the proposed antenna configurations in terms of achieving the wideband dual frequency operations, the Finite Difference Time Domain method (FDTD) was used for required analysis and obtaining the proper geometry parameters in Figure 1.

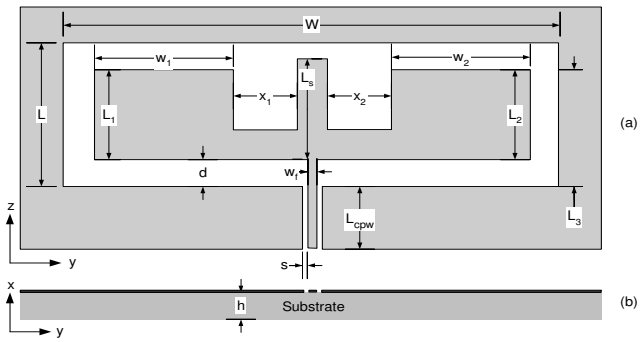

Figure 1. CPW-fed rectangular slot antenna with tuning stub (a) top view (b) cross section

Finally, the antenna dimension is obtained to be

L	= 14 mm.	L_1	= 9 mm.
W	= 48.25 mm.	L_2	= 9 mm.
L_{cpw}	= 7.5 mm.	L_3	= 12.5 mm.
w_f	= 0.75 mm.	x_1	= 5.5 mm.
s	= 0.25 mm.	x_2	= 5.5 mm.
d	= 2.5 mm.	w_1	= 15 mm.
L_s	= 10 mm.	w_2	= 15 mm.

IV. RESULTS AND DISCUSSION

The antennas are analyzed by using Finite-Difference Time-Domain (FDTD) Method and comparing with IE3D software which is based on the Method of Moments (MOM).

The resonant mode at 2.4 GHz band is achieved by W and L parameter adjusting. The upper resonant mode occurs by L_s L_1, L_2, x_1, and x_2 adjusting. In this paper, we will show to adjust the W, L_1, L_2, and Ls parameters by fixing the value of other parameters.

A. *Affect of adjusting the W parameter.*

In this case, the W is adjusted to be 46.25 mm, 48.25 mm, and 50.25 mm, respectively. The simulation result of return loss (S_{11}) are shown in Figure 2. Thus, the lower resonant can shift to any frequency.

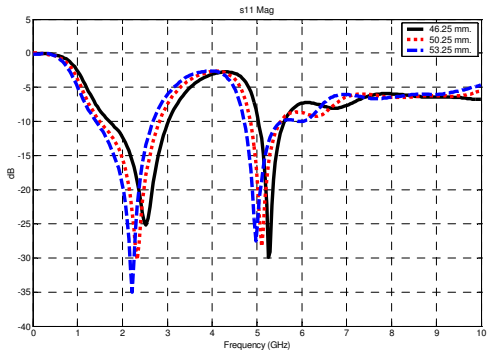

Figure 2. The return loss in the case of W adjusting

B. *Affect of adjusting the L_1 and L_2 parameter.*

The length of L_1 and L_2 are adjusted to 7, 8 and 9 mm, the resulting show that the spacing between the lower and upper resonant frequency can optimize by this condition (see Figure 3).

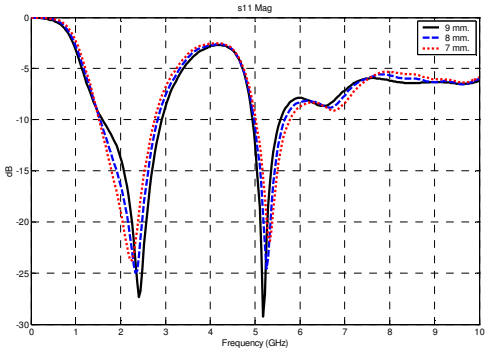

Figure 3. The return loss in the case of L_1 and L_2 adjusting

C. *Affect of adjusting the L_s parameter.*

To follow this condition, the upper resonant can select to the frequency requirement that shown in figure 4.

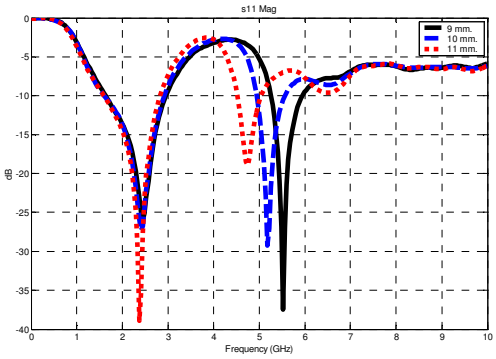

Figure 4. The return loss in the case of L_s adjusting

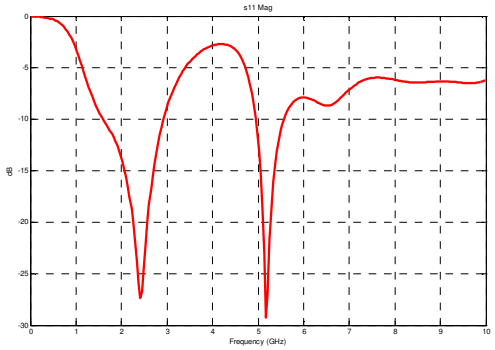
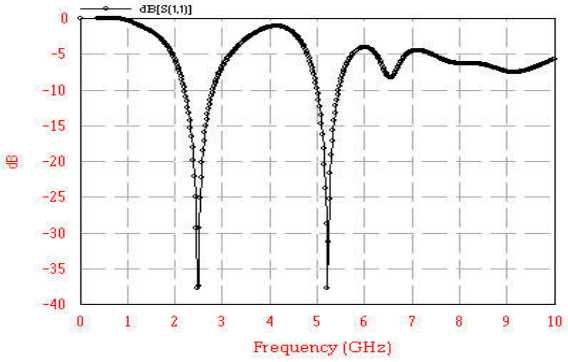
D. The characteristics of proposed antenna.

Figure 5 shows the simulated return loss against frequency for the proposed CPW-fed rectangular slot antenna with W-shaped tuning stub which simulated by FDTD method and MoM.



(a) FDTD



(b) MOM

Figure 5. Simulated return loss of proposed CPW-fed rectangular slot antenna with tuning stub.

The simulation in lower band achieves a -10 dB impedance bandwidth of 55.2% ranging from 1.59 GHz to 2.92 GHz with respect to the centre frequency at 2.41 GHz, and the simulated bandwidth for the upper mode ranging from 4.9 GHz to 5.57 GHz or about 12.97% referred to the centre frequency at 5.17 GHz. Obviously, the antenna can operate over the bands which cover the required bandwidths of the IEEE 802.11 WLAN standards in the bands at 2.4 GHz (2.4–2.4835 GHz), 5.2 GHz (5.15–5.35 GHz) [8]. Figure 6-7 show the simulated of VSWR and input impedance.

Typical radiation characteristics of the frequencies across the lower and higher bands for the proposed dual-band antenna are also examined. The radiation patterns for E_θ are nearly omnidirectional at both operating frequencied. The radiation patterns have symmetric characteristic because the antenna structure is symmetrical. Figures 8-9 show the radiation patterns in the azimuth cut (x–y plane) for the antenna at the lower band of 2.41 GHz, and at the higher band of 5.17 GHz.

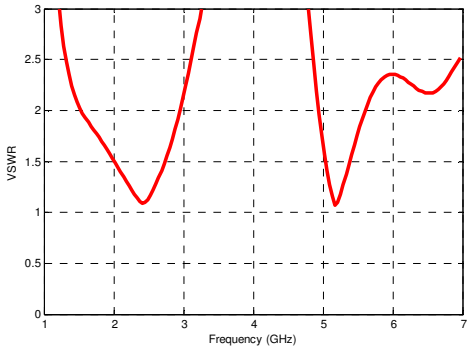


Figure 6. Simulated VSWR of proposed CPW-fed rectangular slot antenna with tuning stub.

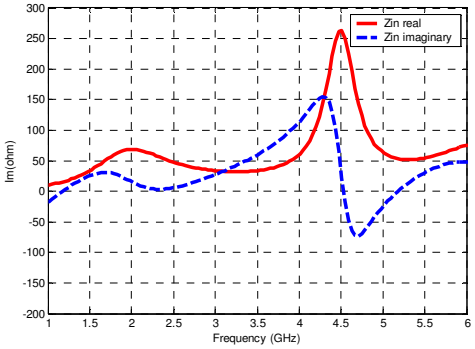

Figure 7. Simulated input impedance of proposed CPW-fed rectangular slot antenna with tuning stub.

V. CONCLUSION

Broadband dual-frequency operations of a simple CPW-fed rectangular slot antenna with tuning stub suitable for WLAN operations in the 2.4 and 5.2 GHz bands have been studied. By the connecting of a tuning stub to the CPW feed line, the proposed antenna can provide dual-band and wide impedance bandwidths of 55.2% ranging from 1.59 GHz to 2.92 GHz with respect to the centre frequency at 2.41 GHz, and the simulated bandwidth for the higher mode ranging from 4.9 GHz to 5.57 GHz or about 12.97% referred to the centre frequency at 5.17 GHz. Also, good antenna performances of operating frequencies across the two bands can be obtained.

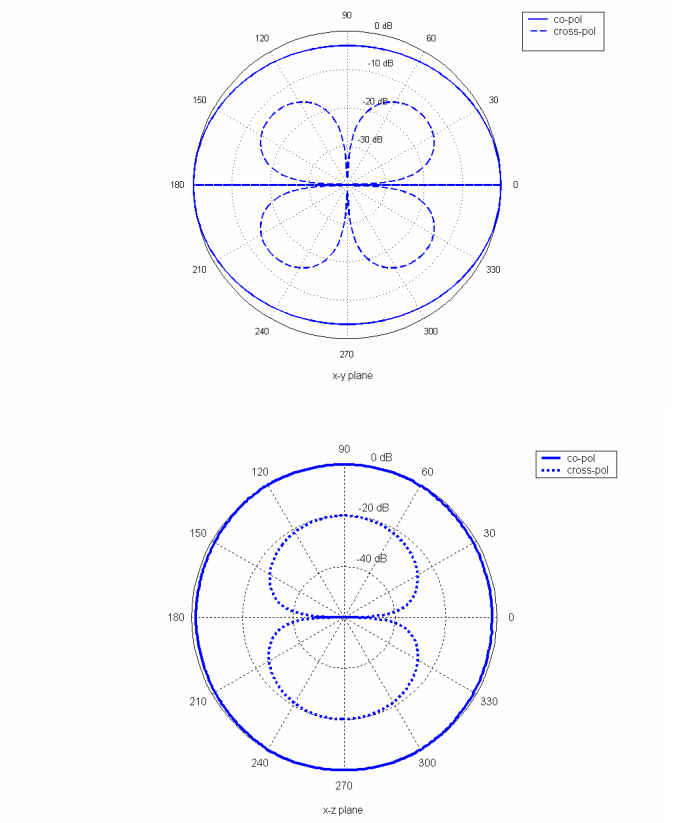

Figure 8. Simulated radiation patterns at 2.41 GHz for the proposed antenna in Figure 1.

***Abstract*—Investigation was carried out on the novel microstrip-fed acute angle wide-slot antennas. These antennas were designed for 2–3 GHz covering Wi-Fi (IEEE 802.11b/g at 2.4–2.4835 GHz) and WiMax (IEEE 802.16 at 2.3 GHz and 2.5 GHz) applications. The antennas achieved the omni-directional radiation pattern and high average gain. Details of the antenna design and simulation results are presented and discussed.**

I. INTRODUCTION

Wide-slot antennas have been studied since 1993. Kahrizi M., Sarkar T. K., and Maricevic Z. A. [1] presented the calculation involved the wide open slot by the Method of Moments. Further investigations by [2] and [3] revealed that wider slot width created wider bandwidth, which was preferable. Microstrip antennas with wide basic rectangular slot then appeared to be an interesting alternative in antenna design.

A wide-slot antenna with acute angle shapes at 45° were first developed by [4] as another novel design alternative. The width of the bandwidth characteristic was maintained while the area of the antenna structure was reduced. The antenna structure was kept simple. The microstrip feed was also kept simple for the ease of manufacturing. In this paper, acute angle shape antennas at 60° were brought into consideration for further understanding.

IEEE 802.16 standard was established by IEEE standards board in 1999. In 2005, IEEE 802.16e standard was developed to serve mobile applications. Presently more applications were found in the frequency range of 2.3 GHz and 2.5 GHz which was the overlapped range to IEEE 802.11b/g standard which operated at 2.4–2.4835 GHz. In this study wide-slot antennas with acute angle shapes were developed to yield the bandwidth covering 2.3, 2.4–2.4835 and 2.5 GHz to satisfy these standards. The Method of Moments (MoM) was adopted to analyze the proposed antennas by simulation through IE3D software from Zeland, Inc, as referred in [5].

II. METHODOLOGY

A. Principle

The slot is edged on the ground plane, while the microstrip feed line is on the other side of the substrate. The middle layer is the substrate with permittivity ε_r F/m and thickness h mm.

As suggested in [6], the wavelength of the fundamental frequency (λ_o) is found from (1).

$$\lambda_o = \frac{c}{f} \tag{1}$$

When light velocity $c = 2.998 \times 10^8$ m/s, and f is the operating frequency used by the antenna in receiving and sending signals.

Effective dielectric constant (ε_{eff}) is known from (2)

$$\varepsilon_{eff} = \frac{\varepsilon_r + 1}{2} + \frac{\varepsilon_r - 1}{2}\left[1 + 12\frac{h}{W_m}\right]^{-\frac{1}{2}} \tag{2}$$

Guided wavelength (λ_g) is determined by (3).

$$\lambda_g = \frac{\lambda_o}{\sqrt{\varepsilon_{reff}}} \tag{3}$$

There are two steps in designing a microstrip antenna, ie. the slot design and the microstrip feeding design.

Slot design

The geometry of an acute angle wide-slot antenna is shown in Fig. 1. The related structural parameters were illustrated in Fig. 2. The slot is responsible for creating resonance. In principle, the length of the slot (L) should be one half of the guided wavelength (λ_g). The antenna designed according to this approach is then a half-wavelength antenna, i.e.

$$L = 0.5\lambda_g \tag{4}$$

At this stage of investigation, the width of wide-slot (W) was kept larger than 0.1 of L so that $W > 0.1L$ or $W > 0.05\lambda_g$.

The acute angle wide-slot has a width $W = W_v = W_h = 9.00$ m and the total length $L = L_v + L_h = 61$ mm ($\approx 0.7\ \lambda_g$). Other parameters were found from tuning for the optimum matching point with 50-Ω transmission line.

Microstrip feed line design

Reference [7] presented equations for width of the feed line (W_m) by (5).

$$\frac{W_m}{h} = \frac{2}{\pi}\{B' - 1 - ln(2B' - 1) + \frac{\varepsilon_r - 1}{2\varepsilon_r}\left[\ln(B' - 1) + 0.39 - \frac{0.61}{\varepsilon_r}\right]\} \tag{5}$$

For $\frac{W_m}{h} \geq 2$, $B' = \frac{120\pi^2}{2Z_o\varepsilon_r^{\frac{1}{2}}}$ and Z_o was a characteristic impedance.

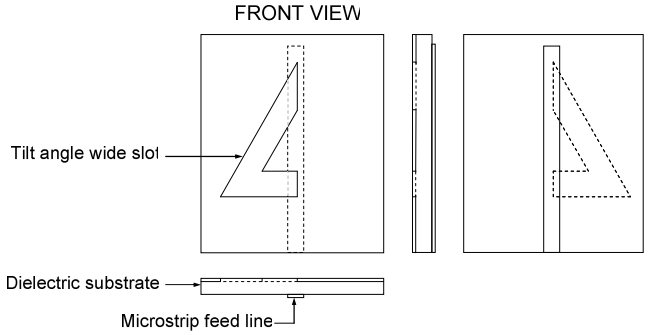

Figure 1. Configuration of the microstrip-fed acute angle wide-slot antenna

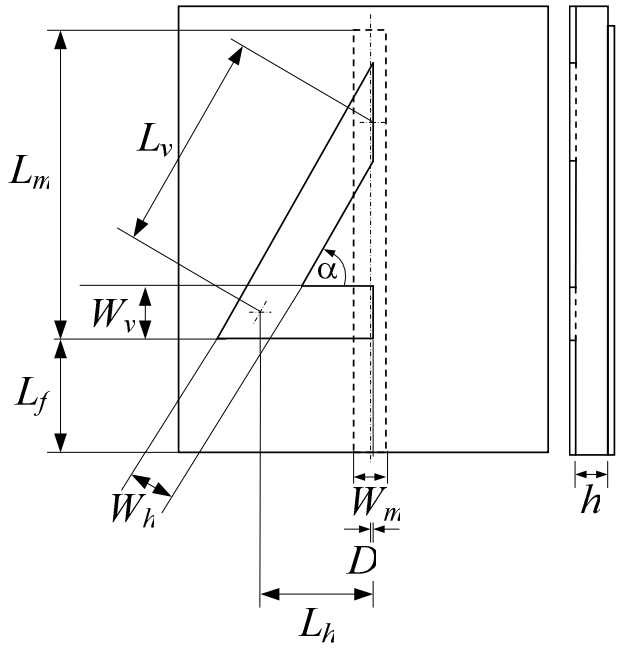

Figure 2. Structural parameters of the microstrip-fed acute angle wide-slot antenna

W_m was determined by numerical method. The theoretical guided wavelength of the lowest order resonant frequency at 2.44 GHz was 91.41 mm. The width of a microstrip feed line was 4.853 mm. The length of a microstrip feed line L_m, and the width of a slot W_s were obtained by arbitrarily adjusting for the optimum matching condition.

The calculated dimensions were then truncated as listed in TABLE I. These dimensions were used in designing a single frequency linear slot antenna. The characteristic of this antenna satisfied to the design objective.

B. Materials

A commercial substrate RT/duroid 5880 was used with the dielectric constant (ε_r) of 2.2 and the substrate thickness (h) of 1.575 mm with the copper coating thickness 0.035 mm.

III. Results

A. Tuning the design parameters

Simulation revealed that for the $0.5\lambda_g$ open slot width the frequency for best matching occurred at a value slightly higher than the designed value. To keep the best matching at the designed frequency, the slot length was allowed to be slightly higher than the original designed value, and position of the feed line was slightly adjusted.

The effects of structural parameters were then studied in the search for the optimum matching. The offset position of the feed line was found to affect input impedance of the antenna as suggested earlier by [8]. Some details of the techniques used in tuning D for the second matching frequency in WLAN range was described in [9–11]. These studies used the technique of varying the offset distance D of an antenna to adjust the characteristic $|S_{11}|$ for two very close frequencies until the wide bandwidth was obtained for that antenna.

The effect of the offset distance D on the characteristic $|S_{11}|$ on the microstrip-fed acute angle wide-slot antenna is shown in Fig. 3 suitable value of offset distance D created wider bandwidth for an antenna. In this case the suitable value for D was between –0.5 mm and 1.0 mm.

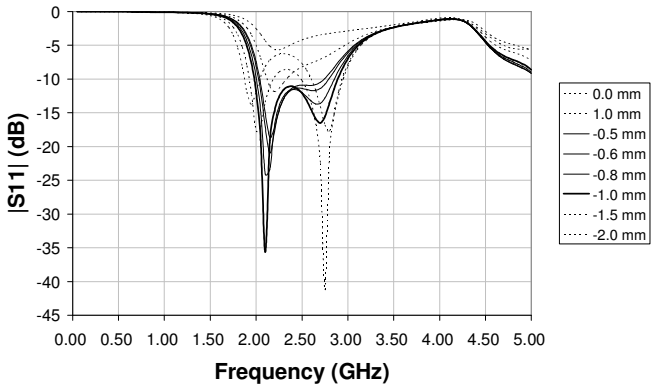

Figure 3. Effect of D on the characteristic $|S_{11}|$ on the microstrip-fed 60° angle wide-slot antenna

After matching was found on the selected frequency, L_m was slightly adjusted for the best matching. The effect of Lm is illustrated in Fig. 4. L_m was also found to affect bandwidth and the suitable value for L_m was between 55 mm to 59 mm. $|S_{11}|$ was reduced between frequencies 2 to 3 GHz until it became a wide bandwidth. As L_m increased $|S_{11}|$ also increased until it lost the wide bandwidth characteristic. It was found that L_m was not a very sensitive parameter and possible error in L_m due to manufacturing should have very little effect on antenna characteristic.

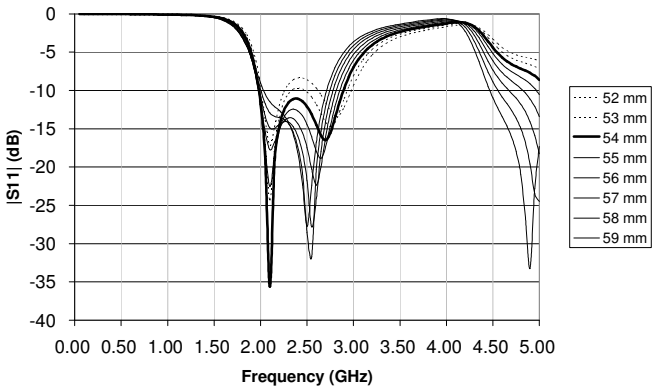

Figure 4. Effect of L_m on the characteristic $|S_{11}|$ on the microstrip-fed 60° angle wide-slot antenna after final matching

B. *Result Antenna Characteristic*

After optimum matching the final dimensions of the microstrip feed line and the antenna were found as shown in TABLE I. The characteristic $|S_{11}|$ of the result 60° angle antenna at was compared with 60° angle antenna which was done by [4] is shown in Fig. 5.

Simulations were run on the design antennas to study their performance characteristics. Fig. 6, 7 and 8 showed far-field radiation patterns at 2.3 GHz, 2.4 GHz and 2.5 GHz respectively which indicated that the far-field radiation patterns were omni-directional. The antennas were linearly polarized in those frequency ranges. The maximum gain in the usual ranges of applications was shown in Fig. 9. The gain was higher than 2 dBi and was considered satisfactory.

TABLE I
THE OPTIMUM DIMENSIONS FOR ACUTE ANGLE WIDE-SLOT ANTENNAS

α (degree)	L_h (mm)	L_v (mm)	L_m (mm)	W_m (mm)	D (mm)	–10 dB BW (%)	f_c (GHz)
45	28.50	40.50	58.77	4.80	–0.88	10.57	2.46
60	20.37	40.75	54.20	4.80	–0.90	18.11	2.43

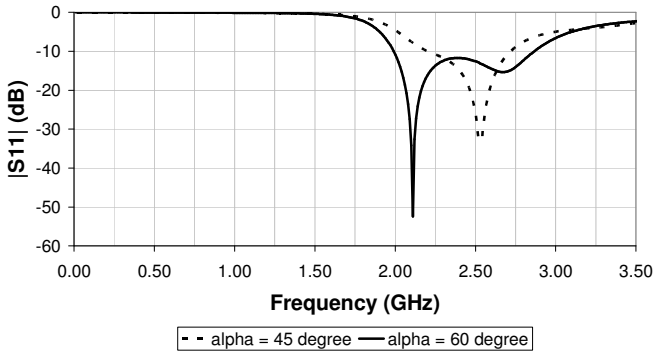

Figure 5. Characteristic $|S_{11}|$ of the 60° angle wide-slot antenna

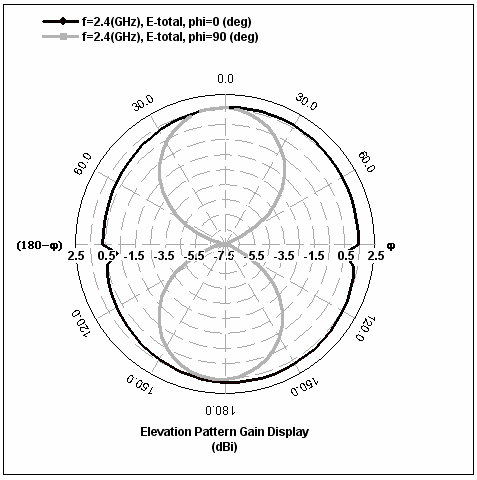

Figure 7. Far-field radiation patterns at 2.4 GHz of the microstrip-fed 60° angle wide-slot antenna

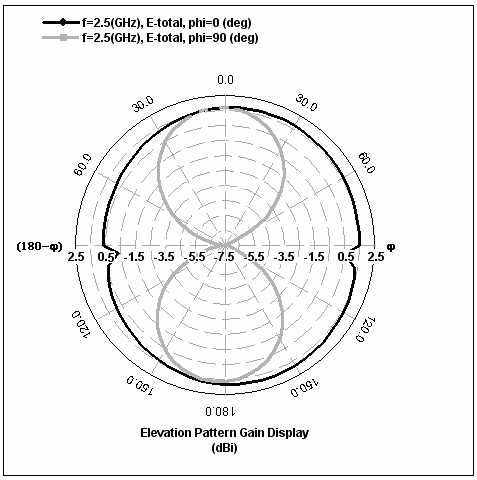

Figure 8. Far-field radiation patterns at 2.5 GHz of the microstrip-fed 60° angle wide-slot antenna

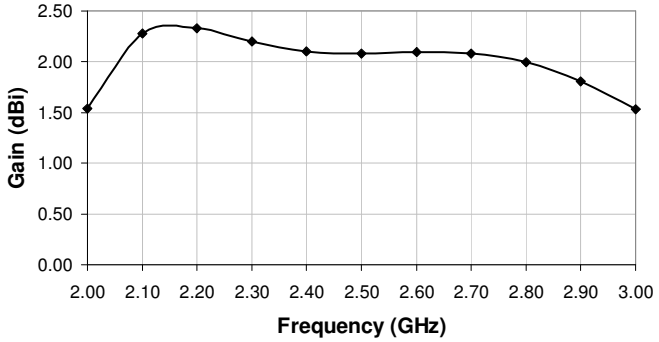

Figure 9. Maximum gain in the utilized frequency range of the microstrip-fed 60°angle wide-slot antenna

IV. CONCLUSION

The 45° and 60° acute angle wide-slot antennas satisfied IEEE 802.16, IEEE 802.16e and IEEE 802.11b/g standard requirements. These antennas are being further developed to satisfy the 3.5 GHz and 5.2 GHz applications, and also to satisfy the dual frequency applications.

These acute angle wide-slot antennas appeared suitable for wide bandwidth applications. The variation of the angle α between 45° and 60° had little effect on the wide bandwidth characteristic. Possible deviation in the angle α due to manufacturing would have little if any effect on the antenna performance. The acute angle wide-slot antenna structure is therefore considered to be a good alternative in antenna design.

ACKNOWLEDGMENT

The authors would like to express their appreciation to Faculty of Engineering, Rajamangala University of Technology Thanyaburi for their kind permission for the use of the licensed IE3D simulation program in this study.

***Abstract*-Analytic expressions are derived and presented for the mutual impedance between two thin perpendicular center-fed dipoles of arbitrary size. The current distribution on the antennas is assumed to be sinusoidal. The expressions are in terms of summation of sine-integrals and cosine-integrals. Mutual impedance curves are presented. The accuracy of the formulas is favorably compared with results from digital computation and electromagnetic simulator. An application of interest is in a dielectric property determination.**

I. INTRODUCTION

Most radiating antenna systems are often suffered from the effect of one antenna upon another in addition to determing the interfered pattern due to guy wires acting as parasitic elements or antennas adjacent to the fed antenna. To find the input impedance or finding induced currents on other wires, it is necessary to determine the unknown quantity which links the various elements called the mutual impedance. Mutual impedance analysis has been published for a long time. King has presented the mutual impedance between unequal length dipoles in echelon which the advantage of this work is ease for using because the expressions are performed in closed-form [1]. Digital computation of the mutual impedance between two arbitrary lengths antennas with unlimited geometrical configuration has been extended [2]. However, the expressions are not in closed-form. Over the past ten years the mutual impedance has been investigated such as the mutual impedances between nonplanar-skew sinusoidal dipoles which have been well documented by Richmond and Geary [3], or sinusoidal electric and magnetic dipoles [4].

Many useful applications of mutual coupling are published such as the dielectric property measurement of subsurface using linear dipoles [5]. One of the most interesting methods is the measurement of amplitudes of transmission and reflection coefficients [6]-[7]. The advantage of this method is that this is no need to measure phase but it is quite complicate to measure amplitudes of both transmission and reflection coefficients.

Although sufficient data of the parallel-in-echelon configuration has been presented in the past for solving the conventional problems, a knowledge of the mutual impedance between perpendicular thin dipoles is accordingly required. Consequently, the purpose of this paper is to present the new closed-form expressions for easily computing the exact mutual impedance between two thin center-fed perpendicular dipoles of arbitrary size. The calculation is assumed for the case of sinusoidal current distribution in each antenna, induced EMF method is used and restricted to two antennas of equal size. The formulations of the mutual impedance are expressed in terms of sine-integrals and cosine-integrals in section II. Analysis by using formulation of mutual coupling for dielectric determination are presented in section III. It shows the possibility to determine dielectric property by measuring mutual coupling of parallel and perpendicular dipoles. This paper is concluded in section IV.

II. MUTUAL IMPEDANCE OF PERPENDICULAR DIPOLES

A. *Near-zone Field of a Thin Dipole*

Consider two center-fed dipoles of length L when the primary antenna is placed along the z axis of a cartesian coordinate system. Its feed point, which is assumed to have infinitesimal spacing, is located at the origin. The secondary antenna with the same configuration, is separated by a distance d and h along y and z axis, respectively, as shown in Fig. 1. As pointed out in [8]-[9], the near-zone field of a thin dipole in free space is

$$E_y = j\frac{\eta I_m}{4\pi y}\left(\frac{(z-H)e^{-jkR_1}}{R_1}+\frac{(z+H)e^{-jkR_2}}{R_2}-\frac{2z\cos(kH)e^{-jkr}}{r}\right). \quad (1)$$

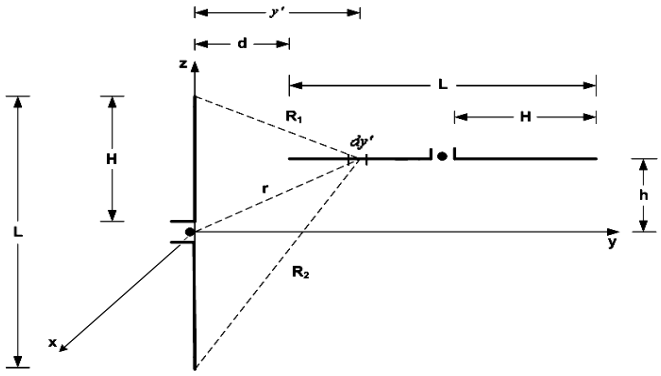

Figure 1. Geometry of two perpendicular dipole antennas.

The antenna current distribution $I_2(y')$ is assumed to be sinusoidal and given by

$$I_2(y') = \begin{cases} I_m \sin[k(y'-d)] & ; \quad d<y'<H+d \\ I_m \sin[k(2H+d-y')] & ; H+d<y'<2H+d \end{cases} \tag{2}$$

where I_m and η denote the maximum current and the intrinsic impedance, respectively.

B. Derivation of Mutual Impedance

With the induced emf method, the mutual impedance between the two antennas in Fig. 1. is defined by

$$Z_{21} = -\frac{V_{21}}{I_1(0)} \tag{3}$$

where V_{21} denotes the open-circuit voltage at the terminals of the secondary antenna, due to the feed-point current $I_1(0)$ in the primary antenna. The open-circuit voltage at the terminal of the secondary antenna which results from the voltage induced along the length of the antenna may be found by the application of reciprocity theorem.

$$V_{21} = -\frac{1}{I_2(0)} \int E_{y21} I_2(y')\, dy' \tag{4}$$

where $I_2(0)$ and E_{y21} are the feed-point current of the secondary antenna and the parallel component of electric field at the secondary antenna due to the primary antenna respectively.

Substituting (1), (2) and (4) into (3), one obtains a standard expression for mutual impedance [8]

$$Z_{21} = -\frac{1}{I_1(0) I_2(0)} \int E_{y21} I_2(y') dy'. \tag{5}$$

Integration of E_{y21} and $I_2(y')$ with respect to y' in (5) can be carried out directly, resulting in

$$Z_{21} = -j \frac{\eta I_{1m} I_{2m}}{4\pi I_1(0) I_2(0)} \left[\left\{ \int_d^{H+d} \sin\left[k(y'-d)\right] + \int_{H+d}^{2H+d} \sin\left[k(2H+d-y')\right] \right\} \times \left(\frac{(z-H)e^{-jkR_1}}{yR_1} + \frac{(z+H)e^{-jkR_2}}{yR_2} - \frac{2z\cos(kH)e^{-jkr}}{yr} \right) dy' \right]. \tag{6}$$

The geometry of Fig. 1 reveals that

$$R_1 = \sqrt{(H-h)^2 + y'^2} \tag{7}$$

$$R_2 = \sqrt{(H+h)^2 + y'^2} \tag{8}$$

$$r = \sqrt{h^2 + y'^2}. \tag{9}$$

The mutual resistance and the mutual reactance are obtained from real and imaginary parts of the complex expression (6). Although Eq. (6) can be evaluated by digital computation method, derived-form computation is more convenient.

Inserting (7)-(9) into (6), and following the integrations to yield the most general expressions for the mutual impedance between two infinite thin perpendicular center-fed antennas, the mutual resistance and reactance of the perpendicular dipoles are shown in (10) and (11), respectively.

$$\begin{aligned} R_{21} = \frac{15}{d\sin^2(kH)} \Big[& (h-H)\Big\{\cos(kd)\big(Ci(u_1)-Ci(u_0)+Ci(v_1)-Ci(v_0)\big)+\cos(k(2H+d))\big(Ci(m_1)+Ci(m_4)-Ci(u_0)-Ci(v_0)\big) \\ & +\sin(kd)\big(Si(u_1)-Si(u_0)+Si(v_1)-Si(v_0)\big)+\sin(k(2H+d))\big(Si(m_1)-Si(m_4)-Si(u_0)-Si(v_0)\big)\Big\} \\ & +(h+H)\Big\{\cos(kd)\big(Ci(u_2)-Ci(u_3)+Ci(v_2)-Ci(v_3)\big)+\cos(k(2H+d))\big(Ci(m_2)+Ci(m_5)-Ci(u_3)-Ci(v_3)\big) \\ & +\sin(kd)\big(Si(u_2)-Si(u_3)+Si(v_2)-Si(v_3)\big)+\sin(k(2H+d))\big(Si(m_2)+Si(m_5)-Si(u_3)-Si(v_3)\big)\Big\} \\ & +2h\cos(kH)\Big\{\cos(kd)\big(Ci(u_5)-Ci(u_4)+Ci(v_5)-Ci(v_4)\big)+\cos(k(2H+d))\big(Ci(u_5)+Ci(v_5)-Ci(m_3)-Ci(m_6)\big) \\ & +\sin(kd)\big(Si(u_5)-Si(u_4)+Si(v_5)-Si(v_4)\big)+\sin(k(2H+d))\big(Si(u_5)+Si(v_5)-Si(m_3)-Si(m_6)\big)\Big\}\Big] \end{aligned} \tag{10}$$

$$X_{21} = \frac{15}{d\sin^2(kH)}\Big[(h-H)\Big\{\sin(kd)\Big(Ci(u_0)-Ci(u_1)+Ci(v_1)-Ci(v_0)\Big)+\sin\big(k(2H+d)\big)\Big(Ci(u_0)-Ci(v_0)+Ci(m_1)-Ci(m_4)\Big)$$
$$+\cos(kd)\Big(Si(u_1)-Si(u_0)+Si(v_0)-Si(v_1)\Big)+\cos\big(k(2H+d)\big)\Big(Si(v_0)-Si(u_0)-Si(m_1)+Si(m_4)\Big)\Big\}$$
$$+(h+H)\Big\{\sin(kd)\Big(Ci(u_3)-Ci(u_2)+Ci(v_2)-Ci(v_3)\Big)+\sin\big(k(2H+d)\big)\Big(Ci(u_3)-Ci(v_3)+Ci(m_2)-Ci(m_5)\Big)$$
$$+\cos(kd)\Big(Si(u_2)-Si(u_3)-Si(v_2)+Si(v_3)\Big)+\cos\big(k(2H+d)\big)\Big(Si(v_3)-Si(u_3)-Si(m_2)+Si(m_5)\Big)\Big\}$$
$$+2h\cos(kH)\Big\{\sin(kd)\Big(Ci(u_4)-Ci(u_5)-Ci(v_4)+Ci(v_5)\Big)+\sin\big(k(2H+d)\big)\Big(Ci(v_5)-Ci(u_5)-Ci(m_3)+Ci(m_6)\Big)$$
$$+\cos(kd)\Big(Si(u_5)-Si(u_4)+Si(v_4)-Si(v_5)\Big)+\cos\big(k(2H+d)\big)\Big(Si(u_5)-Si(v_5)+Si(m_3)-Si(m_6)\Big)\Big\}\Big] \quad (11)$$

where

$$u_0 = k\left[(H+d)-\sqrt{(H-h)^2+(H+d)^2}\right]$$
$$u_1 = k\left[d-\sqrt{(H-h)^2+d^2}\right]$$
$$u_2 = k\left[d-\sqrt{(H+h)^2+d^2}\right]$$
$$u_3 = k\left[(H+d)-\sqrt{(H+h)^2+(H+d)^2}\right]$$
$$u_4 = k\left[d-\sqrt{h^2+d^2}\right]$$
$$u_5 = k\left[(H+d)-\sqrt{h^2+(H+d)^2}\right]$$
$$v_0 = k\left[\sqrt{(H-h)^2+(H+d)^2}+(H+d)\right]$$
$$v_1 = k\left[\sqrt{(H-h)^2+d^2}+d\right]$$
$$v_2 = k\left[\sqrt{(H+h)^2+d^2}+d\right]$$
$$v_3 = k\left[\sqrt{(H+h)^2+(H+d)^2}+(H+d)\right]$$
$$v_4 = k\left[\sqrt{h^2+d^2}+d\right]$$
$$v_5 = k\left[\sqrt{h^2+(H+d)^2}+(H+d)\right]$$
$$m_1 = k\left[\sqrt{(H-h)^2+(2H+d)^2}+(2H+d)\right]$$
$$m_2 = k\left[\sqrt{(H+h)^2+(2H+d)^2}+(2H+d)\right]$$
$$m_3 = k\left[\sqrt{h^2+(2H+d)^2}+(2H+d)\right]$$
$$m_4 = k\left[(2H+d)-\sqrt{(H-h)^2+(2H+d)^2}\right]$$
$$m_5 = k\left[(2H+d)-\sqrt{(H+h)^2+(2H+d)^2}\right]$$

III. Simulation Results

In order to determine the accuracy of the formulas (10) and (11), two thin perpendicular center-fed dipole antennas in Fig. 1 have been analyzed. The mutual impedance are calculated using the formulation (10) and (11), and compared to the results obtained from digital computation [2], and electromagnetic simulator [10]. The comparisons of mutual impedance are shown in mutual impedance curves which spacing between two antennas are extended to two wavelength.

A. Comparison with Digital Computation and Electromagnetic Simulator

As can be easily seen from the curves in Fig. 2, the mutual impedance obtained from the closed-form formulas of this paper are in agreement with those obtained from digital computation [2], and electromagnetic simulator [10]. However, there are deviations of both real and imaginary parts within the range of spacing between antennas d/λ is equal to 0.2-0.6. If the value obtained from the electromagnetic simulator is set as a reference value, resistance values of the closed-form formulations are more accurate than those from digital computation. On the other hand, reactance value of the digital computation is more accurate than those from the closed-form formulations.

B. Mutual Impedance for Different Heights

Height variation shows the trend of mutual impedance which both antennas are half-wavelength and height of the secondary antenna are varied within half of the primary antenna length range. Fig. 3 and 4 present mutual resistance and mutual reactance curves in terms of the parameter d/λ, respectively. It can be noticed from Fig. 3 that the mutual resistance becomes higher as the height increases at the spacing between antennas equals 0.2-0.4 d/λ. However, it decreases to zero as the spacing between antennas increases. Fig. 4 shows that the mutual reactance becomes higher as the height increases at the spacing between antennas equals 0.2 d/λ while it decreases as the spacing between antennas increases.

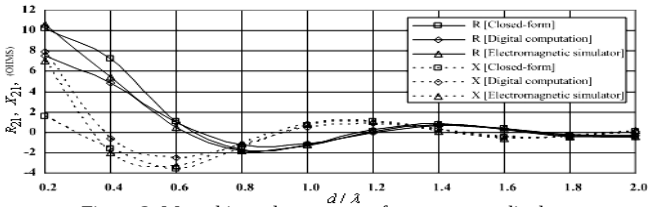

Figure 2. Mutual impedance curves for two perpendicular half-wavelength antennas.

C. *Mutual Coupling in Different Dielectrics*

A new concept for dielectric determination using linear dipoles to measure magnitude of mutual coupling are presented. The presented method uses the concept of switching the antennas configuration which between perpendicular and parallel-in-echelon. The mutual coupling curves with various dielectrics and spacing between antennas, at 2.45 GHz, extended from 0.2-0.8 d / λ are presented in Fig. 5. It can be noticed that there are cross points between S_{21} of perpendicular and parallel-in-echelon configurations with the same spacing. Thus, the cross points can notify the unknown dielectric constant of the object. The result in Fig. 5 is based on the halfwave dipoles in free space and the cross points of mutual coupling of parallel and perpendicular dipoles are in the range of $10 \le \varepsilon_r \le 40$. In order to utilize this method in higher ε_r range, the dipoles must be halfwave long in higher dielectric constant. Fig. 6 shows the results when the dipoles are halfwave in ε_r = 81. It is clear that the dielectric constant in the range of $90 \le \varepsilon_r \le 100$ can be determined.

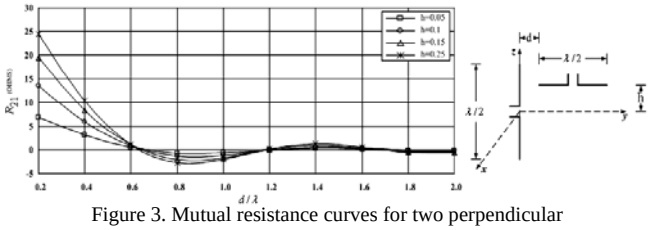

Figure 3. Mutual resistance curves for two perpendicular half-wavelength antennas with various height.

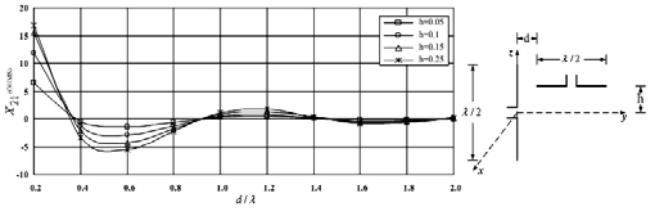

Figure 4. Mutual reactance curves for two perpendicular half-wavelength antennas with various height.

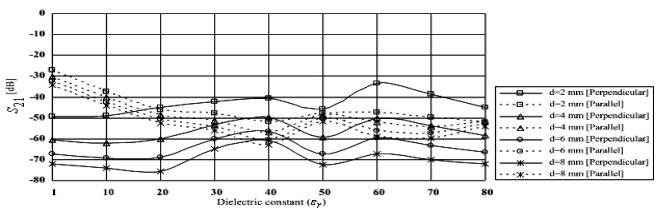

Figure 5. Mutual coupling curves for two perpendicular and parallel half-wavelength antennas with various dielectrics.

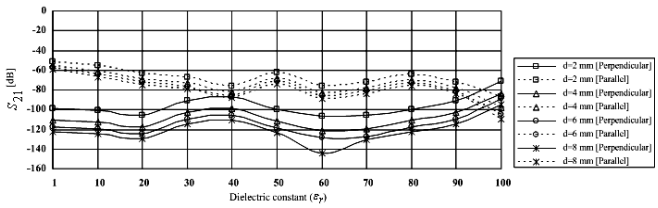

Figure 6. Mutual coupling curves for two perpendicular and parallel half-wavelength of ε_r =81 antennas with various dielectrics.

IV. CONCLUSION

Analytic expressions are derived and presented for the mutual impedance between two thin perpendicular center-fed dipoles of arbitrary size. Both antennas are assumed to have sinusoidal current distribution. The mutual impedances are calculated and presented. In addition, as shown with the mutual impedance curves in Fig. 2, calculated values of mutual impedance using the presented expressions compared with values from digital computation and electromagnetic simulator. The accuracy of the formulas is favorably compared and the integrations in the expressions contain no special functions, furthermore, they are in suitable forms for implementation. This paper has shown an application of these expressions in determination of lossless dielectric property. The future work will be focused on determination of lossy dielectrics.

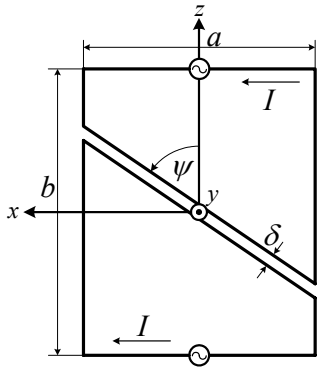
I. INTRODUCTION

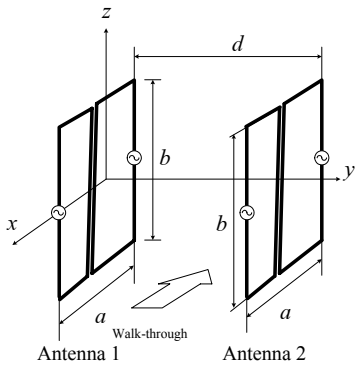
At present, Radio Frequency Identification (RFID) system becomes popular due to their usefulness in many applications. The animal identification in the farm is one of the most promising applications of RFID system at low frequency (LF). This system can assist increase the facilitation and efficiency. The LF band of 125 kHz and 134.2 kHz is used for human and animal safety. The principle of magnetic coupling is applied to communicate between readers and tags. The antenna is a key device to enhance the communication performance of this system. Conventionally, the rectangular- and circular-loop antennas are used as the reader antenna. It is found that those antennas cannot communicate with some tag orientations due to their generating null fields. Recently, the trapezoidal dual loop antenna has been proposed to improve the communication performance in various tag orientations [1]. In addition, the two trapezoidal dual loop antennas must be installed in parallel to make a walk-through gate for animal passing. Therefore, the individual antenna parameters and combined parameters of two antennas affect the communication performance. This paper presents the structural analysis to optimize the system performance. The Genetic Algorithms (GA) is used as an optimization tool, where the optimizing characteristics were simulated by Numerical Electromagnetic Code (NEC) [2]. The communication performance is expressed in terms of percentage of volume for communication achievement. The optimized results are used for the antenna design in the LF-RFID system. The prototype antenna will be fabricated with walk-through gate installation to measure the percentage of volume. Measured results confirm the usefulness of the antenna for further animal identification applications.

II. A TRAPEZOIDAL DUAL LOOP ANTENNA FOR LF-RFID

The proposed antenna consists of two adjacent trapezoidal dual loop antennas made of the conducting wire as shown in Fig. 1(a). The width, total height and angle of the slant line are denoted by a, b and ψ, respectively. The spacing between two trapezoidal dual loops along the slant line is represented by δ.



(a) Trapezoidal loop antenna.



(b) Walk-through gate arrangement.

Figure 1. Antenna configuration and arrangement.

In the animal identification, two trapezoidal dual loop antennas are installed in walk-through gate arrangement as

illustrated in Fig. 1(b). The distance between two trapezoidal dual loop antennas is equal to *d*.

III. METHOD OF ANALYSIS

The structural analysis of the antenna will be optimized by GA. It is well known that GA is robust search techniques based on the principle of evolution. GA maintains a population of encoded solution, and guides the population towards the optimum solution. This process is facilitated through an evaluation procedure, or fitness function, that determines the fitness or worth of each member of the population. Probabilistic genetic operators are employed to recombine highly fit individuals and search the solution space for better and better solutions. Fig. 2 shows a flow chart of the GA used in this paper.

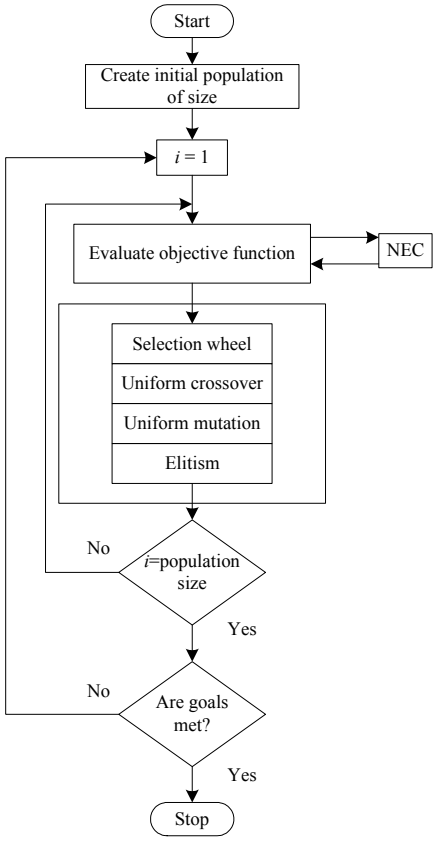


Figure 2. Flow chart of GA used in this paper.

In this paper, GA implements selection wheel for selecting variable in mating pool and uses uniform crossover and mutation operator. The elitism operator forces the best member of each population to progress to the next generation. With a population size of 50, crossover probability is 0.8 and mutation probability is 0.05. The operator parameters are chosen by using the rule of thumb [3].

GA begins a search with a large population of randomly generated individuals that are solutions to a problem. This randomness produces a diverse population of possible solutions representing a broad cross section of the entire solution space. For the problem at hand, each individual in the population represents an antenna design. This random altering of a small percentage of the population helps maintaining the global nature of the search. New population are produced and evaluated for many generations until the population converges to the same solution, or some other stopping criteria are met.

The goal of the design process is to develop the antenna meets or exceeds the desired performance. The desired antenna performance in this paper is the uniformly maximum magnetic field intensity and the percentage of volume.

The percentage of volume for communication achievement is probability of all points in the space that have magnetic field strength stronger than the activation field intensity (H_t) of a tag.

This paper considers the percentage of volume in three principal axes (*x*-axis, *y*-axis and *z*-axis). So the fitness function (F) in this case is the percentage of volume in three axes.

$$F = [P_{vx},\ P_{vy},\ P_{vz}], \tag{1}$$

where P_{vx}, P_{vy} and P_{vz} are the percentages of volume in *x*, *y* and *z* axes, respectively.

The evaluation of percentage of volume starts from considering percentage of line (P_l). It is determined by considering a tag goes through gate along a straight line from the entrance to the exit. If some points in the line (parallel to the *x*-axis) has $H(x,y,z) \geq H_t$, then the percentage of that line is 100%. However, if every point along the line has $H(x,y,z) < H_t$, the percentage of line is 0%. Note that $H(x,y,z)$ is the magnetic field intensity simulated by NEC at any point parallel to the *x*-*z* plane. (H_t is assumed to be 175 mA/m for the ISO card). The evaluation of the percentage of surface is subsequently calculated by (2).

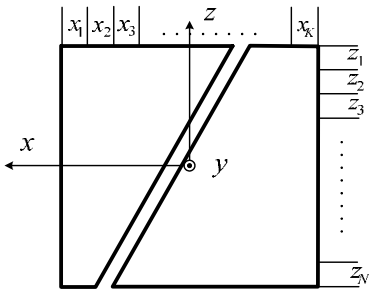

Figure 3. Consideration of the percentage of line parallel to the *x*-*z* plane.

$$P_s(y_m) = \frac{\sum_{n=1}^{N} P_l(z_n)}{N}\ , \tag{2}$$

where N is the total number of lines along the *z* axis, $P_s(y_m)$ is the percentage of surface in the *x*-*z* plane, $P_l(z_n)$ is the percentage of line along the *x* axis. Note that $P_s(y_m) \leq 100\%$. The subdivided area is shown in Fig.3.

The percentage of surface is consequently used to evaluate the percentage of volume (P_v) by equation (3).

$$P_v = \frac{\sum_{m=1}^{M} P_S(y_m)}{M} \quad , \tag{3}$$

where M is the total number of surface parallel to the x-z plane between two gate as shown in Fig.4. Note that $P_v \leq 100\%$.

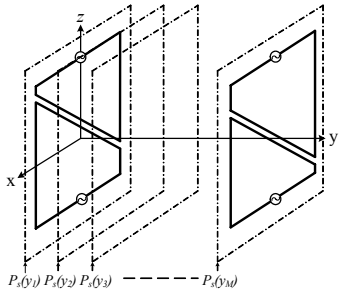

Figure 4. Consideration of the percentage of volume.

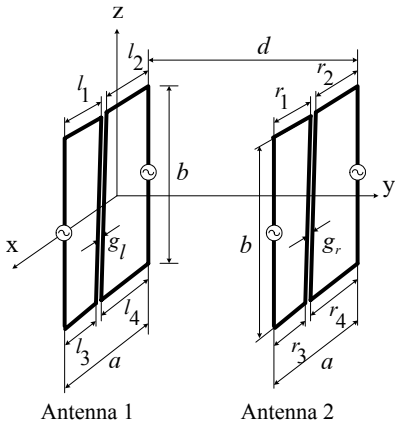
In addition, the considered volume must cover all regions between two antennas. Therefore, this paper uses the following dimension to obtain the percentage of volume: x-axis from -0.3m to 0.3 m, y-axis from 0 to 1 m and z-axis from -0.45m to 0.45 m.

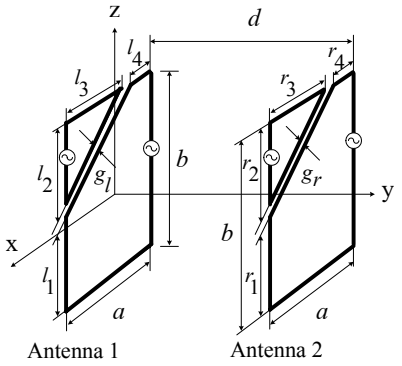
IV. Structural Analysis

Fig.5 shows trapezoidal dual loop antennas set up in walk-through gate arrangement. The total width (b), the length (a) and the distance between antennas (d) are equal to 60 cm, 90 cm and 1m, respectively. These parameters are chosen due to the physical dimension for the actual animal identification in the farm.

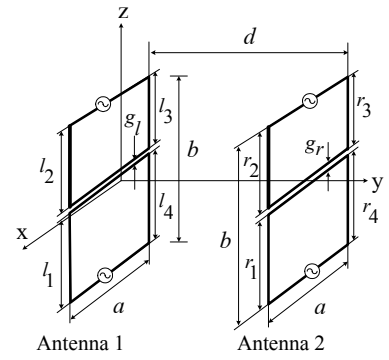
In the previous work [1], the antenna parameters are varied but it cannot cover the entire space of applications. Hence, this paper separates the walk-through gate antenna into six models by considering the ψ angle to cover 0° to 360°. In each of the six models, there are two cases of study. The first case is that Antennas 1 and 2 are fed in-phase, and the other is that the Antennas 1 and 2 are fed 180° out-of-phase. All of them are optimized by using GA.



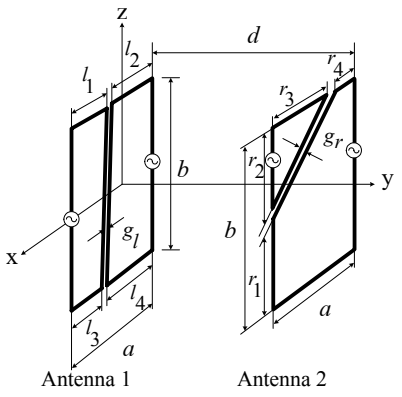
(a) Type I.



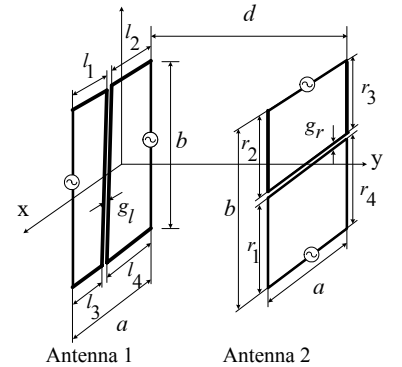
(b) Type II.



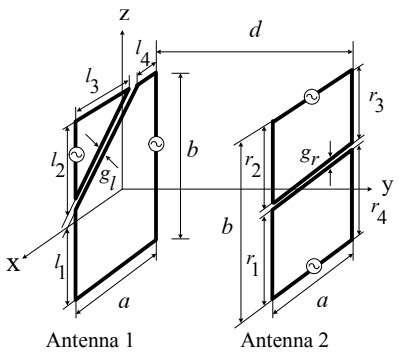
(c) Type III.



(d) Type IV.



(e) Type V.



(f) Type VI.

Figure 5. Trapezoidal dual loop antennas with walk-through gate arrangement of 6 types.

When the intricate manipulation by genetic algorithms is completed, it is found that the optimum model is shown in Fig.6 with the out-of-phase excitation. It has the percentage of volume as P_{vx} = 93.82%, P_{vy} = 91.32% and P_{vz} = 70.78%, respectively.

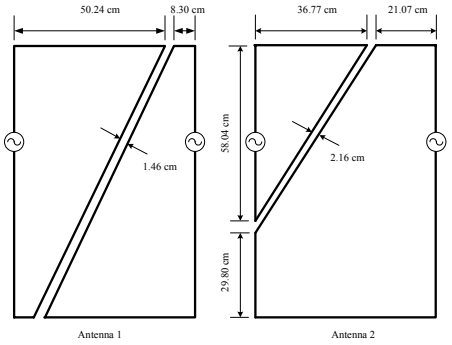


Figure 6. The actual dimension of the optimum trapezoidal dual loop antennas for the walk-through gate arrangement.

TABLE I

ANTENNA DESIGN PARAMETERS

Parameters of Antenna 1	Unit (cm)	Parameters of Antenna 2	Unit (cm)
l_1	50.24	r_1	29.80
l_2	8.30	r_2	58.04
l_3	8.30	r_3	36.77
l_4	50.24	r_4	21.07
g_l	1.46	g_r	2.16

V. MEASURED RESULTS

The measurement set up is carried out in the case that the trapezoidal dual loop antennas with the some dimension as in the optimum model are installed as the walk-through gate configuration shown in Fig.7. The prototype trapezoidal dual loop antenna is constructed by using the wire No. 24 AWG with 17 turns. The left-hand side is Antenna 1 and the right-hand side is Antenna 2. The tag under test is the ISO card.

Figure 7. Fabricated trapezoidal dual loop antennas for the walk-through gate arrangement.

The measured percentages of surface versus the distance along the *y* axis is shown in Fig.8. It is found that the measured percentages of volume are P_{vx} = 100%, P_{vy} = 93.08% and P_{vz} = 91.12%, respectively. The results are significantly better than the previous work [1].The discrepancy between the simulation and measurement is found because the area of tag in the measurement that is larger than the detected point in the simulation. Moreover, the coupling of the magnetic field in other axes around the tag is also making contributes to this discrepancy.

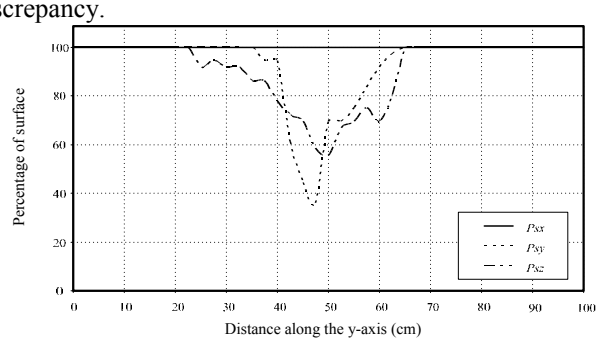

Figure 8. Measured percentage of surface versus the distance along the *y* axis.

VI. CONCLUSIONS

The genetic algorithms in conjunction with NEC are employed to optimize the trapezoidal dual loop antennas with walk-through gate arrangement. Results show the enhancement of communication performance over the previous work. This configuration was also fabricated and tested. The measurement data for percentages of volume are as follows: P_{vx} = 100%, P_{vy} = 93.08% and P_{vz} = 91.12%, respectively. This antenna can be efficiently used in RFID system at low frequency.

***Abstract* -- A new way of implementing SCADA systems is proposed by means of embedded TCP/IP boards and Internet. This kind of embedded boards and ADSL technology are used to integrate Internet as the communication network in the system. The public nature of Internet makes the idea obviously be a low-cost solution providing a high operation flexibility on SCADA systems. The experimental results show that the solution can work in a real-time manner and it is possible to deploy this idea in newly building or upgrading general SCADA systems.**

***Keywords:* Internet, Web-based SCADA, TCP/IP.**

I. INTRODUCTION

Supervisory Control and Data Acquisition (SCADA) systems are now becoming more and more popular in industrial processes and the demands in functionality and high performance have been increasing rapidly. Furthermore, the fast development of microprocessor manufacturing and Internet technology makes it more efficient and cost-saving to design such systems with the embedded network protocol modules.

The Internet has now been dedicating a new and highly-efficient medium for sharing information all over the world. The development of web technologies allows information to be displayed numerically and graphically on any conventional Internet browser. Via Internet browsers (or web-browsers), end users can access, monitor the real-time data and even control the field devices and equipments.

In [1] Andrew, et al. presented a remote data acquisition system for experimenting using power system's hardwares. The application software, based on the server/client module, has the task of performing the data communication over the Internet. Data Socket Server module created by National Instruments, which eliminates the difficulties of Transmission Control Protocol (TCP) programming, was used. The system is protected by password-authentication, approved Internet Protocol (IP) addresses and a physical protection scheme for the power hardwares. The research gave users the ability to monitor the data, which had been logged and saved in the server's database, in the forms of trends and tables via web-browsers. However, the real-time criterion was not mentioned in this work. Again in power system's application, Zhang Donglai, et al. [2] proposed an internet-based SCADA system. A TCP module, which is manufactured by Ubicom, namely IP2012, was used to collect necessary data and transmit those data to the Internet. This module also supports the User Datagram Protocol (UDP). However, UDP is not as reliable as TCP, and it is not preferably used in Internet-based telemetry systems. PPPoE (Point to Point Protocol over Ethernet) was employed to connect the data in the IP2012 directly to the Internet. This led to complexity in term of programming. Nevertheless, this research did not mention about the data transfer speed actually achieved and the system's security issue, though these concerns are very important.

In order to give a solution to improve the communication ability, Wei-Fu Chang, Yu-Chi Wu and Chui-Wen Chiu [3] built a model of a web-based remote load supervision and control. Programmable Logic Controllers (PLCs) were used to collect data from and give control to field devices. The server/client model was used again with two given options: first, the PLC is connected to an RS-232/TCP-IP converter for the data to be sent to the Internet, and remote users can both access the data directly via the IP address of the converter and the server's database; second, there is no converter, but the PLCs are connected to server PC and the data is stored in the server's database. The implemented system followed the second option. A Visual Basic (VB) program was developed in the client PC allowing the client users to connect to the database in the server PC. The data were both displayed on the VB screen and the web-browsers. The control commands to the loads were also issued via these two kinds of interface softwares. In a more general sense, M. Mahmud, et al. [4] used both Ethernet and Internet to build a SCADA system. Under the server/client framework, the system consists of several RTUs (Remote Terminal Units) and one SCU (SCADA Central Unit). The SCU was connected in the same Ethernet/LAN network with the RTUs. A data acquisition card was installed at each RTU to collect the data, and then these data were sent to the database at the SCU to be stored for further use. A VB program was developed in both computers at RTU side and SCU side for data monitoring and remote control. Users anywhere can also access the SCU database using web-browsers. Here, the security issue was not strictly considered in this research. The dial-up technology was used to connect the SCU to the Internet, causing a lot of problems with the speed of transferring data, since the dial-up network is quite slow. A more theoretical analysis about the advantages of utilizing Internet in SCADA applications and a comparison between Internet and other communication options was given in [5], by Robert H. McClanahan. Medida, et al. [6] presented a SCADA system based on the Internet for energy management system (EMS), using Java to make the SCADA database accessible and available to the remote Human Machine Interfaces (HMI) through web-browsers. No vendor dependent hardware, software and application are required at the remote location for SCADA but an Internet connection to gain access to the system from any corner of the world. In [7], Duo Li, et al. proposed a conceptual design for SCADA system with regards to all available Internet technologies. An implementation example was also given with Java and a web-based server application, Internet browser was used as the interface between system and users. Discussions about the security matter and some of Internet-related problems such as congestions, time constraint are given in [8-9].

In this paper, a solution to implement an Internet-based SCADA system is proposed with the presence of an embedded TCP/IP Protocol stack. The solution provides the following features:

- Automatically collect the latest data.
- Real-time data is displayed on web-browser interfaces, users can issue command controls from any internet-connected place.
- Security issue is carefully considered with: two layers of firewalls from router to server and client computers; user authentication and IP approval. This helps reduce the threat of the public nature of the Internet.
- New sites/devices can be added/deleted/tracked.
- Overall data transfer speed and time can also be tracked.

The paper is organized as follows. Section 2 depicts the general idea to build the solution. Section 3 describes the deployment scheme including hardware and software design, and initial experimental results. Discussions and conclusions are given in section 4.

II. System Architecture

The solution is built based on the client-server model with Internet being the communication network (See Fig. 1). Network programming techniques are used to develop the system's software.

- Server Tier

The server is built as a Web-based application composed of four functional modules: Real-time Data Acquisition, Active Data Objects and Remote Data Service, Device Control and Security Management.

These modules bring the ability to collect data from data acquisition part, display data on HMI softwares in real time, give control commands on devices and ensure the security of the entire system.

- Client Tier

There can be more than one client computers in the system, as long as authenticated. Client users can monitor data in real-time and issue supervisory control commands.

There are two communication methods:

1. Via Web-browsers

Authorized users can access and use the provided functions of the system through the web-based application built in server computer.

2. Via the IP addresses of the TCP/IP Protocol Stack

With IP-supported Protocol Stack, client users can interact directly with system's data and devices by a VB program.

- TCP/IP Protocol Stack

This is a special hardware embedded with a Dynamic Link Library (DLL) module. Supporting TCP/IP protocol, this module interfaces with the field device, collects data and sends these data to the Internet. It also has the tasks of receiving the control commands from the users and placing them on the field devices.

- Field Devices

These are the equipments in the real world from which the Protocol Stack collects data. They also perform the actions following the control commands from system's users.

III. Deployment Prototype

See Fig. 2. Internet is used as the communication network between server and client users; the SCADA center lies within the Ethernet LAN network with field devices.

A. Hardware Components

1. Server PC with Windows XP Service Pack (SP) 2, 3.0 GHz for CPU Speed and 1 GB for RAM Memory.
2. Client PCs with Windows XP Service Pack (SP) 2, 2.0 GHz for CPU Speed and 1 GB for RAM Memory.
3. Modem/Router.

Containing a built-in modem, the router has the task of connecting the system with one ISP (Internet Service Provider), making the system available on the Internet.

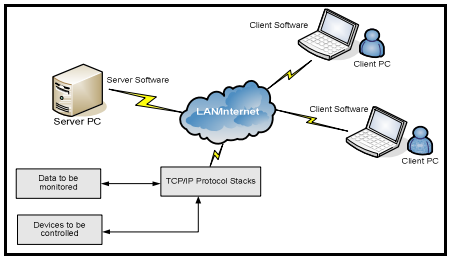

Fig. 1. General System Architecture

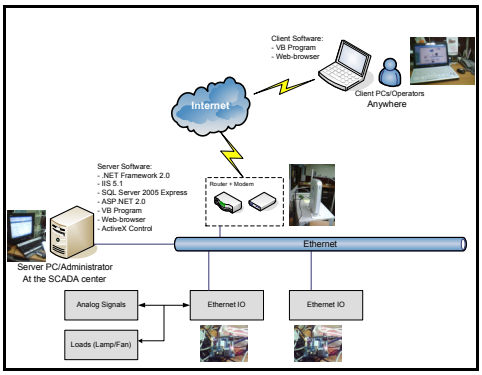

Fig. 2. Deployment Prototype Architecture

4. Ethernet IO boards.

See Fig. 3. The boards, developed by Design-Gateway with a LAN connector, are connected into the Ethernet network together with the server computer. They collect data from the field devices and transmit these data to the server. Additionally, with a network processor, the boards can support the TCP/IP protocol.

5. Field Devices

A voltage signal, which is simulated as the real-time data, will be fed to the Ethernet IO boards. Digital data or text file can also be used.

A fan and a lamp, connected to the Ethernet IO boards, are used to simulate the supervisory control function. They may receive the ON/OFF or Speed Increase/Decrease commands from the users.

B. System Software

- Data Management

The Web-based application in the server is built using the latest technologies from Microsoft, including Internet Information Service (IIS) 5.1, .NET Framework 2.0, SQL Server 2005 (MySQL is also supported), ASP.NET 2.0.

- Real-time Data Acquisition (RTDA): See Fig. 4.
- Real-time Data Viewer (RTDV): See Fig. 5.

This is an ActiveX control embedded into the Active Server Pages at server computer. It gives the ability to display the real-time data on web-browsers. Data can also be displayed on the HMI software written in VB at both server and client sides.

- Supervisory Control (See Fig. 6.)

Being integrated in the web-based application software on the server computer, this module allows placing control commands on devices. The communication is done within the Ethernet network established among the server and all the boards. Therefore, the communication is faster and more reliable.

Since more than one device can be installed in the system, the following functions can be added: devices add/remove and devices tracking by using the IP address of the Ethernet IO board to which the

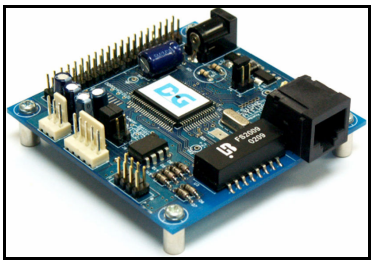

Fig. 3. Ethernet IO Board.

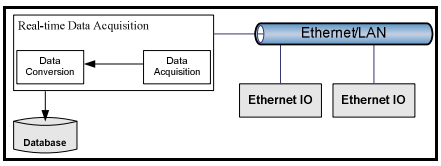

Fig. 4. RTDA Module.

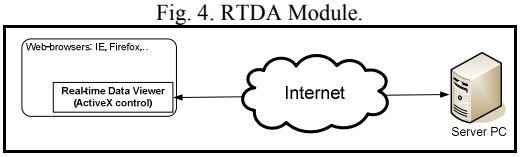

Fig. 5. RTDV Module.

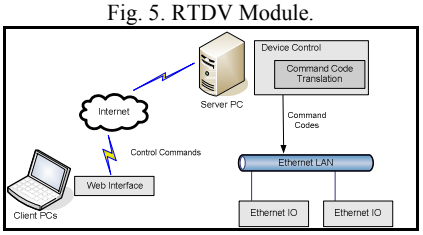

Fig. 6. Supervisory Control Module.

device is connected. A number of possible causes are given if any IP address is found missing.

Users can also use both the VB program and the web-browser to perform this function. At the client side, the communication is done over Internet.

- Security Management

There are four tools to be used: user authentication, permission distribution, IPs approval and router configuration. Two types of system operators are defined which are administrator and users. The administrator can create or delete accounts (users), pass or withdraw the right of other users. These jobs are done on web-interface, giving the administrator the ability to manage the system from any place as long as connected to the Internet. Normal users only have the right to perform actions which have been defined or distributed by the administrator. The IP approval tool is activated only when necessary, since it may reduce the flexibility of the system. A user with legal username and password may still not be able to access the system if the computer being in use does not have the IP address which is in the approval list. We can also use the router configuration page to perform the IP approval feature.

Firewalls in the router and in each computer using the system should also be turned on to prevent unwanted outsiders.

- System Performance Consideration

- The use of the IP-supported Ethernet IO boards makes it possible for the system administrator to add/remove/track the field devices. This lead to a flexible operation.
- Users can be anywhere; only an internet connection is required. This provides an easy and unlimited-range operation.
- Every necessary change to the system is done within the SCADA center, on the server PC.

Regarding the real-time issue, we have two communication stages, one is from the Ethernet IO board to the server and another is from the server to the client computer. Since the communication among the server and IO boards is in Ethernet network, the experimental results showed that we can achieve the real-time satisfactory and the data transfer speed can be up to 200 kbps. However, the communication over Internet between server and client computer may not be real-time and it depends on the Internet's traffic intensity. Nevertheless, the use of Asymmetrical Digital Subscriber Line (ADSL) technology gives a quicker access speed and we still can perform system's functions in a real-time fashion most of the time. A display of the estimated values of the data transfer speed from the IO boards to the client computer and the variance time between the server and client side are given. This brings a visual view about the performance of the system.

C. Implementation Results

Throughout the paper, we can see there are two ways to build the system software by using a VB program and using web-based software tools. Fig. 7 is a simple VB program used to connect to the IO boards directly over Internet and to do some testing experiments. Login step is illustrated in Fig. 8. After successful login, user can enter the overall web-based interface with the entire system, see Fig. 10. From here, user can perform the full system's features as mentioned.

The real-time data display functions are depicted in Fig. 11. Here, approximated numbers describing the data transfer speed and time between server and client side are also given. Fig. 9 describes the possible actions users can place on attached devices. Experimental system allows users to turn on/off a lamp, turn on/off as well as change the speed of a motor/fan.

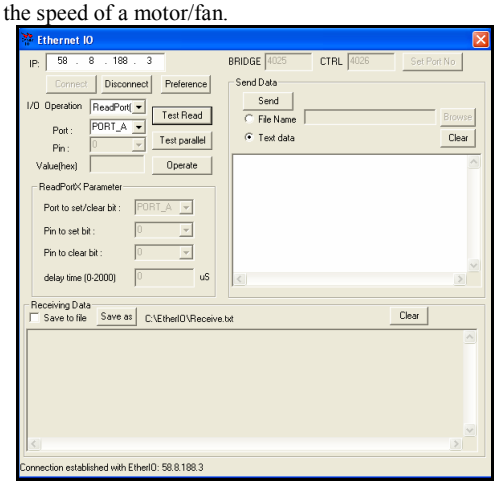

Fig. 7. Operation on Ethernet IO board over Internet using VB.

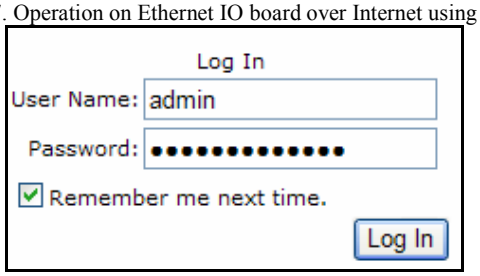

Fig. 8. Login Screen.

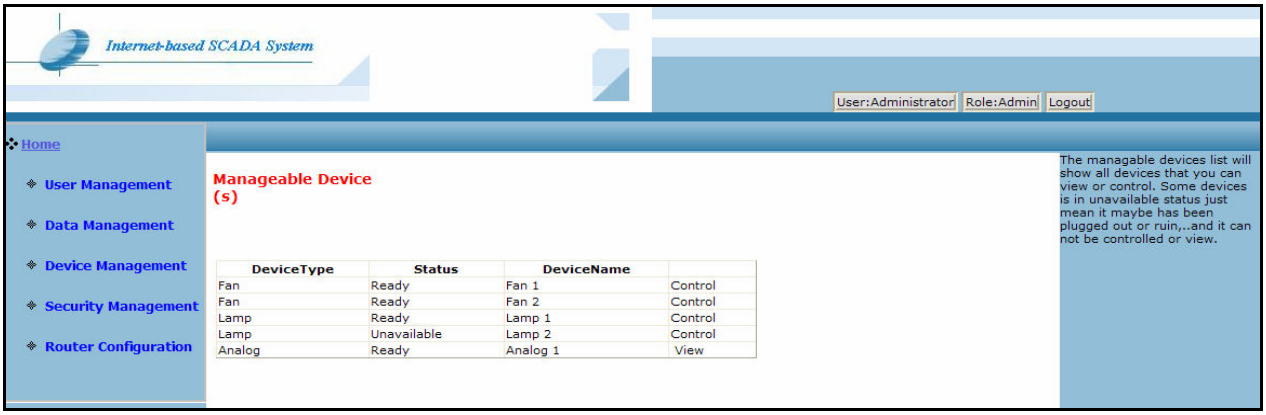

Fig. 10. Overall Web-based Interface

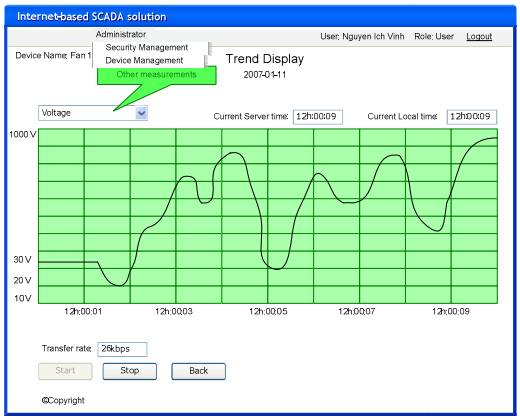

Fig.11. Real-time Data Display

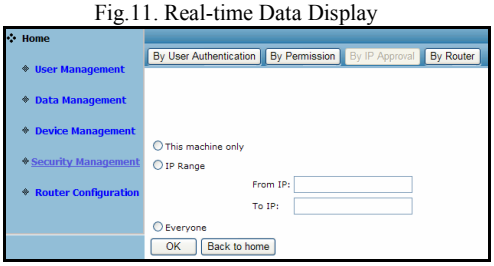

Fig. 12. Security Management by IP Approval.

See Fig. 12 for security management by IP approval. Other tools can be accessed by clicking the next tabs.

The web-based interface is friendly and easy-to-use. Information about how to perform each system's feature is also provided on the right column accordingly. Users can use this information for more appropriate actions.

IV. Conclusions

It is now becoming more and more visible and desirable for the ability to monitor data and even to place control commands on devices in a real-time manner with Internet used as the communication network. In this paper, an implementation of SCADA systems with real-time data monitoring, device control and security features has been presented. The proposed system was built on a web-based solution with IIS, ActiveX control and ASP programming; a VB program was also used as a testing tool and as optional HMI software. First experimental results showed that we can achieve the system's features as stated. Users, as long as stay connected to Internet, can monitor system's data in a real-time fashion and perform control actions on system's devices. The security issue has also been considered carefully. The presented solution is low-cost and easy to implement, while it still provides a high flexibility feature by using the IP-supported hardware components. With the development of hardware devices and Internet-based software technologies, this solution promises to give a more and more stable and reliable method in upgrading or newly building SCADA systems for various industries. The solution proposed in this research is most suitable for such applications as Fuel Unloading/storage and Feed, Water Supply Monitoring, Irrigation, Flood Warning, Oil and Gas Tracking.

Further study on this research can be based on other web technologies such as Java or Ajax to provide a more interactive operating environment in the system. A web camera server can also be added at the device or process places to provide a visual image of the devices' reactions for better system's performance evaluation.

Acknowledgement

Financial support from the AUN/SEED-Net JICA project for this presented research is greatly acknowledged.

A great thank is sent to Mr. Dao Quang Minh, who is an IT expert, for his significant advices on IT-related matters in the research.

Abstract

This paper presented the effects of attenuation from rain rate together with rain drop size distribution analysis on the model of transmitter broadband satellite in Ka-band frequency. We illustrated a new model by simulating transmission broadband signal and studied the rain attenuation which has effects to high frequency. The results of the model were represented by the relation between error probability and S/N. Moreover, the numbers of re-transmission cycles for completing the amount of data were also presented. The attenuation would be illustrated in log normal distribution forms and in PDF terms. The simulation would be run by taking error probability (Pe) of noise at 0.4, 0.04, 0.004 and 0.004.

Keywords : Ka-band, broadband satellite

I. INTRODUCTION

The rapid growth of telecommunication services, both in satellite and terrestrial links using higher frequency bands above 10 GHz has highlighted the need for estimating the effects of hydrometer such as rain, clouds, fog and gangues. The demand of ultra wide bandwidth for high speed, high quality, and multimedia transmission was driving the use of the higher radio frequency spectrum. However, attenuation and fading due to rain have long been recognized as a major limitation to reliable communication systems operating at higher frequencies. The presence of hydrometer in radio wave propagation, particularly rain, can produce major impairments to microwave propagation. Raindrops can be absorbed and scattering radio wave energy in signal attenuation, which can degrade the reliability and performance of the communication links. Rain attenuation can be obtained through measurement or predicted from knowledge of rain rate and drop size distribution. The modeling of the rain drop size distribution in temperature and tropical region is different. It is because tropical region has experiences heavy rain rate compared to temperature region.

Rain-induced attenuation on satellite earth communication links at frequency above 10 GHz is the predominant signal impairments. However, for the design of law margin systems, especially those at high frequency and low elevation angles, scintillation effects must be accounted for to complete a link budgets accurately. With an increased demand for direct-to-user satellite services, Ka-band has become a preferred alternative for many new systems as it offers a large bandwidth needed to support the anticipated need for capacity. While offering a solution to the problem of spectrum congression, Ka-band suffers from fading due to rain. Fade depths of dBs are commonly caused by rain. However, the ITU-R has mentioned that the attenuation in Ka-band is more than in C/Ku-Band and sensitive to location.

Chi and Chen[1] studied effect of rain fading of Ka-band for Taiwan and analyzed new model for LMDS. The results compared signal between measured and simulated in BER and S/N. Filip and Vilar[2] studied effect to channel capacity of satellite link which have effect amplitude scintillation and rain attenuation for optimal utilization. Paraboni, Masini and Eila[3] have found new model for analysis attenuation in high frequency. After that Germont and Filip[4] have brought Paraboni, Masini and Eila's model to analysis and to predict fade detection and also Germont and Filip[4] prove fading terms BER and S/N. Otherwise, M.Aloini, A.Borgsmiller and G.Steffes[5] presented many factors effect to Ka-band and create another model for high performance in the system. This paper presented the analysis of rain attenuation from rain rate and drop size distribution. The research was similar to A.Maitra[6] and Sekine,Chen and Musha[7] but considered in different frequency.

This paper presented new model for analysis broadband satellite at frequency Ka-band (30/20) GHz and the effect of the model was in the high value attenuation. The noise had log normal distribution forms The rain attenuation in Ka-band are described in section 2. In section 3, new model consider in new analysis. Analytical model was illustrated the relation between error probabilities versus S/N in binary bits and re-transmission for completing the data in section 4 and finally conclusion in section 5

II. RAIN ATTENUATION IN Ka-BAND

The capacity of white noise (AWGN) is given by Shannon's Expression method [8] by

$$C = BLog_2\left(1+\frac{S}{N}\right) \quad \text{(b/s)} \qquad (1)$$

B is the channel bandwidth in hertz and S/N is signal-to-noise power ratio for the channel in order to make the

analysis independence for the actual bandwidth of the channel can be written as

$$\frac{C}{B} = Log_2\left(1+\frac{S}{N}\right) \quad \text{(b/s)/Hz} \tag{2}$$

Where C/B represents the channel capacity due to propagation fading, the term S/N in (2) is random with un arbitrary but defines distribution depending on the type and characteristics of the fading process considered, the channel capacity is also random. The random variable of the channel capacity imposes performance degradation on the system that utilizes the channel. Therefore, one many wish to determine the probability density function (PDF) and cumulative (CDF) of the channel knowing those of S/N on equivalently, those of the fading process. The standard transformation of random variable, the PDF of C/B can be written in term of S/N. The rain attenuation reflected the signal to noise ratio level detailed in [2], [3] and [9]

$$\left(\frac{S}{N}\right) = \left[\frac{S}{N}\right]_0 - A \quad \text{(dBw)} \tag{3}$$

$\left[\frac{S}{N}\right]_0$ is signal to noise ratio level (dB) in clear condition

A is Attenuation from rain in satellite link

The CDF of the channel capacity is given by

$$F_{\frac{C}{B}}(Y) = F_{\frac{C}{A}}(X) = \Pr ob\left\{\frac{C}{B}\langle Y\right\} = \Pr ob\left\{\frac{S}{N}\langle f^{-1}(y)\right\} \tag{4}$$

$$= \Pr ob\left\{A\rangle\left(\frac{S}{N}\right)_O - f^{-1}(y)\right\} \tag{5}$$

$$= F_{\frac{C}{A}}\left[\left(\frac{S}{N}\right)_O - f^{-1}(y)\right] \tag{6}$$

if $y = \frac{C}{B}$

$$f^{-1}(y) = 10Log(2^y - 1) \tag{7}$$

so that

$$F_{\frac{C}{X}}(X) = P\{A\rangle X\} = \int_X^\alpha P_A(a)da \tag{8}$$

$$\text{X} = \left(\frac{S}{N}\right)_O - 10Log(2^y - 1) \tag{9}$$

A is approximately log normal distribution random variable. Therefore, the overall long-term distribution PDF of rain attenuation along the link has the term [10]

$$P_A = \begin{cases} \frac{1}{a\delta\sqrt{2\pi}}.\exp\left\{-\frac{(\ln a-\mu)^2}{2\delta^2}\right\} & a\rangle 0 \\ 0 & a\langle 0 \end{cases} \tag{10}$$

Where the term mean and standard variation will be discussed in later. We can expressed as

$$F_{\frac{C}{B}}(Y) = F_{\frac{C}{A}}(X) = \int_x^\alpha P_A da = Q\left(\frac{\ln x-\mu}{\delta}\right) \tag{11}$$

So that

$$Q = \int_\varphi^\alpha \left(1/\sqrt{2\pi}\right)e^{\frac{-t^2}{2}}.dt$$

For the log normal distribution, we have

$$P = F(\ln A) = \int \frac{1}{\delta\sqrt{2\pi}}.\exp\left[-\frac{(x-\mu)^2}{2\delta^2}\right].dx = Q\left(\frac{\ln A-\mu}{\delta}\right) \tag{12}$$

and

$$\frac{\ln A-\mu}{\delta} = Q^{-1}(P) = \alpha\ln A+\beta \tag{13}$$

$$\mu = \frac{-\beta}{\delta} \tag{14}$$

$$\delta = \frac{1}{\delta} \tag{15}$$

Equation (14) and (15) are mean and standard deviation respectively. They can be find by linear regression, where the slop δ and intercept β. From equation (12) we can get A (attenuation due to rain). This paper considered rain attenuation from rain drop size distribution and the specific attenuation A in dB/km due to rain is calculated by integrating over all of the drop size as

$$A = 4.343\int Q(D,\lambda,m)N(D)dD \tag{16}$$

Q is the attenuation cross section which is a function of the drop diameter D, the wavelength of the radio wave λ and the complex refractive index of the water drop m, which is a function of the function and temperature, and N(D) is the drop size distribution. The attenuation cross section Q is found by applying the classical scattering theory of Mie's for a plane wave impinging upon a spherical absorbing particle. By N(D) for Gamma distribution can be written

$$N(D) = N_T A^{n+1}D^n \exp\left[-\text{AD}/\Gamma(n+1)\right] \ (m^{-3}.mm^{-1}) \tag{17}$$

N(D) for Log normal distribution can be written

$$N(D) = \frac{N_T}{\sigma D\sqrt{2\pi}}.\exp\left[-\frac{1}{2}\left(\frac{\ln(D)-\mu^2}{\sigma}\right)\right] \ (m^{-3}.mm^{-1}) \tag{18}$$

Consider in Log normal distribution terms and froms (12)

$$P = F(\ln A) = \int_{\ln A}^\alpha \frac{1}{\delta\sqrt{2\pi}}.\exp\left[\frac{-\left(x-\mu^2\right)}{2\delta^2}\right].dx = Q\left(\frac{\ln A-\mu}{\delta}\right)$$

And (16), (18) -- [6], [7], [11]

$$A = 4.343\int Q(D,\lambda,m).N(D)dD$$

The cross section Q is expended as

$$Q(D,\lambda,m) = \frac{\lambda^2}{2\pi}.\sum_{n=1}^{\alpha}(2n+1)\,\mathrm{Re}[a_n + b_n]$$

$$A = (4.343)\left(\frac{\lambda^2}{2\pi}\right).\sum_{n=1}^{\alpha}(2n+1)\,\mathrm{Re}[a_n + b_n].\frac{N_T}{\sigma D\sqrt{2\pi}}.\exp\left[-\frac{1}{2}\left(\frac{\ln D - \mu^2}{\delta}\right)\right] \quad (19)$$

Where a_n and b_n are the Mie scattering coefficients and analysis in Bessel function [13], [14], which are complex function of m, D and λ. In equation(19), *A* is rain attenuation analysis in rain drop size distribution having log normal distribution term. We can be find N(D) for log normal distribution[7] and written as.

$$N(D) = \frac{N_T}{D(2\pi)^{\frac{1}{2}}\ln\sigma}.e^{-\left[\ln\left(\frac{D}{D_M}\right)/2\ln\sigma\right]^2}$$

Case 1 (Showers) $5\langle R\langle 50mm/hr$

$$N_T = 40R^{0.64}$$

$$D_M = 1.14 + 0.18\ln R$$

$$\sigma = e^{0.29-0.001R}$$

Case 2 (Showers) $5\langle R\langle 50mm/hr$

$$N_T = 46R^{0.55}$$

$$D_M = 0.222 + 0.397\ln R$$

$$\sigma = e^{0.5--.0035R}$$

Case 3 (Thunderstorms) $50\langle R\langle 200mm/hr$

$$N_T = 8.8^R$$

$$D_M = 1.76 + (7.33*10^{-4}).\ln R$$

$$\sigma = 1.37$$

III. MODELING CONSIDERATIONS

We designed the model for considering and simulating the generation of the random variables r_o and r_1 which constitute the input to the detector. The research has begun by generating a binary sequence of 0 and 1 that occur with equal probability and being mutually statistically independent. To accomplish this task, the random number generator was used to generate a uniform random number in range (0,1). If the generated number is in the range (0,0.5), the binary is 0. Otherwise, it is a 1. Additive noise components n_0 and n_1 are taken in equation (12) and (19), we analysis in rain rate is 50mm/hr and diameter of rain is 10mm. From [15]

$$\gamma_r = kR^{\alpha} \quad (20)$$

and

$$A = a_n R^{b_n} \quad (21)$$

From CCIR recommendation at 20GHz

$$a_n = K_H = 0.0751 \text{ (Horizontal Polarization)}$$
$$a_n = K_V = 0.0691 \text{ (Vertical Polarization)}$$

and

$$b_n = \alpha_H = 1.099 \text{ (Horizontal Polarization)}$$
$$b_n = \alpha_V = 1.065 \text{ (Vertical Polarization)}$$

Take value in (19), attenuation (*A*) was found from rain with rain rate at 50mm/hr and diameter of rain at 10 mm

Case 1 (Showers) $5\langle R\langle 50mm/hr$

A=-3.7369 dB/km

Case 2 (Showers) $5\langle R\langle 50mm/hr$

A=-3.186 dB/km

Case 3 (Thunderstorms) $50\langle R\langle 200mm/hr$

A=-3.4852 dB/km

The mean and standard deviation in PDF can be found from

$$\ddot{A} = \alpha R^{\beta}$$

and

$$\frac{\ln A - \mu}{\delta} = \delta\ln A + \beta$$

that

$$\mu = \frac{\beta}{\alpha} \qquad \delta = \frac{1}{\delta}$$

Horizontal Polarization has

$$\mu = \frac{\beta}{\delta} = \frac{1.099}{0.0751} = 14.633821$$

$$\delta = \frac{1}{\delta} = \frac{1}{0.0751} = 13.31557927$$

Vertical Polarization has

$$\mu = \frac{\beta}{\delta} = \frac{1.065}{0.069} = 15.4347826$$

$$\delta = \frac{1}{\delta} = \frac{1}{0.069} = 14.4927536$$

From $P = F(\ln A) = Q\left(\frac{\ln A - \mu}{\delta}\right)$, the PDF terms is in log normal distribution

IV. RESULT FROM SIMULATED

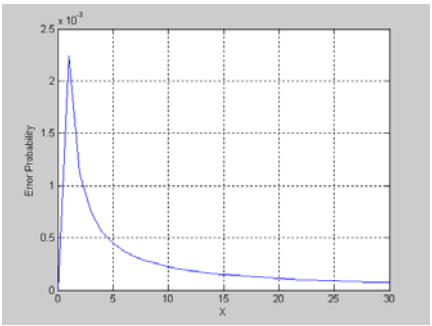

Figure 1 Simulation PDF rain attenuation

Figure 1 was the noise signal which was log normal distribution format. It was considered by using rain rate at 50 mm/hr and rain diameter at 10 mm. The noise was dope into the channel model ($P = F(\ln A) = Q\left(\frac{\ln A - \mu}{\delta}\right)$) by using different error probability (Pe).

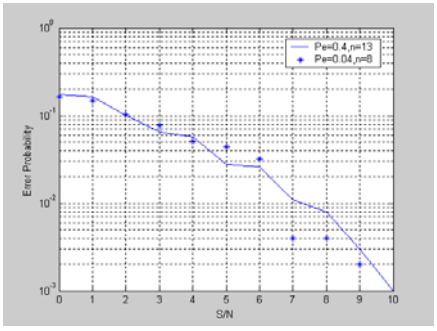

Figure 2 Illustrate Probability and S/N
Pe (0.4and 0.04)

The result from taking noise with error probability (Pe) at 0.4 and 0.04 was illustrated in figure 2. The system with Pe(0.4) needed to re-transmit data totally 13 times comparing to 8 times from Pe(0.04). In addition, the output error probability around the lower zone of S/N (0.1-4 dB) was not much different between Pe(0.4) and Pe(0.04). When the S/N got higher (more than 5 dB), the output error probability from Pe(0.4) was tentatively lower than Pe(0.04)

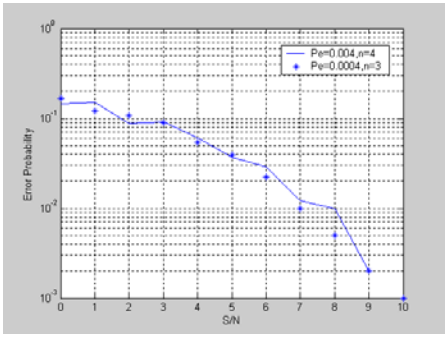

Figure 3 Illustrate Probability and S/N
Pe (0.04and 0.004)

Figure 3 was illustrated the result from taking noise with error probability (Pe) at 0.004 and 0.0004. The system with Pe(0.004) and Pe(0.0004) required data re-transmission wholly 4 and 3 times respectively. For the relation between error probability and S/N of the system by taking Pe(0.004) and Pe(0.0004), there was likely similar.

CONCLUSION

In this paper, the Ka-band transmission system was newly modeled by analyzing error probability from considering the noise from rain drop size and the high-value attenuation from rain. The results were shown in relation between error probability and S/N (in binary bits). Determinately, the higher the error probability was taken to the system, the more the re-transmissions were required by system. In conclusion, the rain rate and rain drop size destroyed the quality of Ka-band transmission channel.

ACKNOWLEDMENT

***Abstract* - In this paper, we study the variability of critical frequency (foF2) in F2-layer of the ionosphere. The foF2 data are obtained from the ionosonde at Chumphon campus of King Mongkut's Institute of Technology Ladkrabang (latitude 10.72°N and longitude 99.37°E), Thailand. The measurement data in 2004 and 2006 are analyzed diurnally and seasonally and compared with solar activity. The data established are proposed as equatorial input values used in the model development of the International Reference Ionosphere (IRI).**

Keywords: Equatorial Ionosphere, Ionospheric Variability, Ionogram, Critical Frequency

I. INTRODUCTION

The ionosphere is the ionized region in the earth's atmosphere extending from about 50-2000 km above the earth surface, containing the oxygen which ionizes resulting into free electrons and ions. The ionization level differs depending on the time and height of ionosphere. The F2 region of the ionosphere is the most effective layer for long distance high frequency (HF) radio communication as it is above other layers where the signals reflect. The F2 layer is the high altitude layer that has the most irregularity of electron density, which also severely affects to satellite signal using VHF and UHF bands. Accurate characteristics of the F2 layer are important to atmosphere understanding and design of HF, VHF and UHF communication systems. The knowledge of the critical frequency of (foF2) layer is essential in the range of usable HF frequencies and implication in atmospheric study. The critical frequency is usually given in terms of average value. This parameter is taken into consideration of the effect of time of the day, seasons, solar cycle and the coordinate location of the station on the surface of the earth. Even though the HF radio system is well studied and the F2 layer characteristics have been measured and compiled in many catalogs, continuous data collection is essential responding to continually changing atmospheric conditions and emerging digital HF radio systems.

Many results on ionospheric variability have been published in the literature. In [1], the ionospheric variability using hourly values data of different characteristics from nine ionospheric stations in the Northern hemisphere for one year of high solar activity is presented. In [2], the variability of foF2 at low and mid-latitude, obtained from 14 locations, is analyzed using the reduced standard deviation (r.s.d) technique. The monthly foF2 data are shown to depend on hours, seasons and solar cycle phase. Hourly foF2 data during 1967-89 are examined to quantify F-region ionospheric variability in [3]. In addition, variabilities from day-to-day and hour-to-hour of the ionospheric characteristics are done in. Ezquer et al. [4] presented the variability of the critical frequency and propagation factor M(30000)F2 observed at Tucuman in Argentina. The data are analyzed for different seasonal conditions and two levels of solar activity: low and high [5]. The deviation of hourly values of foF2 from the monthly median values is used to study the variability of foF2 for the period of high and low solar activity in [6]. Zhang et al. presented the ionospheric characteristic parameters to obtain from ionograms record by the DPS-4 digisonde at Hainan, China and analyzed the diurnal and seasonal behavior of the ionosphere variability [7]. Bilitza et al. presented the monthly variability of foF2; data from two equatorial stations in the African longitude sector are used to analyze variation diurnal, seasonal and solar activity effects [8]. A quantitative study on ionosphere variability is necessary for developing such a model for the International Reference Ionosphere. Recently, the observation of ionospheric variability in Thailand is conducted to analyze the ionospheric height changes [9] and the spread F phenomenon of the ionosphere [10]. Despite many studies of foF2 in many parts of the world and a few studies of ionospheric conditions in Thailand [9-10], the observation of the ionospheric variability of foF2 in Thailand is scarce.

In this paper, we study on the ionopheric variability of foF2 using data from bottomside ionograms recorded by the ionosonde at Chumphon campus of King Mongkut's Institute of Technology Ladkrabang (KMITL), Thailand, located near the magnetic equator. The measurement data in 2004 and 2006 are analyzed based on the diurnal, seasonal period and solar activity**.** The ionosonde technique is described in Section II and then the ionogram is explained in Section III. The experiment setup and measurement method is described in Section IV followed by Results and Discussions in Section V. Finally, in Section VI, the conclusions are made.

II. IONOSONDE TECHNIQUE

One of the traditional techniques used to monitor ionosphere is the ionosonde (or ionopheric sounder). This technique is still widely used today. The ionosonde is special radar that sweeps the shortwave band frequencies; it transmits

pulsed radio wave into the ionosphere and receives an echo in return [11]. The delay time is computed by multiplying the speed of light with the value of one-half the echo (propagation time up to the point of reflection) as the apparent altitude of reflection (h'(F)), then h'(F) will be higher than the actual altitude of reflection h(F); this value depends on the sounding frequency and the electron density distribution up to the point of reflection.

III. IONOGRAM

Ionogram is a photographic display of echo strength as a function of transmitted frequency produced by a sweep-frequency ionosonde [11]. In the frequency of sweep of the ionosonde, as the frequency of the pulsed radio wave is increased step-by-step, the echo returns from sequentially higher altitudes, where electron density is higher. By using observation technique, the echo is returned at an altitude below where maximum electron density. The maximum frequency with echo corresponding to the maximum electron density is referred as a critical frequency. Any pulse signals with frequency exceeding critical frequency will penetrate the ionosphere. Ionogram is used to infer the structure of the ionospheric layers and, hence, to predict radio transmission concentration.

The delay time of the echo pulse is illustrated as apparent height (h') versus frequency (f) with the ionogram shown in Fig. 1. The figure shows the apparent height in the F layer (h'F) and the critical frequencies in the F2 layer for ordinary waves (foF2) and extraordinary waves (fxF2) , by extra-ordinary frequency waves higher than ordinary waves. We also read the ionogram trace directly to obtain minimum value for apparent height of the F2 layer, the critical frequencies. Minimum apparent heights for the daytime F1 layer and E regions. Since electron densities are low in the D region and ionosonde cannot be used for detecting echoes.

The ionogram measurement is divided into topside and bottomside ionograms [11]. In this paper, we use bottomside ionogram. A major difference between topside and bottomside sounding is that the sounding pulse transmits from a point, where an electron density level already exists in the topside sounding, whereas for bottomside sounding, the pulse is transmitted from ground level, where the electron density is zero. In Fig. 2, the idealized topside and bottomside ionograms are shown. The ionograms vary greatly in appearance depending on several factors such as geographic locations, sunspot numbers, seasons, local time and degrees of noise.

IV. EXPERIMENTAL SETUP

The parameters used to study variability of critical frequency (foF2) of ionosphere are shown in Table 1. The data were collected from the ionosonde station located at Latitude 10.72°N, Longitude 99.37°E and magnetic latitude 3.22° at the Chumphon campus of King Mongkut's Institute of Technology Ladkrabang (KMITL), Thailand. The ionosonde station is near the magnetic equator. The ionosonde continuously transmits radio waves from 2 to 30 MHz for each round with transmission starts from 2 MHz and increases the frequency with an increment of 100 KHz s^{-1} up to 30 MHz The echoes from the ionosphere provide the bottom plasma density profile every 5 minutes. The sampled data interval is 15 minutes.

The analysis is done on hourly and yearly bases. The data analyzed in 2004 and 2006 are compared with moderate and low solar activities, respectively. Seasonal effects were investigated by using data (combining the hourly values of foF2 for all days of the months) from three months for each season: March Equinox (February, March, April), June Solstice (May, June, July), September Equinox (August, September, October) and December Solstice (November, December, January). We select years with comparable solar activities. Table 2 lists the years selected from the Chumphon station and average annual sunspot numbers.

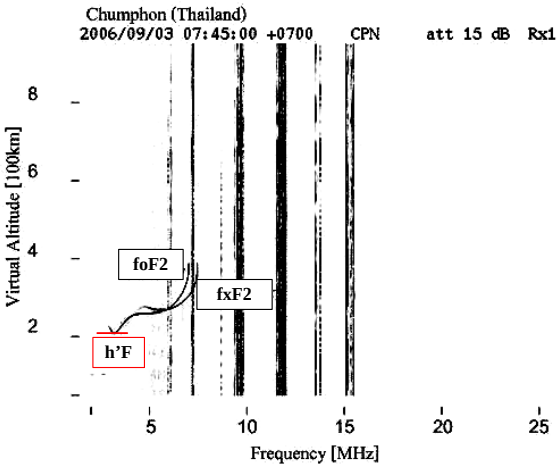

Fig. 1. Ionogram recorded at Chumphon.

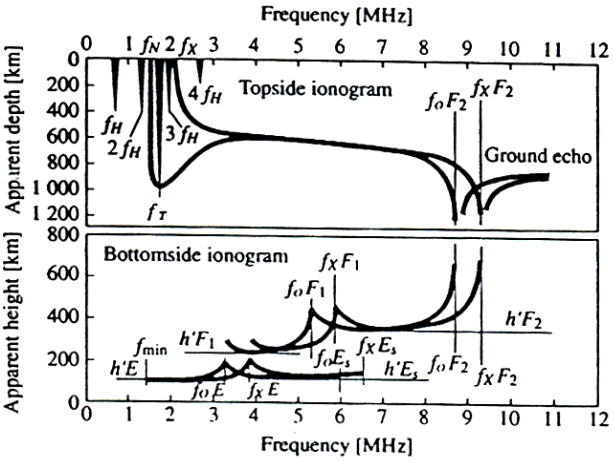

Fig. 2. Topside and bottomside ionograms.

Following the example of [3], [8] and others, we use the monthly mean of foF2 (μ) and standard deviation (σ) to evaluate the monthly variability as seen in the ionosonde data. Therefore, the relative standard deviation **VR** is given by:

$$VR\left[\%\right] = \left(\sigma/\mu\right) * 100 \qquad (1)$$

TABLE I
OBSERVATION PARAMETER OF IONOSONDE AT CHUMPHON

System	Frequency Modurated-Continuous Wave (FM-CW) With pseudo-random Tx/Rx switching
Peak Tx Power	20 W
Average Tx Power	10 W
Frequency Range	2-30 MHz
Sweep Rate	100 kHz s^{-1}
Sweep Repetition Period	5 min
Antenna	height 27 m, Folded dipole

TABLE II
DATA-YEARS USED IN THIS STUDY AND THEIR AVERAGE SUNSPOT NUMBER

Solar activity	Low	Moderate
Chumphon	2006 (Rz = 15.2)	2004 (Rz = 40.44)

The hourly values are representative of the monthly-hourly averages for the day of month. These monthly averages are used to compute the seasonal averages. On other hand, it is a good measure for describing the average deviation from monthly averages, but it is more difficult to interpret in terms of probability. The probability of the foF2 values falling between $\pm\sigma$ centered around μ is obtained for each hour in each seasons of the years under investigation.

V. MEASUREMENT RESULTS

Figure 3-4 show the diurnal variation patterns of the relative standard deviation (VR) of foF2 observed at Chumphon, Thailand, respectively. Each plot shows the variation of local time for four seasons. Generally, the average diurnal of VR follows the same trend at all solar activity levels. Variability is lowest during daytime (6-15%), and increases during nighttime (15-60%) and reaches highest values during sunrise (30-60%) with a second peak during sunset (15-30%). The variability percentage is evident during nighttime, resulting from the lower monthly mean μ , The lower values of μ during nighttime causes recombination of electron density, This reverse relation is also found during daytime, the variability percentage changes during daytime is due to higher values of μ and causes ionization of electron density.. Therefore, the peaks at sunrise and sunset are the results of the onset and turnoff of solar ionization.

Considering the variation for each seasons of all solar activities of Chumphon data, we find the June solstice values in the afternoon section is higher than data for other seasons, resulting in the lowest foF2 data in the afternoon. Seasonal effects in the Chumphon data are most likely a result of seasonal changes in the buildup of the equator anomaly crests.

The diurnal variation pattern of the relative standard deviation averaged over the whole year for low and moderate solar activity is shown in Fig. 5. The average diurnal of VR follows the same trend at all solar activity levels. The variability percentage for the year 2004 is lower than the year 2006, because in 2004 has solar activity values higher than year 2006, while the foF2 data in 2004 are higher than that in 2006. Therefore, the variability percentage in 2004 lower than year 2006.

Figure 6 show comparisons diurnal foF2 data of in 2004 and 2006 with moderate and low solar cycle, respectively. Generally, the average diurnal of foF2 follows the same trend at all solar activity levels, the foF2 values increase during sunrise, decrease during sunset, and increase during sunrise again. The foF2 values in 2006 are less than those in 2004, because of solar activity is higher in 2004. The results of the percentage variability of foF2 decrease during daytime and increase during nighttime, which is the most irregularity of electron density in the ionosphere as a result of the most irregularity of percentage variability in nighttime.

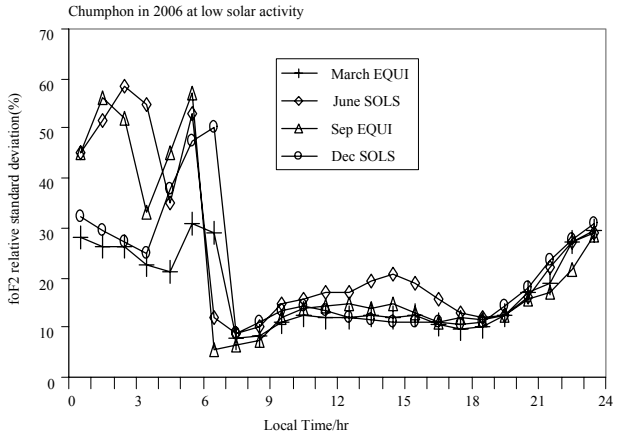

Fig. 3. Diurnal variation of the relative standard deviation for all season and low solar activity for Chumphon (2006).

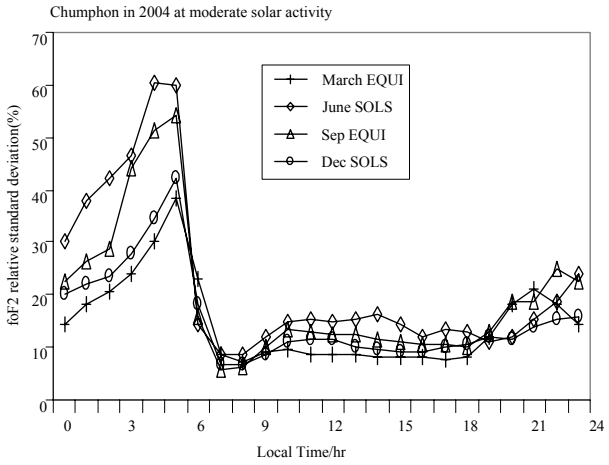

Fig. 4. Diurnal variation of the relative standard deviation for all season and moderate solar activity for Chumphon (2004).

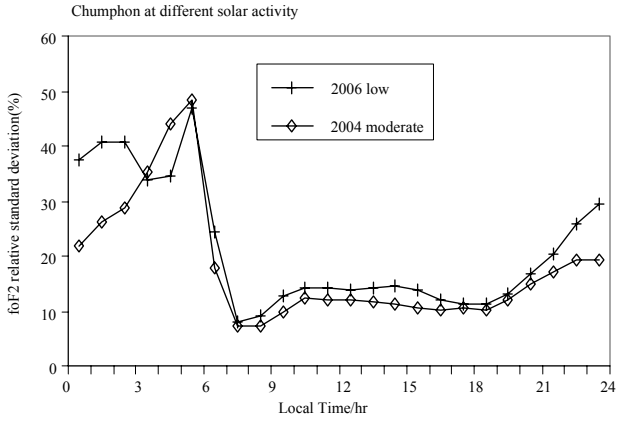

Fig. 5. Diurnal variation of the relative standard deviation Averaged over the whole year for low and moderate solar activity for Chumphon.

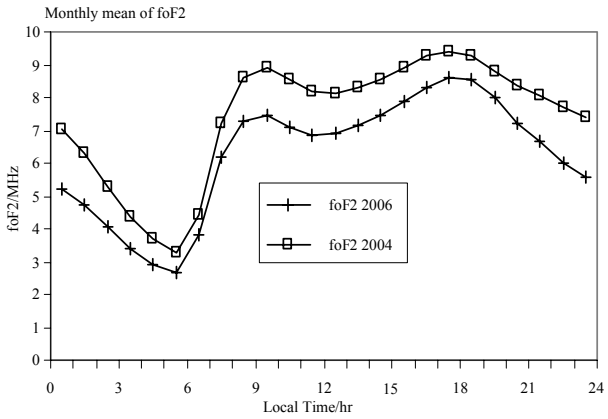

Fig. 6. Comparison diurnal variation of variability of foF2 observed at Chumphon, Thailand.

VI. CONCLUSIONS

The hourly interval foF2 data obtained from bottomside ionograms are recorded by the ionosonde at the low latitude station Chumphon, Thailand in 2004 and 2006, respectively. The data analyzed and compared with relation to monthly variability with local time, season and solar activity.

The variability of VR is lower during daytime hours than during nighttime, the maximum variability occurs at pre-sunrise hours for all solar activities. The percentage of variability is typically 6-15% during daytime, 15-60% during nighttime, 30-60% at sunrise and 15-30% at sunset. From the results, we find the maximum of solstice in the afternoon section in June in Chumphon data for all solar activities. Relative variability generally decreases with increasing solar activity most noticeable during nighttime. The changes of relative variability can be explained in terms of absolute foF2 values (higher foF2 values result in lower percentage variability). From the experimental results in this paper, we found the variability of VR nearly the results of Bilitza et al. [8]. However, the results in this paper higher than the results of Bilitza et al. [8] during nighttime, because the different of intensity of sunspot activity in each year and geographic location. The monthly relative variability values obtained by this study can be used in development of a variability model for the International Reference Ionosphere.

ACKNOWLEDGMENT

The authors are grateful to the National Institute of Information and Communications Technology (NICT), Japan for the necessary equipment and for the Research Center for Communication and Information Technology (ReCCIT) for the use of facility in this research.

***Abstract*-The IEEE 802.17 Resilient Packet Ring (RPR) is the latest standard for ring based packet in the Metropolitan Area Network (MAN). Some scenarios of RPR in the aggressive mode suffer from severe and permanent oscillation which make system unstable and cause low bandwidth utilization. In this paper, we propose a novel dynamic fair rate estimation method. The proposed method produces higher bandwidth utilization, achieves system stability and supports fairness weight which does not obtain in the original aggressive mode. The proposed method is compared with conventional algorithms [1] & [7] and higher bandwidth utilization with minimum oscillation is obtained.**

I. INTRODUCTION

The RPR [1] is a Media Access Control protocol (MAC) of the ring topology in the MAN. It combines the advantages of the Synchronous Optical Network (SONET) [2] and the Ethernet [3] by providing protection in case of links failure and maximizing the bandwidth utilization. The RPR uses the buffer insertion method [4] and consists of dual unidirectional rings which use to transmit the data traffic and control message between two adjacent nodes. It provides automatic topology discovery, fast protection mechanism, multiple classes of services, dynamic bandwidth allocation, spatial reuse through destination-stripping and fairness [5]. The RPR MAC layer is designed to control the transmission of frames on the ring [5]. Frames are allowed to add to the ring only if the transit queue is empty and there is no frame to transit. The transiting frame arrives to a node and is temporary stored in the transit queue when the node adds the local frames. To avoid frame losses in the ring, node stops to add frame when the transit queue occupancy for Fairness Eligible (FE) traffic exceeds the configured threshold (High threshold). The architecture of RPR node can be designed into single transit queue (1TB) [8] and dual transit queue (2TB) as illustrated in Fig. 1.

RPR congestion control operates to avoid buffer over flow in the case of demand for the bandwidth is greater than the total available bandwidth. The congestion domain is defined within the region specified by two boundary nodes. The node which attaches upstream of the most congested link is called head node of the congestion domain. The opposite end of the region is called tail node. The head node estimates fair rate to limit the amount of FE traffic which is distributed to upstream node in the congestion domain as fairness control message (FCM). The tail node tasks to stop the distribution of FCMs by dropping those FCMs.

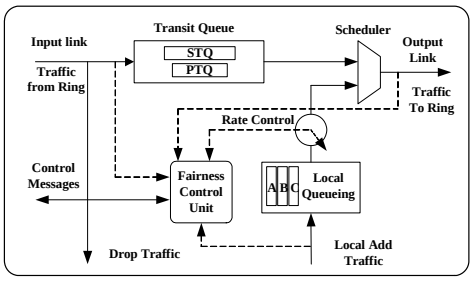

Figure 1. RPR node architecture.

Aggressive mode fairness operates unfair sharing of the bandwidth and unstable for the parking lot scenario where head node transmits the modest traffic [7]. The main reason of these deficient is the application of own local add traffic as the fair rate estimate which it is less than actually fair rate. The proposed algorithm uses dynamic rate control by observing the STQ occupancy to determine the fair rate estimation.

The structure of this paper is organized as follows: the explanation of aggressive mode is in Section 2. Section 3 is the proposed algorithm. The results of the simulation and conclusion are in Section 4 and 5 respectively.

II. AGGRESSIVE FAIRNESS MODE IN FAIR RATE

Aggressive mode is developed from the Spatial Reuse Protocol (SRP) [6]. It is defined as a congested station when the occupied buffer is either greater than the configured threshold which is known as the *stqLowThreshold* or the sum of the local add traffic (*addRate*) and the transit traffic (*fwRate*) is greater than the total available bandwidth. Head node estimates the fair rate by using its own *addRate* and distributes this rate across congestion domain every time interval (*agingInterval*). The original aggressive algorithm [1] is shown in the Table I.

TABLE I
THE ORIGINAL AGGRESSIVE FAIRNESS MODE

Current State		Row	Next State	
State	**Condition**		**Action**	**State**
INIT		1	*L = R*	UNCG
UNCG	*AgingInterval Expired && (STQ > STQLowThreshold)*	2	*L = LpAddRate*	CGST
	AgingInterval Expired	3	*L = R*	UNCG
CGST	*AgingInterval Expired && (STQ <= STQLowThreshold)*	4	*L = R*	UNCG
	AgingInterval Expired	5	*L = LpAddRate*	CGST

Where *L* is the estimated Fair Rate, *R* is the unreserved rate (Normally equal to link capacity (*C*) – reserved rate for A0 traffic [5]), *LpAddRate* is local add traffic of a head node, UNCG is uncongested state and CGST is congested state.

III. DYNAMIC FAIR RATE ESTIMATION

To solve the problem of modest traffic transmission in head node, a new fair rate estimation that does not depend on the local add traffic is proposed. The proposed algorithm is separated into two parts: (1) maximum and minimum rate estimation values and (2) STQ occupancy control.

The maximum rate of the algorithm which is the upper bound of fair rate is defined as:

$$Max_Rate = (R - LpaddRate) * W_i / \sum_{n-1} W_n \quad (1)$$

where R is the unreserved rate, *LpAddRate* is the local add traffic of the congestion domain, W_i is the weight station of node i and W_n is the total weight in the congestion domain n. (1) shows that the traffic of the head node is excluded in the maximum rate calculation. The minimum rate which is the lower bound of fair rate is the same as the Zhou fair rate estimation [7] which is defined as.

$$Min_Rate = R * W_i / \sum_n W_n \quad (2)$$

Our algorithm observes STQ occupancy to control the fair rate estimation. When STQ occupancy is greater than the *stqMedThreshold* (Normally equal to (*stqHighThreshold* + *stqLowThreshold)/2*) and the occupancy rate is increasing, the algorithm will reduce the fair rate by gradually decreased to the *Min_Rate* using:

$$L = L_c - (L_c - Min_Rate) / \alpha \quad (3)$$

where L is the estimated fair rate, L_c is the current fair rate and α is the coefficient factor (default value is 64). Otherwise if the STQ occupancy is lower than the *stqMedThreshold* and occupancy rate is decreasing, the fair rate will be gradually increased up to the *Max_Rate* as:

$$L = L_c + (Max_Rate - L_c) / \alpha \quad (4)$$

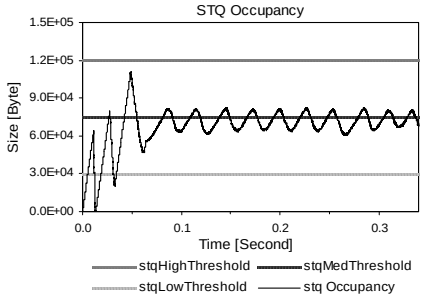

Figure 2. STQ Occupancy Control *stqhighThreshold* is configured as 120000 byte, *stqLowThreshold* is configured as 31812 byte.

(3) and (4) show that we control the STQ occupancy oscillated around *stqMedThreshold*. The first reasons is to avoid the unwanted effects of the local station stops to transmit local traffic when STQ occupancy greater than *stqHighThreshold*. The second is the switching state between CGST to UNCG when STQ occupancy lower than *stqLowThreshold*. The STQ occupancy control is illustrated in Fig. 2.

If the STQ occupancy falls below the *stqLowThreshold* and the scenario remains unchanged, the lower bound will be increased in order to avoid unwanted state changed (CGST switch to UNCG) which causes the *Min_Rate* drops below the actually fair rate. The *Min_Rate* can be calculated using:

$$Min_Rate = max\ (Min_Rate, L) \quad (5)$$

Otherwise the upper bound will be decreased to avoid buffer overflow in the STQ when the active transmitting node in the congestion domain is increased. The *Max_Rate* can be obtained from:

$$Max_Rate = min\ (Max_Rate, lpAddRate) \quad (6)$$

TABLE II
THE IMPROVEMENT OF FAIRNESS ALGORITHM

Row	Next State	
	Action	State
1	$L = R$	UNCG
2	*If ($\sum W_n$ changed) {* *Max_Rate = (R – LpaddRate) * W_i / $\sum_{n-1} W_n$* *Min_Rate = R * W_i / $\sum_n W_n$ }* *L = Min_Rate*	CGST
3	$L = R$	UNCG
4	$L = R$ *Min_Rate = max (MinRate, L)*	UNCG
5	*If ($\sum W_n$ increase)* *Max_Rate = min (Max_Rate,LpAddRate)* *If (STQ rate increase) && (STQ > stqMedThreshold)* *L = L_c – (L_c – Min_Rate) / α* *Else if (STQ rate decrease) && (STQ > stqMedThreshold)* *L = L_c + (Max_Rate – L_c) / α*	CGST

The congestion domain status and fairness control message are determined as the standard of aggressive fairness. The main difference between the proposed algorithm and the aggressive mode is the fair rate estimation method. The state diagram of the proposed algorithm is shown in the Table II.

IV. EXPERIMENTAL METHODOLOGY

The simulations are based on java simulator and the experimental results are compared with the standard aggressive mode [1] and Zhou algorithm [7].

TABLE III
CONFIGURATION PARAMETER FOR FAIRNESS MODES

Parameter Name	Value
Link Capacity	1000 Mb/s
Packet size	500 [B] (fixed)
stqLowThreshold	31812
stqHighThreshold	120000
ageCoef, lpCoef	4,64

The configured parameters of the simulator are as shown in the Table III. We simulate the performance with different scenarios where the traffic generations are FE traffic.

A. Convergence for all nodes transmits greedy traffic.

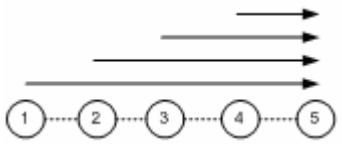

Figure 3. The parking lot scenario with the link capacity of 1Gb/s.

Consider the scenario in Fig. 3 where all traffics transmit the greedy traffic at the time 0.01s with link delay of 1ms. Fairness algorithm defines the head node and tail node of the congestion domain to be Node 4 and Node 1 consequently. The experimental results are shown in Fig. 4 and Fig. 5.

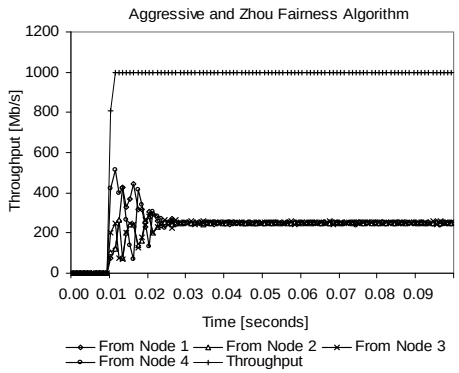

Figure 4. The results of aggressive fairness mode when all nodes transmit greedy traffic.

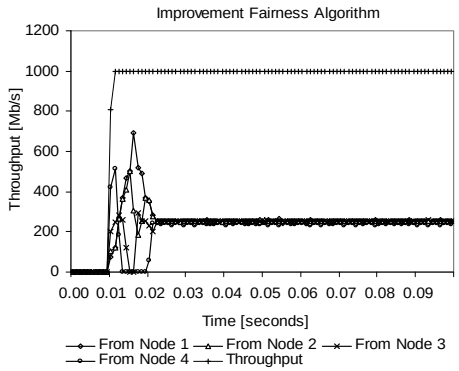

Figure 5. The results of the proposed algorithm when all nodes transmit greedy traffic.

All tested algorithms perform to achieve fair sharing of the total available bandwidth. Fig. 4 shows that the results of the aggressive mode and the Zhou algorithm are identical. The system reaches stable state at time 0.026s while the proposed algorithm reaches the stable state at time 0.022s as show in Fig. 4 and 5 respectively. This is proved that the proposed algorithm reaches stable state faster than the aggressive and Zhou algorithm.

B. Convergence for head node transmits modest traffic.

To simulate the deficient of aggressive mode, the same scenario as in the previous section is used when node 4 transmits the traffic of 50Mb/s. The experimental results are as shown in Fig. 6 -8.

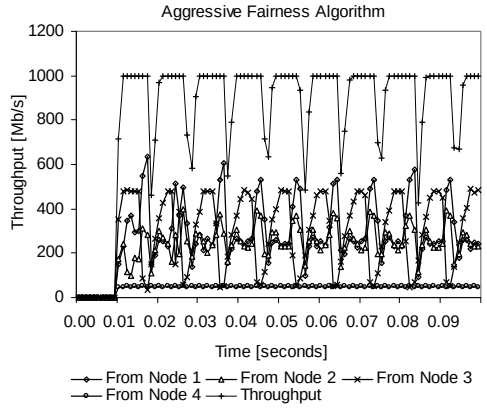

Figure 6. The result of aggressive fairness mode when head node transmits modest traffic.

We consider the results of aggressive mode are as show in Fig. 6. The each traffic oscillates and the system unable to reaches the stable state and become low link utilization.

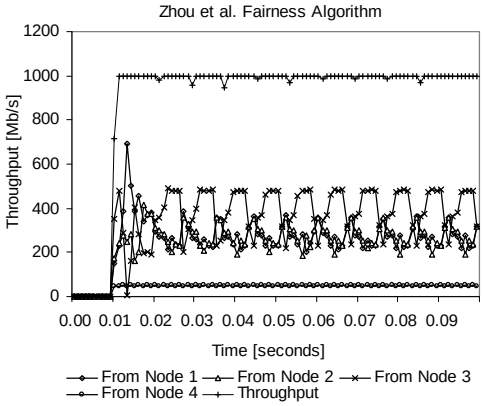

Figure 7. The result of Zhou algorithm when head node transmits modest traffic.

The results from Zhou algorithm, as shown in Fig. 7, improve deficient of the aggressive mode which only alleviated the range of traffic oscillation of each node and overall throughput loss. The system also unable to reaches the stable state.

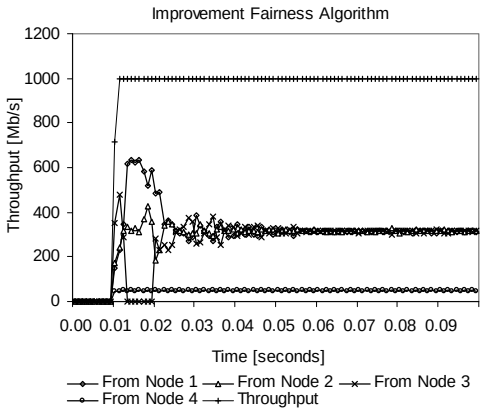

Figure 8. The result of our improvement fairness algorithm when head node transmits modest traffic.

Fig. 8 shows that our algorithm achieves bandwidth fair sharing and maximizes bandwidth utilization. The system reaches stable state at time 0.046s. These are proved that the proposed algorithm solves the deficient of head node transmits with modest traffic which is mentioned in the previous section.

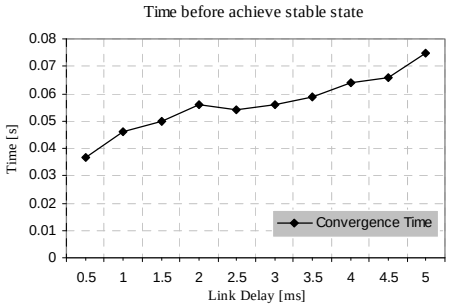

Figure 9. The comparison between difference link delays.

The graph of link delay versus stable state is shown in Fig. 9 where the scenario in Section B is re-applied with various link delays.

C. Convergence for weighted fairness.

In this section, we show that the proposed algorithm supports weighted fairness. The scenario in Fig. 2 is reconsider, the weight of the transmitting node 1, 2 and 3 were set as 2, 3 and 4 respectively.

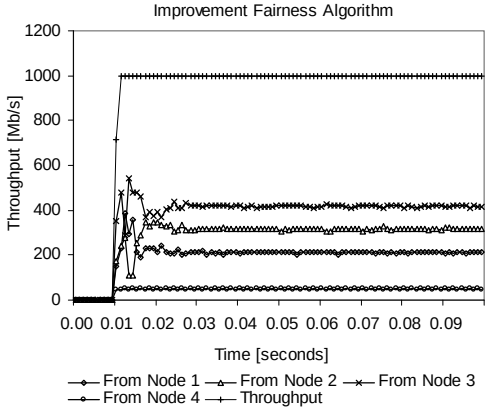

Figure 10. The result of our improvement algorithm with weighted fairness.

Fig. 10 shows the throughput of individual node, demonstrating that all nodes are able to obtain the fair sharing of bandwidth proportional to their weights. In order to test system stability, dynamic scenario is used in the next sub-section.

D. Convergence for dynamic scenarios.

In this section, the congestion domain is increased to 9 nodes as illustrated in Fig. 11 in order to test the proposed algorithm with the dynamic scenario. Fairness algorithm determined the head node and tail node of the congestion domain as Node 8 and Node 1 respectively.

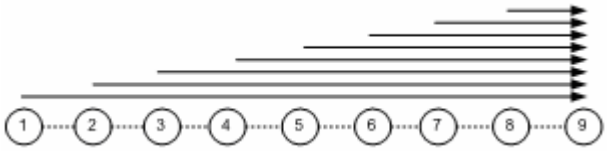

Figure 11. The parking lot scenario with the link capacity of 1Gb/s and link delay of 1ms.

The dynamic scenario shows that all active nodes transmit traffic to the destination node (node 9). To simulate the convergence when head node transmits modest traffic (node 8) of 50Mb/s and the rest nodes transmit greedy traffic with the link delay of 1ms. All nodes start to transmit traffic at the time 0.01s except the node 4 and 5 start to transmit traffic at the time 0.3s. Finally when the time 0.6s, the node 2 and 3 stop to transmit traffic.

Consider the results of dynamic scenario as shown in Fig. 12 at the time 0.01s where node 1, 2, 3, 6, 7 and 8 start to transmit traffic, the system became stable state at the time 0.03s until 0.3s. At the time 0.3s the traffics from node 4 and 5 start to transmit, the proposed algorithm detects this changed and perform to achieve stable state at the time 0.33s and when the time 0.6s node 4 and 5 stop to transmit the traffic. The system became to stable state again when the time 0.64s. The result shown that, our algorithm achieves fair sharing for bandwidth with dynamic scenario.

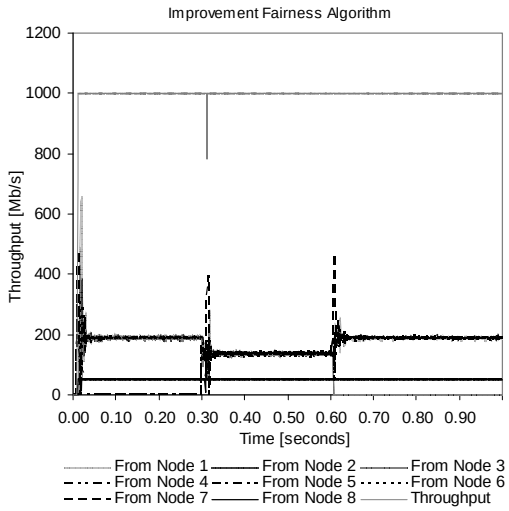

Figure 12. The result of dynamic scenario.

V. CONCLUSION

In this paper, we show that in some scenarios the aggressive mode performs low link utilization and unfair for sharing of bandwidth. The result from the section 4B, the average throughput of the aggressive algorithm approximate to 911.69 Mb/s and the average throughput of Zhou algorithm approximate to 982.33 Mb/s but each traffic unable to achieve the stable state. We propose the improvement algorithm which uses dynamic fair rate estimation. The average throughput of proposed algorithm able to reach to the maximum link capacity (approximate 1000 Mb/s) and each traffic achieve the stable state. The simulation's results verify that our algorithm achieve fair sharing for bandwidth, gain the maximum throughput, faster convergence time and support the fairness weights.

Abstract **This paper present the effect of rain attenuation on Ku band satellite propagation path with difference polarizations.The vertical and horizontal polalized signal received from Thaicom 2 and Thaicom 3 satellites by one dish antenna with two LNBs. The observation of rainfall rate and rain attenuation at KMITL Bangkok Thailand are investigated.The reduction of satellite signal passing through the same rain rate on difference polizations has some difference . Finally the rainfall rate and rain attenuation are estimated and compared to ITU-R rain attenuation prediction model.**

Keywords Ku band rain attenuation, vertical and horizontal polarizations, yearly cumulative time of rainfall rate, ITU-R model.

I. INTRODUCTION

Rainfall attenuation has been recognized as the main source of atmospheric attenuation in satellite links. Raindrops absorb and scatter radio wave energy, resulting in signal attenuation. It causes both attenuation and depolarization.The result is reduction in separation between vertical and horizontal polarizations in an orthogonal polarized signal. B.Fong et.al. had reported the effect of rain attenuation on orthogonally polarized LMDS (local multipoint distribution service) system in tropical region. The attenuation from both polarized is 2 dB difference. [1]

This paper is to study the difference in attenuation due to polarizations from two Thaicom satellites with difference polized signals. Both Thaicom satellites are located at the same position as the detail listed in table 1. The signals are received by one antenna and convert to IF frequencies. The polarizations are separated by two LNBs and received by two receivers. The experiment had been carried out in one year from January to December 2006 and denoted that from 14 June 2006 Thaicom 5 had been replaced to Thaicom 3 at the same position. Furthermore the authors proposed the cumulative time of rainfall rate in year 2005 and 2006 compare to ITU-R model.

II. EXPERIMENT METHOD

Fig.1. is illustrated the configuration of the propagation experiment system at KMITL. The pulse numbers of rain gauge are counted to data logger and recorded by the computer parallel with the satellite signals.

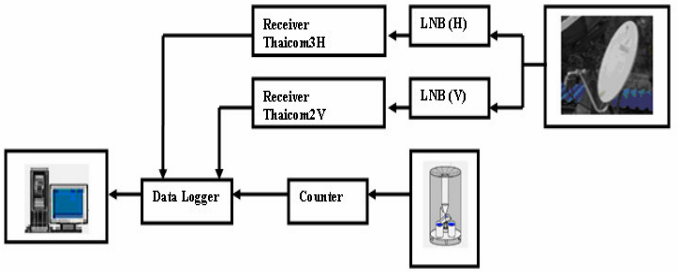

Fig.1. The experiment block diagram of rain attenuation on two polarizations of Ku band system .

The data of the received signal and the rainfall amounts are sampled at every 1-second and the dynamic range of attenuation of the instrument is approximately 15 dB below the clear sky level. The resolution of the tipping-bucket type rain gauge is 0.5 mm/tip. Since June 2006 the data from Thaicom3 are changed to Thaicom 5 with the same parameters.The receiving parameters are listed in table1.

TABLE I
PARAMETER OF RECEIVING SYSTEM

Parameters	Thaicom2	Thaicom3 (Thaicom 5)
Polarization	Vertical	Horizontal
Down link frequency	12.567 GHz	12.594GHz
IF frequency	1.467 GHz	1.280 GHz
Antenna diameter	0.5 meter	0.5 meter
Position satellite	78.5° E	78.5° E
Elevation angle	59.83°	59.83°
Azimuth angle	239.652°	239.652°
Sample data interval	1-second	1-second
Rain guage type	Tipping bucket	
Longitude (KMITL)	100.7° E	
Latitude (KMITL)	13.7° N	

Calibration of receiving system

The recording system has been calibrated by signal generator with the normal level of Thaicom2 and Thaicom3 before collecting data.The received signal from Thaicom 2 equal to -63.752 dBm while Thaicom 3 is -60 dBm. These are the reference values. The strength of signal are measured at AGC output of receivers. For calibration of satellite level, the signal generator is replaced to satellite signal. The calibration level is step in dB value. When the rainfall rate and satellite level has been converted to correct unit we can calculate the rain attenuation or losses of signal during rain by equation:

$$L_r = P_{ref} - P \qquad (1)$$

Where L_r : Rain attenuation level (dB)
P : Measuring signal level (dBm)
P_{ref} : Reference level (dBm)

III. EXPERIMENT RESULTS

A. Rainfall Rate and Rain Attenuation Measurement Results

The results of rain attenuation on 4 June 2006 are presented in Fig. 2 and Fig. 3. From the configurations, the rainfall rate 90 mm/hr caused to signal attenuate 12 dB via horizontal polarized signal and 9 dB from vertical polarized signal .This is the result of one event. The attenuation depends on rain intensity and period of measurement.

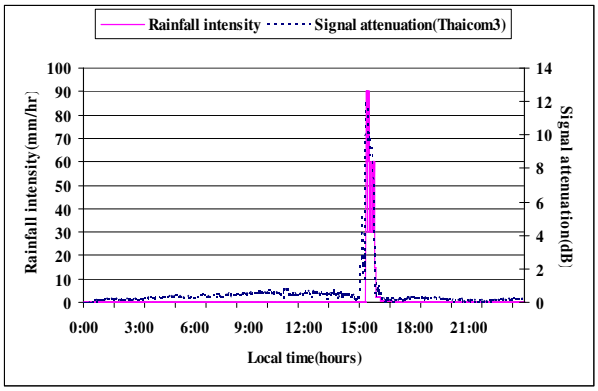

Fig. 2. Example of intense rainfall event and signal attenuation in horizontal polarization on June 4,2006.

The reliability of satellite link is described by the yearly cumulative time of rain attenuation. The result at 0.01% cumulative time of rainfall rate cause rain attenuation about 9 dB and 11 dB from Thaicom2 and Thaicom3 respectively as shown in Fig. 4. and Fig. 5.The attenuation difference between both satellites is 2 dB which is the difference in polarizations.

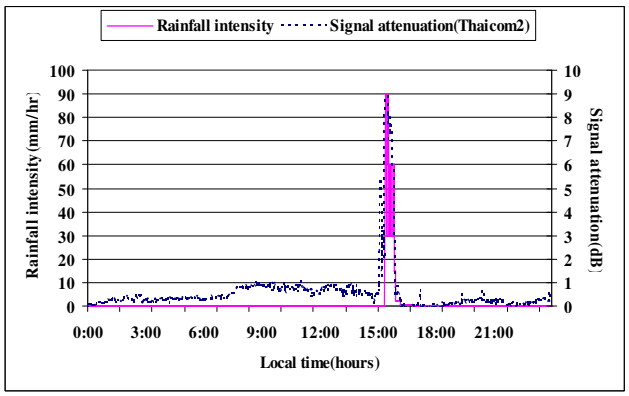

Fig. 3. Example of intense rainfall event and signal attenuation in vertical polarization on June 4,2006.

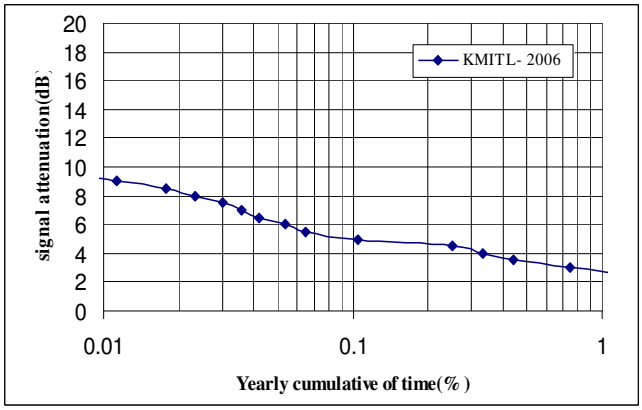

Fig. 4. Cumulative time distribution of rain attenuation in Thaicom2 (vertical polarization) .

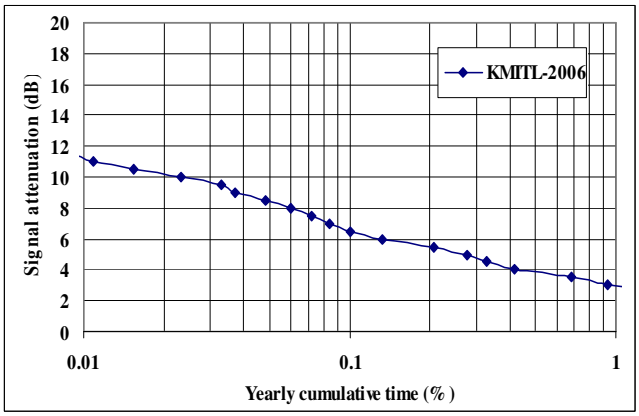

Fig. 5. Cumulative time distribution of the rain attenuation in Thaicom3 (horizontal polarization).

B. Measurement and Predicted Rainfall Rate by ITU-R.model.

The yearly reliability of satellite signal should be 99.99% in each year. Fig.6. indicated one year cumulative distribution of rainfall rate. It is indicated the short percentage time of rainfall rate exceed 0.01%, the rainfall rate is 94 mm/hr.

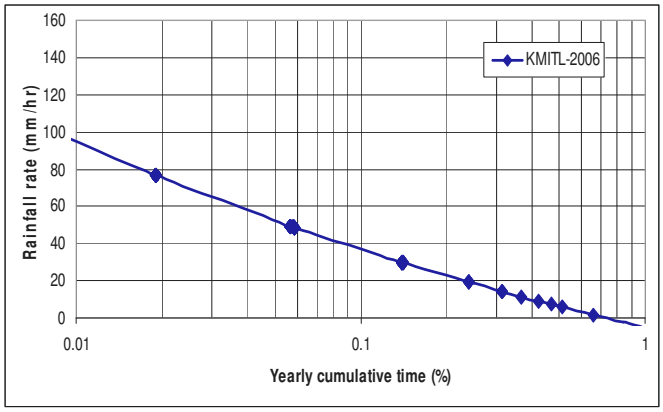

Fig. 6. Yearly cumulative time of rainfall rate on year 2006.

The rain attenuation in Fig.7. are indicated one year cumulative distribution time of rain attenuation from both polarizations included the result of ITU-R prediction model. The rainfall rate is more effective to satellite signal. In Fig. 7. we found that the yearly cumulative time of rainfall rate at 0.01% the rain attention is about 9 dB from vertical polarization and 11.5 dB from horizontal polarized signal. The signal attenuation from horizontal polarization of Thaicom3 is higher than the vertical polarization of Thaicom2 about 2.5 dB. The comparison of rain attenuation between ITU-R model and measured value are indicated that the measuring results from horizontal polarization are closed to ITU-R zone N.

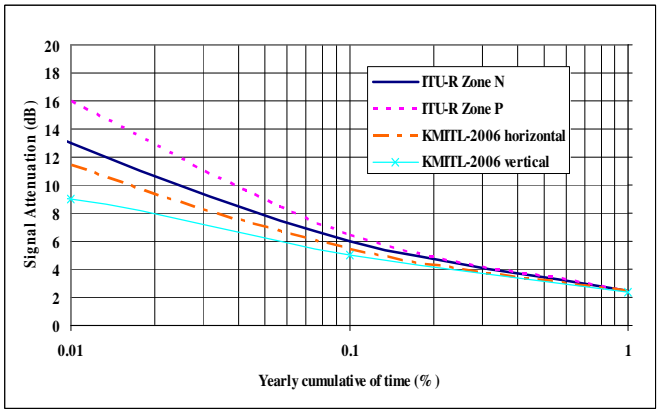

Fig.7. Comparison between ITU-R zone P, zone N and rain attenuation at KMITL.

Moreover, we also proposed the comparison of rainfall rate in year 2005 and 2006 with ITU-R model which presented in Fig. 8. The rainfall rates are measured in every 1 minute. We found that at 0.01% of cumulative time distribution of rainfall rate in year 2005 is about 155 mm/hr and 165 mm/hr in year 2006 which close to ITU-R zone N. The ITU-R rain zone model is shown in Fig. 9. Thailand is located between zone P and N.

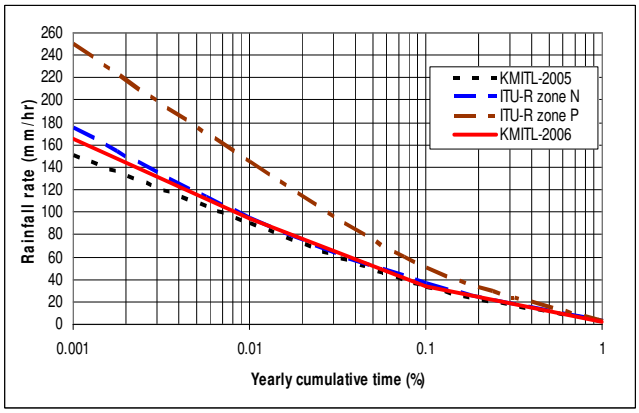

Fig. 8. One year comparison between rainfall rate in year 2005 and 2006 at KMITL and ITU-R zone P, zone N model.

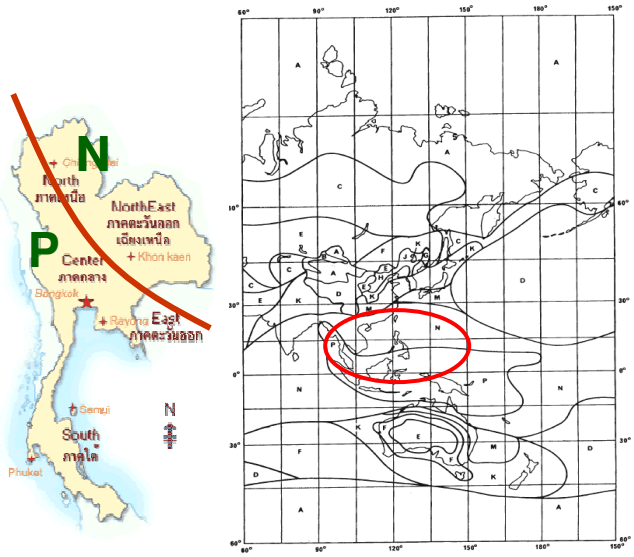

Fig. 9. ITU-R P.837-1 rain zone

IV. CONCLUSION

This paper present the effect of rain attenuation on vertical and horizontal polarized signal of Ku band satellites.The studies are received strength of signal from Thaicom2 and Thaicom3 include Thaicom5 by one antenna and two LNBs in difference polizations.The satellite signals pass through the same propagation path because both satellites have same elevation angle.The effect of rain probably small difference in practical.The monthly and yearly cumulative time distribution of rainfall rate and rain attenuation at KMITL, Bangkok are closed to ITU-R zone N model. From the results, the rain attenuation on both sattellites of Ku band are about 11.5 dB and 9 dB at 0.01% of exceed time. The result of satellite attenuation from horizontal polarized signal is higher than the vertical polarized signal which is same as the investigation result of B. Fong et al.[1].

***Abstract*- Stereoscopy is the method to recover depth from the scene. This method suffers from the correspondent problem especially when there are multiple points to extract 3D information from the scene. This paper concentrates on the solution to correspondent problem. Our idea is to project the binary-coding light point on the object while capturing the image sequences. The image sequences are later analyzed to detect the binary code of various projected points. The correspondence of points on the right and left image are established when the binary code is similar. Our technique has been tested to extract the shape of the face model. The result is very promising.**

I. INTRODUCTION

Shape extraction is the first step of many 3D applications, including a 3D modeling, object recognition, robot navigation, machine inspection, geometry measurement, and so on. To satisfy these applications, it requires an appropriate shape extraction method. Nowadays, several shape extraction systems are proposed, and each one is suitable in the limited range of applications. Some of those, including stereoscopy, laser range finder, structured-light projection, and shape from shading, will be reviewed here concisely.

The first 3D perception method, which was explored for a long time, is stereoscopy [1]. Its concept is simulated from the human visual system by using two images from two different angles to perceive the depth of the scene. Practically, an orientation of each camera as well as a correspondent problem is elaborate, and the decision for the points of landmark must be done manually. Laser range finder technique [2] straightforwardly measures the distances from the viewer to points on surfaces in the scene by using the time-of-flight of a laser beam. Giving a high precision of a depth map, the "Laser Plane Range Finder" [3] is claimed about 0.5 mm in depth's resolution. Commonly, the machine is fragile and costly. Structured-light projection technique [4] projects some light patterns, for instance – plane or grid, onto a surface of the object, captures the scene, and then computes the shape from the distorted light. This has a main advantage in that the discontinuity and monotony of the surface are abruptly replaced by the readily-computed artificial light pattern. This method, similar to the stereoscopy, suffers from the correspondent problem. Shape from shading [5] – the shape information could be inferred from only a monocular image if the illuminating position and the surface property were known. However, the result sensitively depends on the surface's reflectance property. For some kinds of images, never does the shape from shading provide a correct solution [6].

In the tomographic process [9] , by directly replacing the projections of an object with the silhouetted photographs from sufficient viewpoints, one can acquire the pseudo cross-sections of an object, which means that only the outlines are correct, regardless to the internal regions [7, 8]. Therefore, the photographic tomography could be inferred as the one of shape extraction systems capable of reconstructing the volumetric data of an object from the sequence of photographs taken around the object. This technique, however, suffers from concave occlusion. In this paper, we revisit the stereoscopy method with an objective to facilitate the corresponding process. Our idea is to project the binary-coding light point on the object while capturing the image sequences. The corresponding point on the right and left images blinks at the binary coding. The captured video image is then analyzed, decoded the binary code among various points to establish correspondence.

This work is organized as the following: - Section 2 discusses stereoscopy. Binary-encoding process is provided in section 3. The experiments and results is discussed in section 4. Discussion and conclusions are given in section 5.

II. STEREOSCOPY

The 3D coordinate of the object can be recovered from the scene using stereoscopy techniques. In the technique, the two identical and perfectly aligned cameras, namely left and right cameras, take the image of the same object. The 3d coordinate of the world points, as shown in figure 1, can be derived as follows:

$$Z = f - \frac{fB}{x_2 - x_1} \quad (1)$$

$$X = \frac{x_1}{f}(f - Z) \quad (2)$$

$$Y = \frac{y_1}{f}(f - Z) \quad (3)$$

Where

(X, Y, Z) is the 3d coordinate of the world point W,

(x_1, y_1) is the image of world point in the left camera,

(x_2, y_2) is the image of world point in the right camera,

B is the distance between the two cameras.

f is the focal distance of the camera.

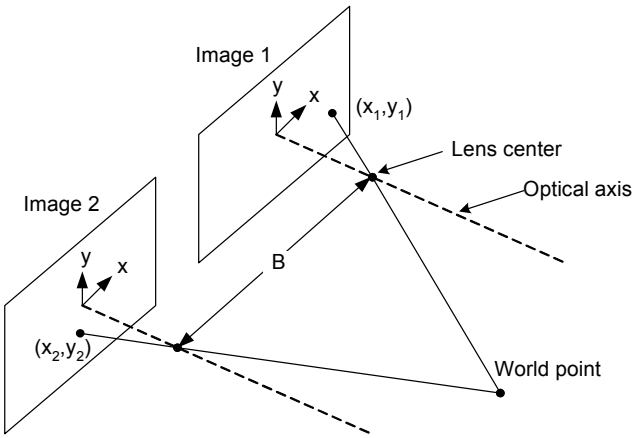

Figure 1. Stereoscopy system

III. FREQUENCY-ENCODING PROCESS

One of the major drawbacks of shape recovery using stereoscopy is the problem of point correspondence. To overcome the problem, the point projected on the object will be binary encoded. Firstly this method project a mask pattern of an all illuminated dots to the object. The left and right

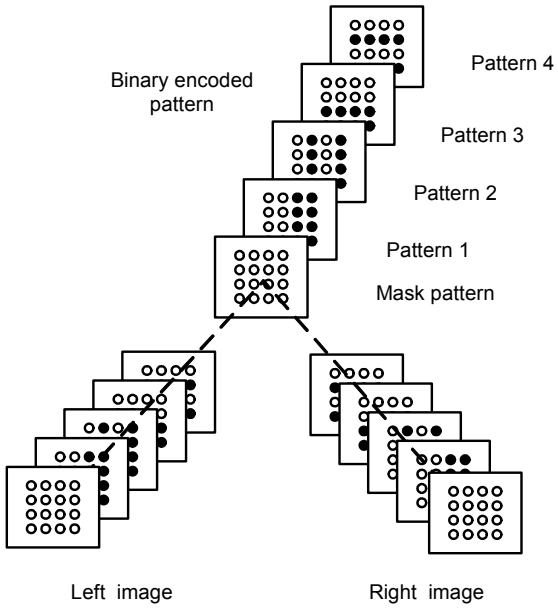

Figure 2. Frequency-Encoding Process

cameras image all the dots and keeps their positions. In the following steps, a series of patterns consisting of patterns one to four is projected and then a series of left and right images is stored. After all the patterns were projected, all dot positions of image series were analyzed for blinking dots to assign a bit one or zero. Figure 2 shows the configuration of 4x4 points and the binary-encoded light pattern. In each case, four bits is required for the encoding process. The light will be projected one frame per one bit and hence 4 frames are required. Bit "0" means that the black dot is projected, while bit "1" means that a white dot is projected. In case of the first point, for example, the black dot will be projected for all the 4 frames. For the second point, the first three frames will project the black dot and the fourth frame will project the white dot contributed for "0001".

IV. EXPERIMENTS AND RESULTS

Figure 3 shows the experimental set up. The 4 mm focal length two identical and perfect-aligned cameras are installed on the rail. The distance between cameras is 10 cm. The object is located at 50 cm from the camera plane. The 32x32 dot will be projected on the object with the NEC VT47 projector. The number of dots is hence 1024 dots. The number of bit required is 10 bits and hence 10 frames are required. The size of the light point projected on the model is 2 mm. The distance between point centers of the successive point both horizontally and vertically is 7.5 mm. The image capture card is Matrox

Meteor-II installed on a Pentium IV 2.8 GHz. The acquisition time of the 10-Bit pattern is about 30 seconds. The computational time for the 3D coordinate is 2-3 seconds. The total time is about 35 seconds. Figure 4 shows 10 bit binary-encoded light pattern used in the experiment which has ten patterns. The first pattern represents the first digit of each binary encoded light point while the last pattern represents for the last digit. Figure 5(a) shows the left image of all projected points and figure 5(b) displays the right image of all projected points. The dot correspondence obtained from figure 5(a) and 5(b) was used to reconstruct three dimensional object as shown in figure 5(c).

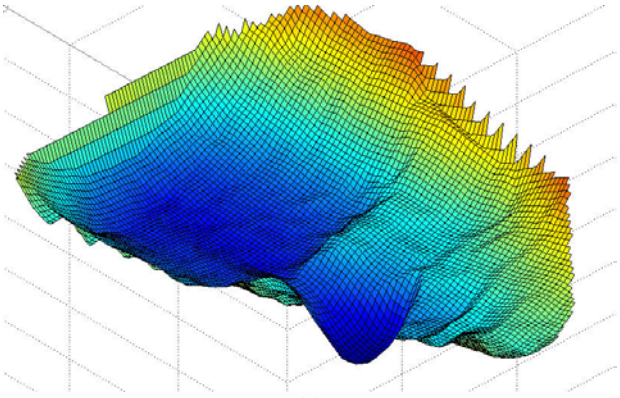
(b)



(c)

Figure 5 (a) Left Image (all projected points) ; (b) Right Image(all projected points; (c) Shape Extraction Result

V. CONCLUSIONS AND SUGGESTIONS

The purposed technique to correspondence establishment of shape extraction using stereoscopy technique has been discussed in this paper. The technique exploits the binary-coding light pattern by projecting multiple points which blinks at distinct binary code on the object while recording the image sequence. The captured video image is then analyzed, decoded the binary word among various points and established correspondence. The modified stereoscopy can be hence applied for real-time application.

***Abstract*-Numbers of white blood cells in different classes help doctors to diagnose patients. A technique for automating the differential count of white blood cell is presented. The proposed system takes an input, color image of stained peripheral blood smears. The process involves segmentation, feature extraction and classification. The segmentation procedure, a novel simple algorithm, is proposed for localization of white blood cells and the different cell components are separated with automatic thresholding. Features extracted from the segmented nucleus are motivated by the concept of the well-known Eigen face. The derived Eigen value and Eigen vector contributes to the important feature in the classification process. To further improve the performance, the concepts of principal axis are adopted to automatically align the white blood cell prior to the classification process. The results of the classification are very promising.**

I. INTRODUCTION

White Blood cell composition reveals important diagnostic information about the patients as well as patient follow-up. One of the important counts required by hematologist is differential blood count in which an expert counts 100 white blood cells on the smear at hand and computes the percentage of occurrence of each type of cell counted. The result gives important information about patient's health status and plays an important role in diagnosis. Counting each classes of the white blood cell manually is a tedious, time consuming and qualitative process. An automated differential white blood cell counter is attempting to perform the counting process automatically by analyzing smear images of white blood cell. The process of counting blood cells on smear image requires three steps (1) segmentation, (2) feature extraction and (3) classification.

Automatic white blood cell analysis requires good segmentation algorithm to locate white blood cell. Many conventional image segmentation methods are based on thresholding selection, edge detection or region growing. Among all, thresholding techniques is the simplest method yet produces the acceptable results. They usually combined with mathematical morphology operation to improve the accuracy of segmentation [1-3]. Edge detection performs poorly on cell images because not all cell boundaries are sharp and hence it is difficult to get all the edge information and locate the cell accurately [4]. Region growing methods group neighbouring pixels of similar characteristics to form a segmented region. The method provides reasonably accurate segmentation result of simple scenes with few object and little texture. Region growing methods is hence rarely used for segmenting white blood cell.

Feature extraction is the important process for automated white blood cell classification. The accuracy rate of the subsequent classification relies on the number of extracted feature as well as the characteristic of the feature. Features of white blood cell can be classified into 3 groups: (1) Morphological feature, (2) color feature and (3) texture feature. Morphological feature includes shape and size of nucleus, shape and size of white blood cell, number of nucleus lobe, cell circularity, and nucleus rectangularity [6]. Color feature results from the unique and distinguish characteristic of individual white blood cell to the blood smear. The color information of nucleus is then served as an important feature. Texture features results from the specific granule and chromatin in the nucleus. Texture feature includes mean, standard deviation, skewness, kirtosis, entropy of luminance. A number of classifiers have been purposed for white blood cell classification including Bayes classifiers [7], learning vector quantization (LVQ) [8] and multilayer perceptrons [9]. Performance results vary significantly in the literature depending data set and the extracted features ranging from 61% to 78% with the neuron network achieves the highest accuracy.

In this paper, we introduce the classification of white blood cell based on using principal component analysis to a representative dataset of images of white blood cell. The system functions by projecting white blood cell images onto a feature space that spans the significant variations among known white blood cell images. These significant features are termed "*Eigen cells*" because they are the principal components of the set of training white blood cell image.

The concepts have been widely used for face recognition which is known as *"Eigen faces"* [10]. The performance of the principal component analysis, however, requires that the cell images must be in the same orientation. To rectify the problem, the concepts of principal axis are used to automatically align the white blood cell before the classification process.

II. SEGMENTATION

Images of blood smear are imported to the computer via a color CCD camera. Each color blood-smear image is disintegrated into tristimulus components, i.e. red, green and blue image. We elect to use the green component due to the high contrast between the nucleus and cytoplasm provided as shown in figure. The nucleus is first segregated using automatic thresholding [11]. The noise remained in the segmented image is removed using basic morphological process which is erosion and dilation. The centroid of the nucleus is then determined to locate the nucleus position. The white blood cell is then cropped at the centroid location and later used in the subsequent process.

III. EIGEN CELL

Principal Component Analysis (PCA) is a statistical technique which used to describe a large dimensional space with a relative small set of vectors. It is a popular technique for finding patterns in data of high dimension, and is used commonly in both face recognition and image compression [12]. Application of PCA to face recognition is known as Eigen face. The Eigen face technique is a powerful yet simple solution to the face recognition dilemma. It uses much more information by classifying faces based on general facial patterns. Here we focus on the application of PCA for white blood cell classification –the so-called Eigen cell

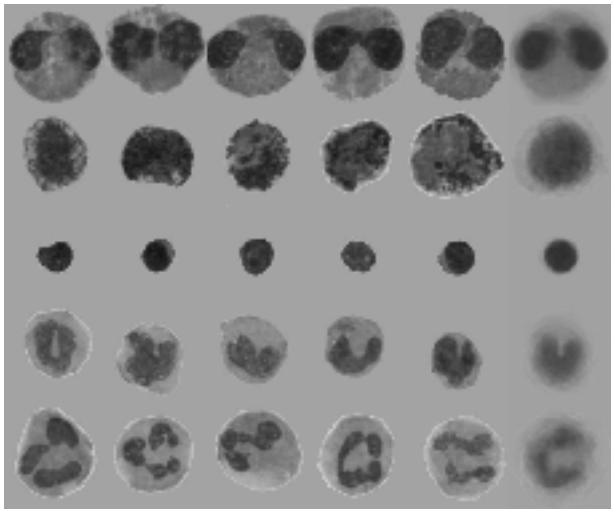

Figure 1 Sample of white blood cell (column 1:5) and averaged Cell (column 6). Row 1: Eosinophil; Row 2: Basophil; Row 3: Lymphocyte; Row 4: Monocyte; Row 5: Neutrophil

The procedure for using Eigen cell is divided into 2 steps. (i) Training step and (ii) Classification step.

The Training step is as follow:

(i) Convert each cropped white-blood-cell image into a vector T_i of length N (N=imagewidth*imageheight). For the M data set, we let the training set represented by, $\{T_1, T_2, T_3, ..., T_M\}$ where T_i is the vector of N^2

(ii) Compute the mean vector Ψ and the set of deviation from the mean vector $\Phi = [\Phi_i, \Phi_2, ...\Phi_M]$ which is defined as

$$\Psi = \frac{1}{M}\sum_{I=1}^{M} T_i \quad (1)$$

$$\Phi_i = T_i - \Psi \quad (2)$$

Figure 1 show the mean vector for each white blood cell (after converted to matrix)

(iii) Compute the covariance matrix C which is defined as

$$C = \frac{1}{M}\Phi\Phi^T \quad (3)$$

(iv) Compute the Eigen value and Eigen vector of C represented as

$$Cv_i = \mu_i v_i \quad (4)$$

Where μ_i is the corresponding Eigen value of Eigen Vector v_i

(v) Project each training set on the Eigen cell-space using the operation

$$\omega_K = (Cv_k)^T (T_i - \psi) \quad (5)$$

$$1 \le k \le M', \ 1 \le i \le M$$

Where v_k is ranked according to their significance. Therefore, for each cell image we would have a set of M' weight

$$\Omega_k = [\omega_i, \omega_2, ..., \omega_{M'}] \quad (6)$$

Which describe the contribution of Eigen Cell to the cell image.

The training process and classification process is summarized in figure 2 and 3 respectively

The classification step is as follow:

(i) Project vector form of the tested cell image T_p to the Eigen cell space using equation (4) to derive Ω_p. The tested cell image is classified to class k which minimized

$$\varepsilon_k^2 = \left\| \Omega_p - \Omega_k \right\|^2 \qquad (7)$$

With $1 \le k \le M$

IV. AUTOMATIC ALIGNMENT USING PRINCIPAL AXIS

The principal axis of arbitrary 2D binary shape of size J x K is the axis that passes through the center of gravity of the shape, namely centroid. Hence the principle axis trends to balance the mass on either side of the axis. In this research, the concepts of principal axis are adopted to align the white blood cell. The axis of white blood cell has a distinct direction. To compute the principal axis, the white blood cell is converted to binary such that on their nucleus remained. Then the covariance matrix of second-order central moment is evaluated on the binary image, .i.e.

$$\mathrm{U} = \begin{bmatrix} \mathrm{U}_{(2,0)} & \mathrm{U}_{(1,1)} \\ \mathrm{U}_{(1,1)} & \mathrm{U}_{(0,2)} \end{bmatrix} \qquad (8)$$

Where Row Moment of Inertia, U(2,0) is defined as

$$U(2,0) = \frac{1}{K^2} \sum_{j=1}^{J} \sum_{k=1}^{K} (x_k - \bar{x}_k)^2 F(j,k)$$

Column Moment of Inertia as

$$U(0,2) = \frac{1}{J^2} \sum_{j=1}^{J} \sum_{k=1}^{K} (y_j - \bar{y}_j)^2 F(j,k)$$

And Row-Column Cross moment of Inertia as

$$U(1,1) = \frac{1}{JK} \sum_{j=1}^{J} \sum_{k=1}^{K} (x_k - \bar{x}_k)(y_j - \bar{y}_j) F(j,k)$$

And where the centroid $(\bar{\mathrm{x}}_\mathrm{k}, \bar{\mathrm{y}}_\mathrm{j})$ is defined as

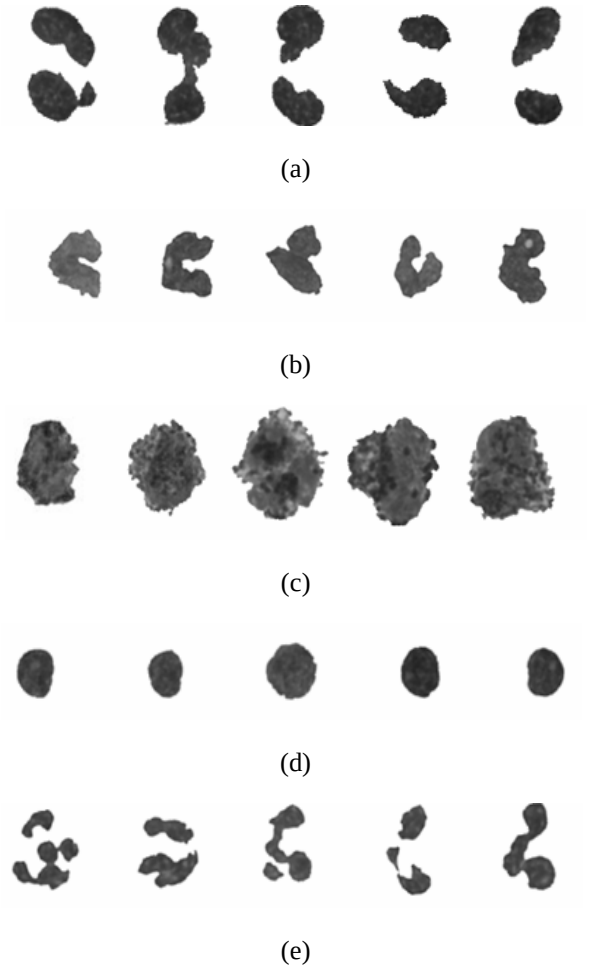
$$\bar{x}_k = \frac{M(1,0)}{M(0,0)}$$

$$\bar{y}_j = \frac{M(0,1)}{M(0,0)}$$

Where

$$M(m,n) = \frac{1}{J^n K^m} \sum_{j=1}^{J} \sum_{k=1}^{K} (x_k)^m (y_j)^n F(j,k)$$

The principal direction of the white blood cell is then the Eigen value of the covariance matrix *U*. Figure 2 shows the results of the automatic alignment of the white blood cell.



(a) (b) (c) (d) (e)

Figure 2 Aligned White Blood Cell (Only Nucleus Shown); (a) Eosinophil (b) monocyte (c) Basophil (d) Lymphocyte (e) Neutrophil

V. EXPERIMENTAL RESULTS AND DISCUSSION

A library set of 50 patterns of white blood cell is used in the training process. 100 samples of blood smear image which are not in the trained group are used for classification. Before classification, the white-blood cell image requires the pre-processing step to segment only the cell nucleus image and align the individual images as described in section IV. To further improve the performance, the white blood cell is divided based on the number of nucleus lobes into 2 groups which are (i) one lobes and (ii) more -than- one lobes. Each group is then trained and classified separately. For comparison purpose, the classification result is shown in table 1 without the alignment and table 2 with alignment process. The averaged accuracy of 93.64 % can be achieved

with the alignment process while that without the alignment process is only 78.18 %.

Table I
Classification results without alignment

Cell name	Classi-fied No	Misclassified No / As	% Accuracy
Eosinophil	25	16/ Neutrophil	36
Basophil	10	3 / Monocyte	70
Lymphocyte	25	0	100
Monocyte	25	4 / Lymphocyte	84
Neutrophil	25	1 / Eosinophil	96

Table II
Classification results with alignment

Cell name	Classi-fied No	Misclassified No / As	% Accuracy
Eosinophil	25	0	100
Basophil	10	3 / Monocyte	70
Lymphocyte	25	0	100
Monocyte	25	3 / Lymphocyte	88
Neutrophil	25	1 / Eosinophil	96

VI. DISCUSSION AND CONCLUSION

The automatic alignment of white blood cell prior to the application of the principal component analysis has been applied to improve the classification of white blood cell. The alignment is based on using the principal axis. The results of the classification shows significantly improved

***Abstract*-Today videoconferencing is more popular because the Internet is more widespread and faster than it was in the past few years. Multipoint videoconferencing requires a multipoint control unit (MCU) to mix video/audio and manage the floor. MCU load increases as much as user's growth worldwide. Therefore, distributed MCUs can balance the load from all users. However, we need to equally balance the MCUs by introducing a load-balancer. The contribution of this paper is the balancing algorithm taking into account of %CPU used, %memory used and %bandwidth used.**

I. INTRODUCTION

Videoconferencing is very popular because people do not need to spend the time for conference just 1-2 hours but take more time in traveling. And now internet is faster and cheaper than past e.g. ADSL, leased line and broadband. And internet price is cheaper. Videoconferencing is one choice to saving time and money. Multipoint videoconferencing requires a multipoint control unit (MCU) to manage the floor and connection, encode and decode video from users, mix audio and send to users. Encoding and decoding video and mixing audio consume a lot of resources. When we talk about resource computer, we almost think about CPU, memory and harddisk but for MCU another resource that is important is network resource. Except encoding and decoding video and mixing audio, MCU has a task to manage connection both signaling and data packet.

MCU load increases as much as user's growth. For supporting large users Centralized MCU is changed to distributed MCU and optimized MCU. When we distributed MCUs there are problems about balance of MCU load. Therefore we need to manage MCUs to work equally and accordingly. The main contribution of this paper is the balancing algorithm taking into account of %CPU used, %memory used and %bandwidth used.

This paper is organized as follows. Section II explains H.323 and general load balancing algorithms. We describe our own algorithm and show the experimental results in Section III and IV, respectively. Section V concludes this paper and suggests some future works.

II. H.323 AND LOAD BALANCING ALGORITHM

A. H.323 Multipoint Conference

H.323 protocol is developed by ITU-T (International Telecommunications Union- Telecommunications section) for real-time multimedia communication over IP.

Today H.323 conference system is one of the most famous conference systems. H.323 basically supports one-to-one remote conference, and H.323 also supports multipoint conference using MCU (Multipoint Control Unit).

MCU communicates with all hosts. MCU collects audio and video streams from all hosts, mixes them, and distributes the mixed stream to all hosts. In other words, MCU holds one-to-one conference with all hosts. Therefore, when the number of hosts increases, CPU and network load on MCU become heavier and conference system may become overloaded. To avoid this bottle neck about load on MCU, conference system should adopt the method of distributing the load on MCU. The existing method of load sharing is using multiple MCUs as Fig.1. It distributes the hosts of which MCU has to take care to two or more MCUs to reduce the load on each MCU. This method reduces the load on each host, but it has some problems. When the number of hosts increase, the number of MCUs which is required for load sharing also increases. And the number and location of hosts change dynamically in the conference. But, the number and location of MCUs should be static. Therefore if the number of hosts becomes enormous, MCUs may become overload after all. And if hosts crowd around somewhere, the MCU near the hosts should deal with them, and becomes overload after all.

B. MPEG4MCU [1]

MPEG4MCU [1] can be partitioned into 2 sections as follows

a) Audio Section

Each Connection object corresponds to each client. The client always sends encoded audio stream to the MPEG4MCU. The decoded audio is used by the DetectVoice function for detecting the speaking client.

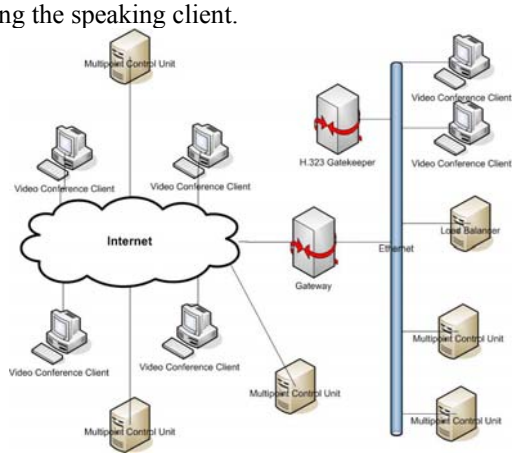

Figure 1 Distributed MCUs [6] Video Conference

b) Video Section

When the video stream from the client come to, the MPEG4MCU will decode and then detect whether this terminal is in the position for video displaying or not. If it is, it copies the video data to the center video buffer in the appropriate position. Finally, it reads the video data from the center video buffer, encode, and then send back to the terminal.

Note that, at any time, the MPEG4MCU will display only 4 users in the video position. So the video data of users outside the video position are still decoded and then leave these resulted in the waste of the network incoming traffic and the CPU Load of the MPEG4MCU.

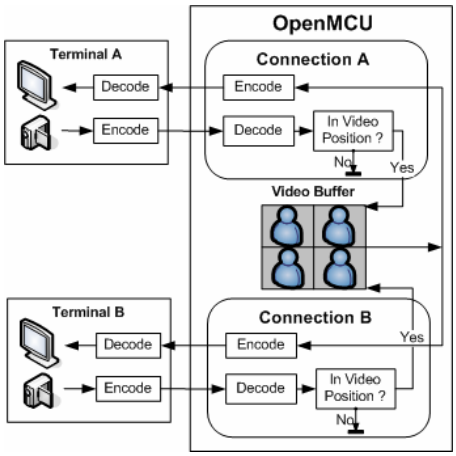

Figure 2 Block Diagram of MPEG4MCU in the video section with 2 terminals

C. Load balancing algorithms

In load-balancing schemes, the two most important policies are information policy and location policy. Information policy will collect load information of each host for location policy decision. When a new task location policy has will consider sending this task to proper host by load information from information policy.

GLOBAL: Every *P* seconds, *load information center* (LIC), receives load updates from all the other hosts and assembles them into *load vector,* which is then broadcast to all the other hosts. When the task arrives to host A, A will look at load vector to find the lowest load host and send the task to. [3]

RANDOM: This algorithm uses only local load information. When a job is found to be eligible for load balancing, it is sent to a randomly selected host. [3]

CENTRAL: In Global algorithm, placement decisions are made by each host using the load vector. In the [3] CENTRAL algorithm, the LIC acts as a central scheduler for all the hosts, in addition to receiving load information from the other hosts periodically. When a host decides that a job is eligible for load balancing, it sends a request to the LIC, together with the current value of its load. The LIC selects a host with the shortest queue length and informs the originating host to send the job there. It is assumed that the loads of all the hosts are known to the placement decision maker(s), with some delay. [3]

THRHLD: A number of randomly selected hosts, up to a limit *Lp* (probing limit), are polled when an eligible job arrives, and the job is transferred to the first host whose load is below load threshold *TI.* If no such host is found, the job is processed locally. [3]

LOWEST: This is similar to THRHLD except that, instead of using a threshold for the placement, a fixed number of hosts *L,,* are polled and the most lightly loaded host is selected. The probing stops if an empty host is found. [3]

Credit-based: The credit-based load-balancing model focuses on these two policies. We assign a numerical value, called credit, to every host. The credit indicates load of the host. The lower its credit has chance to take new task. The credit of each host changes in accordance with the behavior of the system and interaction [2]

III. OUR LOAD BALANCING ALGORITHM

There are two important policies, information policy and location policy in dynamic load balancing algorithm.

A) Information policy:

Load information from each host is very small size when compare with data packets in video conference. So we make decision to collect load from all MCUs to Load Balancer (LB) periodically.

The task of MCU is encoding and decoding video, mixing video and audio and managing floor and transfer data. Therefore load of MCUs is combining of computation load and communication load

$$C_{MCU} = C_{CP} + C_{NW} \quad (1)$$

C_{MCU} = MCU Credit

C_{CP} = Computation Credit

C_{NW} = Communication Credit

A.1) Computation credit is combining of central processing unit (CPU) and memory available because MCU task is encoding and decoding video, mixing video and audio that consume CPU resource and memory.

$$C_{CP} = f_{CP}(W_{cpu}A_{cpu}, W_{mem}A_{mem}) \quad (2)$$

A_{cpu} =Available Central Processor Unit (CPU) (%)

A_{mem} = Available Memory (%)

W_{cpu} = Weight number for CPU load

W_{mem} = Weight number for Memory used

f_{CP} = Computation Weight Function

MCU has variations of CPU powers, memory capacities and network performance. We use MCU_j to represent one of the MCUs in a heterogeneous network of MCUs [4]. We also use

variable P to represent the total number of MCUs in the system. The CPU weight of a workstation refers to its computing capability relative to the fastest workstation in a distributed system. The value of the CPU weight is less than or equal to 1. Since the CPU weight is a relative ratio, it can also be represented by the CPU speed of each node measured by millions of instructions per second (MIPS). If $V_{cpu}(j)$ is the speed of MCU_j in MIPS, j = 1, …, the CPU weight can be expressed as follows:

$$W_{cpu}(j) = \frac{V_{cpu}(j)}{Max_{i=1}^{P} V_{cpu}(i)} \quad (3)$$

Similarly, the memory weight is calculated by comparing the memory sizes among the MCUs:

$$W_{mem}(j) = \frac{Mem_j}{Max_{i=1}^{P} Mem_i} \quad (4)$$

Where Mem_j is the amount of user available memory space in MegaBytes on MCU_j for j = 1, …, P.

A.2) Communication credit is network bandwidth available and delay between host and client. Because each MCU is not on the same network bandwidth and speed between host and client will be different.

$$C_{NW} = W_{bw} A_{bw} + T \quad (5)$$

A_{bw} = Bandwidth usage (%)

T = Percentage of delay time between MCU and client (%)

W_{bw} = Weight number for bandwidth used

$$W_{bw}(j) = \frac{BW_j}{Max_{i=1}^{P} BW_i} \quad (6)$$

H.323 video conference acceptable delay is between 150 – 300 ms [8] so if MCU has delay from MCU and Client > 300 ms we will not choose it and we use 300 ms to convert delay time from ms to percent as below:

$$T = \begin{cases} (300 - delaytime^*) \times 0.33 & delaytime \le 300ms \\ -\infty & delaytime > 300ms \end{cases} \quad (7)$$

* Size of test packet = 64 kilobyte (Maximum size of ping command)

B) Location Policy:

When LB gets load information from each host, LB will convert received load to credit and collect in LB. Conversion method needs to weight the receiving load from each host.

Whenever a new conference room is created, LB will compute the collected credit of each MCU and select any MCU with the highest credit at that moment to serve that new room.

IV. EXPERIMENT AND RESULTS

Our experiment is consist of, Load balancer, MCU and Call generator as show in Fig 3.

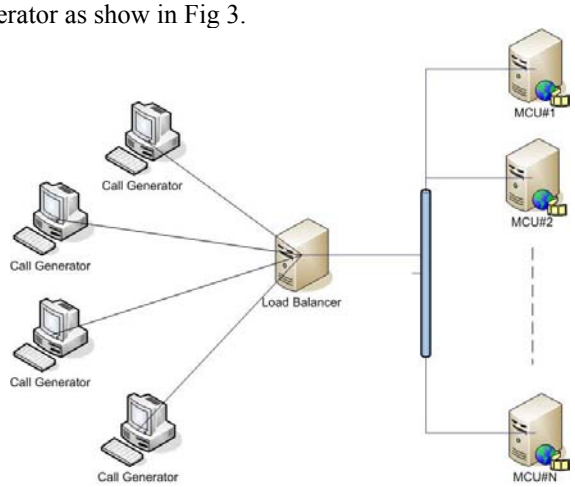

Figure 3 Environment in our experiment using our load balancing algorithm in Eq. (2)

A)Load Balancer(LB)

Load balancer (LB) is an opensoure application from www.codeproject.com that we enhance to collect memory and bandwidth used by the applications to calculate computation and communication credits. LB is developed using Microsoft Visual C++. NET 2003 with winpcap library version 3.01.

B)MCU

We install MPEG4MCU from [1] with no Gatekeeper on several machines as follows:

1) MCU1 = Pentium D CPU 3.0GHz, Memory = 512 MB
2) MCU2 = Pentium 4 CPU 2.8 GHz, Memory = 512 MB
3) MCU3 = Pentium M CPU 1.4 GHz, Memory = 768 MB
4) MCU4 = Celeron 2.6 GHz, Memory = 384 MB

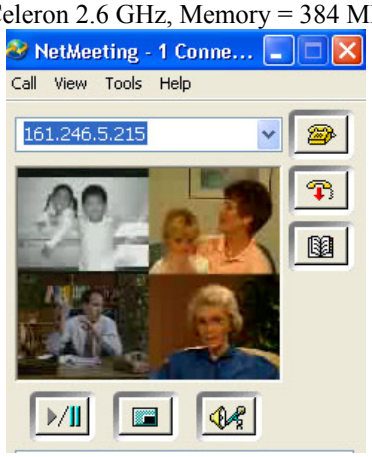

Figure 4. Netmeeting with OpenMCU [7]

C)Call generator

We use call generator from [1] that can send and receive audio and video with following parameters:

Video codec = MPEG-4
Frame rate = 10 Frames/sec
Audio codec = G.711-uLaw-64k (PCM)
Audio Sampling rate = 8 kHz
Users per room = 4 users per room

D) Results

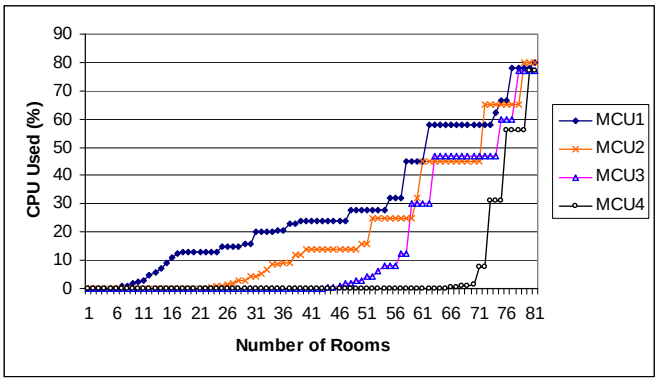

Figure 5. %CPU Used on each MCU

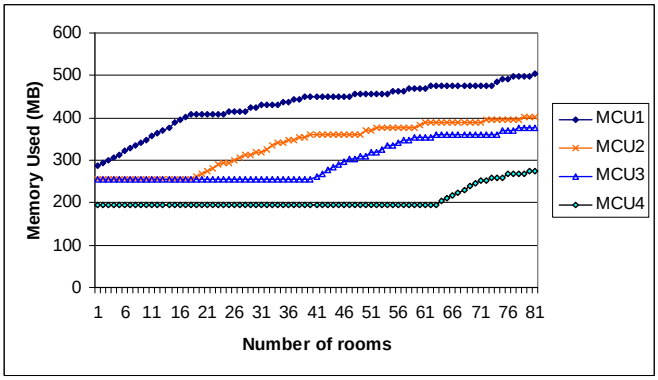

Figure 6. Memory Used in MegaBytes on each MCU

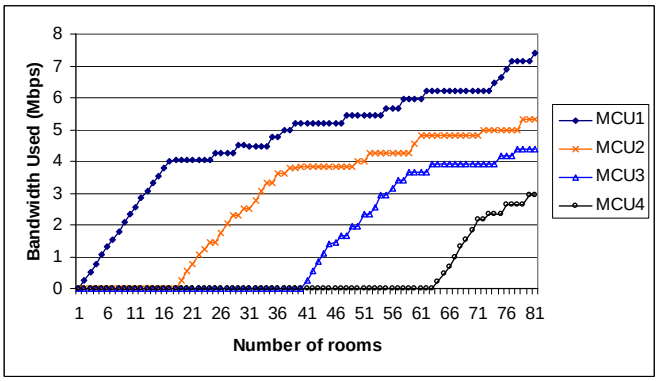

Figure 7. Bandwidth Used in Mbps on each MCU

From the experiment, the proper weighting function between CPU and memory is:

$$f_{CP}(W_{cpu}A_{cpu}, W_{mem}A_{mem}) = W_{cpu}A_{cpu}^2 + W_{mem}A_{mem} \quad (8)$$

we use weighting function (f_{CP}) according to Eq.(8). It can be noticed in Fig. 5, 6, and 7 when we start adding conference rooms until 23 rooms into the system, the LB chooses only MCU1 because MCU1 has the fastest CPU. Then, the LB chooses MCU2 together because of low % CPU used. At 46 rooms in the system, the LB just chooses MCU3 because MCU1 and MCU 2 are quite loaded. Eventually, when Room 70 is added, it is redirected to MCU4 which has the slowest CPU but the least %CPU used.

After we use LB with weighting function, CPU, memory and bandwidth used of all MCUs gradually increase together and no MCU has critical CPU, memory and bandwidth used at anytime.

VI. CONCLUSION

This paper presents a load balancing algorithm for videoconference multipoint control unit (MCU) to manage distributed MCUs in video conference system. We take into account the computation load(%CPU load and %memory used) on the MCUs and communication load between each MCU and its H.323 clients. The decision is based on credit that is a sum of weighted available loads. The load balancer picks the MCU with the highest credit to serve the newly arriving videoconference room.

For future work, we will do more experiments by setting up MCUs running on a variety of CPUs with different memory sizes over an emulated IP network using NISTNET [9] as shown in Fig. 15. Hence, we will measure CPU load, memory used, and bandwidth used in order to compute the proper weighting function for different MCU specification and different network environments. Finally, we will compare our algorithm with others.

Continuous Thai Sign Language Recognition using HMM with Transition Models

Arunee Jaruwanawat and Nopporn Chotikakamthorn
Faculty of Information Technology, and
Research Center for Communications and Information Technology
King Mongkut's Institute of Technology Ladkrabang, Bangkok Thailand
(E-mail: s5066025@kmitl.ac.th)

***Abstract*-This paper addresses the problem of continuous Thai sign language recognition. Sign language is typically composed of hand shapes and gestures formed by the movement of hands, arms and perhaps body also. One of the problems in performing continuous sign recognition is the existence of hand and arm movement in transition between two signs. This spontaneous transition movement conveys no meaning. However, not taking it into account results in poor recognition performance. This papers proposes the inclusion of algorithmic-based HMM transition movement models within a HMM-based sign language recognition system. A transition movement is represented by a single-state HMM model, of which its model parameters are obtained algorithmically based on the HMM parameters of the two signs involved in the transition. This avoids the need to collect extensive training data for modeling all possible transition movements in a conventional manner. In addition, to realize continuous sign language recognition, in this paper a pruning strategy for reducing the complexity of a Viterbi search is also described. Based on the experiment result, inclusion of such model within a HMM-based recognizer was found to offer improved recognition performance.**

***Keywords*- Sign Language, Hidden Markov Model, Transition Movement**

I. INTRODUCTION

People with hearing and speech impairments communicate within their communities through the use of a sign language. Use of this specialized language, however, is limited to those who have acquired knowledge of the language. This largely prevents deaf people from communicating with those outside their communities. Also, while currently there exists a speech recognition system, allowing a computer user to input textual data through voice, there is not yet an equivalent product for deaf people. A sign language recognition system has been seen as an enabling technology to allow for natural human-computer interaction, as well as to assist in communications between those who understand the sign language as those who do not.

Previous works in continuous sign language recognition, with the emphasis on problems related to transition movement, include those of [1-6]. In [1], equipped with an electronic glove device and a 6-DOF tracking sensor, a method was proposed to segment continuous sentences such that transition movement can be removed before the segmented data being processed by a HMM-based recognizer. This 'hard' pre-segmentation strategy is, however, suboptimal as compared to a 'soft' segmentation inherent in a general HMM-based pattern recognition method, where segmentation and recognition are jointly performed to achieve optimal result. In [2, 4], transition movements are first extracted. This extracted data is then used to perform data clustering using a Dynamic Time Warping (DTW) method. The so-obtained clusters are used to form HMM models for transition movements. The problem with this method based on conventional HMM model construction is its need for extensive training data to sufficiently cover possible transition movement patterns.

In [3], a large vocabulary sign language recognition is considered. Due to a large sign database, extensive Viterbi search is required. The solution suggested in [3] is based on a two-stage classification strategy. A sign gesture input is first classified into one of the clusters of similar signs. Then, a Viterbi search is performed on a small subset of HMM models corresponding to signs belonging to that cluster. Although efficient computation is obtained, this two-stage classification method is suboptimal for the search is performed over a subset of a set of all feasible solutions. It also results in poorer recognition rate as compared with a direct search over all feasible HMM models [1].

Most research works in sign language recognition deal with languages used by people of large population such as American and Chinese sign languages. However, it is known that a sign language, like its spoken language counterpart, is different from one region to another. For Thai sign language, early works include those of [5-6]. In [5, 6], a Thai sign language recognition system based on a statistical-based estimator was described. The method performs a pre-segmentation of input data from an electronic glove into static and dynamic gestures. Recognition is performed from the classified data using a Bayesian estimator. The method can perform recognition of signs with certain regularity in the movement patterns. However, it cannot deal with signs of irregular patterns, as well as transition movements. A solution to automated Thai sign language recognition based on HMM models was suggested in [5]. Use of HMM models allows signs of arbitrary movement patterns to be handled in a unified manner. However, the method in [5] was applied on a single-sentence basis. In [6] a method was developed to classify periodic gestures as found in Thai sign language and those with non-periodic nature, of which transitional gestures form a large part of them. However, the method in [6] can not differentiate between some non-periodic and yet meaningful gestures from those due to transition movements. No known work has been done on recognition of continuous Thai sign language containing both periodic and non-periodic gestures.

In this paper, a problem of continuous Thai sign language recognition is considered. In particular, the problem due to the existence of a transition movement is addressed. It is known that, by neglecting such spontaneous movement in modeling the recognition system, recognition performance is degraded [3]. The method described in this paper is based on a HMM model. Unlike those in [2, 4], this paper proposes an algorithmic-based method for construction of a transition model. This avoids the need for

collection and processing of extensive training data for transition movements. Also, it can be used to handle transition movement between any two arbitrary signs. To address complexity in performing Viterbi search on continuous signs, a pruning strategy based on the detection of static signs is also described.

This paper first introduces a general framework of a Thai sign language recognition system in Section 2. Then, a detailed discussion on modeling a transition movement is described in Section 3. A Viterbi search strategy is also given. Experimental result is provided in Section 4, with concluding remarks given in Section 5.

II. THAI SIGN LANGUAGE RECOGNITION SYSTEM

Like other sign languages, Thai sign language is composed of hand shapes and gestures formed by the movement of hands, arms and body. Sometimes, facial expression also plays a crucial role in sign interpretation. Here, only part of the gestures formed by hand shapes and movement of hands and arms are considered. In this study (see Figure 1), a sign gesture is roughly classified into static (posture) and dynamic gestures. Dynamic gestures are further classified into sign movements and transition movements.

- Static gesture (posture) is a sign of which there is no hand or arm movement. Only the hand posture that defines the meaning of the sign.
- Dynamic gesture contains a hand/arm movement. It is further divided into
  - dynamic signs, which are meaningful hand movement, and
  - transition movements, which occur during the transition from one sign to another and convey not meaning.

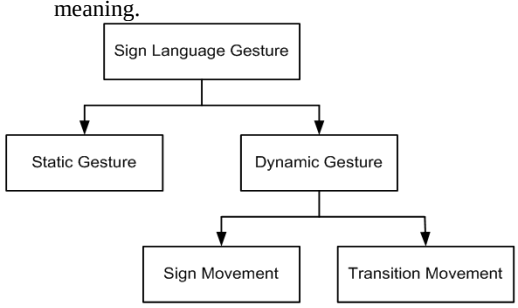

Figure 1. Classification of Thai sign gestures

An overall view of the Thai sign language recognition system, which contains the work described here as its part, is illustrated in Figure 2.

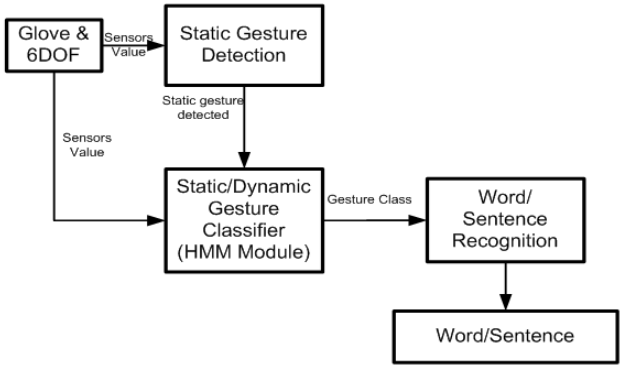

Figure 2. Block diagram of the continuous Thai sign language recognition system.

From the figure, the system is composed of four main parts. The first one is responsible for acquisition of hand shapes and movements. Here, an electronic glove with a 6-DOF electro-magnetic sensor is used as an acquisition device. The second part is the HMM-based gesture recognizer. The third part is the static gesture detector. The result of the detection is used to assist the HMM recognizer in selecting feasible Viterbi paths (pruning). And the last part is the word/sentence recognizer. This part uses the result from the gesture recognizer, along with a sign language model, to produce the final recognized word/sentence. In this paper, the focus is mainly on the second and, to a lesser extent, the third parts of the system.

III. CONTINUOUS THAI SIGN LANGUAGE RECOGNITION WITH ALGORITHMIC-BASED TRANSITION MODELS

A. Modeling the transition movement

Here, an HMM model is adopted for the recognition of both static and dynamic signs. As pointed out by previous work [2, 4], transition movement should be incorporated in the model to improve recognition rate. Instead of directly training the model using data of transition movements, in this paper we propose that a transition movement is modeled using a single state HMM of which its model parameters are obtained algorithmically at run-time. Thus, given two signs (the last states of the word models A and B respectively) connected by a particular transition movement, the series of interconnected HMM models is described by Figure 3.

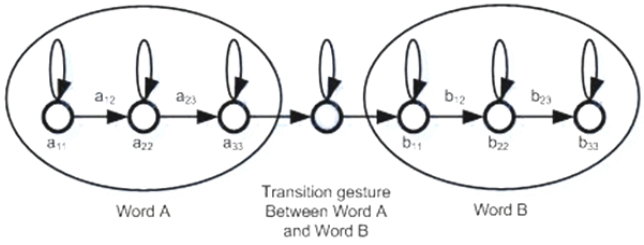

Figure 3. Series of HMM states, connected by a transition state, to model continuous signing.

In our study, a single-state HMM transition model is constructed at run-time based on HMM parameters corresponding to the last state of Word A and the first state of Word B. To explain the algorithm, some notations for HMM models are first introduced. Let (π, A, μ_i, U_i) be an HMM model parameters corresponding to the first word (Word A in Figure 3). Here, π is the initial probability of being in the first state. **A** is a matrix of state transition probabilities. In addition, μ_i is the means vector of the i^{th} state outcome and U_i is the corresponding covariance matrix. Similarly, (π', A', μ_i', U_i') are HMM parameters corresponding to the second word (Word B in Figure 3). In addition, we define $(\overline{\pi}, \overline{A}, \overline{\mu}, \overline{U})$ as model parameters corresponding to the single-state transition model. These parameters are obtained below.

First, because each transition model is designed for a particular pair of sign words, its initial probability can be set to $1 - a_{33}$, where a_{33} is the probability that the system, once reaching the last state in

Word A, remains on the same state. Next, because the model contains a single state, $\overline{A}$ is scalar. It is set to 1 - π'. The model parameters related to the outcome probability is obtained according to the following equations.

$$\bar{\mu} = \frac{\mu_3 + \mu'_1}{2} \quad (1)$$

$$\overline{U}_{11} = \frac{U_{3,11} + U'_{1,11}}{2} \quad (2)$$

$$\overline{U}_{12} = \overline{U}_{21}^{T} = 0 \quad (3)$$

$$\overline{U}_{22} = \begin{bmatrix} \sigma_1^2 & & & \\ & \sigma_2^2 & & \\ & & \ddots & \\ & & & \sigma_N^2 \end{bmatrix} \quad (4)$$

From Eq. (2), $\overline{U}_{11}$ is the $M \times M$ top-left submatrix of $\overline{U}$, where M is the number of data points obtained from an electronic glove. Similarly, $U_{3,11}$ and $U'_{1,11}$ are the $M \times M$ top-left submatrice of U_3 and U'_1 respectively. In Eqs (3, 4), $\overline{U}_{12}$, $\overline{U}_{21}$, and $\overline{U}_{22}$ are the remaining submatrice of $\overline{U}$ (see Figure 4, for an illustration). The size N of $\overline{U}_{22}$ is equal to the number of data points obtained from a 6-DOF electromagnetic location sensor (N = 6). The variance parameters in Eq. (4) are obtained from the following equation.

$$\sigma_i^2 = \{|\mu_{3,M+i} - \mu'_{1,M+i}| / \alpha\}^2 \quad (5)$$

Here, $\mu_{3,M+i}$ is the mean value at the third state in the first word model, corresponding to the ith data point from the location sensor. In addition, $\mu'_{1,M+i}$ should be interpreted similarly. From the same equation, α is a scaling factor, arbitrarily chosen as 6.

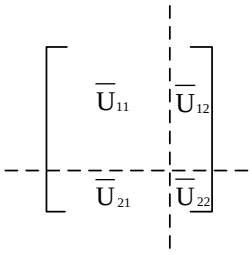

Figure 4. Decomposition of $\overline{U}$ into four submatrice

B. Viterbi search strategy

Generally, pattern recognition by HMM model involves a search for a best path (i.e., a sequence of HMM states) using a Viterbi algorithm. However, for continuous sign language recognition, with medium to large vocabulary support, the search complexity and space is increased significantly. To maintain the search complexity and memory space requirement to a practically realizable level, certain search strategy must be applied to a standard Viterbi algorithm. Here, by observing that many words in Thai sign language are composed at least partly of static signs, those static moments are detected and utilized (along with some heuristic rules) as part of the pruning strategy in an attempt to keep the number of active paths to an acceptable figure. The search strategy used here is summarized in Figure 5.

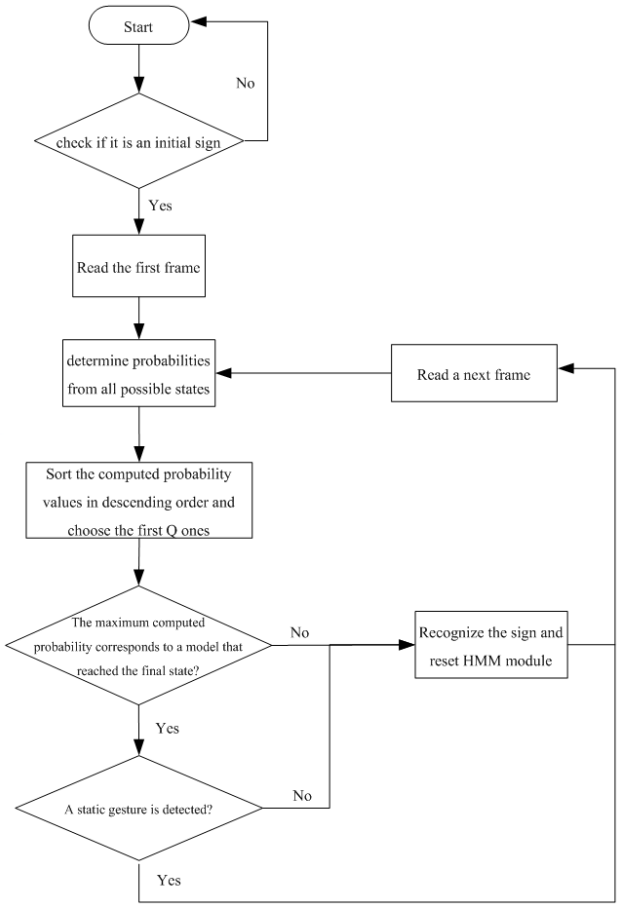

Figure 5. A flow chart describing a pruning strategy, to be used with a standard Viterbi algorithm

From Figure 5, the parameter Q is the maximum number of feasible Viterbi paths that can be kept at any time instance. Therefore, from time to time, rules must be enforced to select Q best paths from all candidates. Here, in addition to a simple accumulated probability sorting, it is proposed that a detection of static sign is used to significantly reduce infeasible paths. Detail of a static sign detector is not given here. It is, however, similar to that used in [6].

IV. EXPERIMENTAL RESULT

The experiment was carried out based on 13 sentences of everyday use. Each sentence is composed of 2-3 words on average and was selected from [7]. For each sentence, 20 data sets were collected using a right-hand electronic glove and a 6-DOF location sensor. A signer performed each sentence by starting in the pre-defined initialized position. In summary, 40 data sets were collected for each sign word. Of these, 30 sets were used for training and the remaining data sets were used for testing.

Two HMM-based sign language recognition techniques were applied to the same data sets. The first one employed the proposed transition models as part of the HMM models. The second one did not model the transition movement. For the latter model, each HMM sign model was simply connected to the next one. The results are shown in Tables 1 and 2. From the tables, it is seen that the proposed method offers noticeable performance improvement. It is noted, however, that this is achieved without additional work on training the transition movement.

Table 1. Recognition performance using the method with algorithmic-based transition models

Sentence	Word sequence	Accuracy (%)
1. I was born in Denmark.	Born-Denmark	100
2. I met him in Denmark.	Meet-Him-Denmark	80
3. Please, sit down.	Please-Sit	100
4. Your mom is fine.	Mother-Fine	95
5. Today is Monday.	Today-Monday	95
6. I take a rest on Friday.	Friday-Rest	80
7. I have ten relatives.	Relative-Ten	85
8. I have ten goats.	Goat-Ten	85
9. I study English on Monday.	Monday-Study-English	90
10. I'll go swimming in the day after tomorrow.	Swim-The day after tomorrow	100
11. Orange has a sour taste.	Orange-Sour	90
12. Elephant is big.	Elephant-Big	80
13. Frog eat fly.	Frog-Eat-Fly	90

Table 2. Recognition performance using the method without modeling transition movement.

Sentence	Word sequence	Accuracy (%)
1. I was born in Denmark.	Born-Denmark	75
2. I met him in Denmark.	Meet-Him-Denmark	70
3. Please, sit down.	Please-Sit	85
4. Your mom is fine.	Mother-Fine	80
5. Today is Monday.	Today-Monday	85
6. I take a rest on Friday.	Friday-Rest	70
7. I have ten relatives.	Relative-Ten	70
8. I have ten goats.	Goat-Ten	75
9. I study English on Monday.	Monday-Study-English	75
10. I'll go swimming in the day after tomorrow.	Swim-The day after tomorrow	80
11. Orange has a sour taste.	Orange-Sour	75
12. Elephant is big.	Elephant-Big	70
13. Frog eat fly.	Frog-Eat-Fly	75

V. CONCLUSION

In this paper, the problem of modeling transition movements for Thai sign language recognition has been addressed. The transition models, based on algorithmic construction at run-time, have been described. It has been verified through the experiment that the use of the proposed transition model offers improved performance over the standard HMM-based method without transition movement modeling. The improvement is attained without the need for additional training work for modeling these spontaneous movements.

***Abstract*- In this paper, we propose the shape-based object segmentation method. Our method is divided into two stages. In the first stage, we estimate the coefficients of the eigenshape of the object and the pose parameters to match the eigenshape to the actual object shape. In the second stage, we fine tune the result of the first stage. Level set method is used in the second stage. We test our method on both synthetic and cardiac MRI. From the experiment, our method gave the boundary that was near the actual boundary in every test.**

I. INTRODUCTION

Extracting organs from medical images is a tedious and time consuming task. So, automatic segmentation is preferable. The desired accuracy of medical image segmentation is high; however, segmentation algorithms, which work well on general image, do not give the satisfy results because medical images have poor contrast, high noise and missing boundary information.

Active contour methods, introduced by Kass *et al*. [1], are widely accepted as the efficient segmentation algorithm. Edge contour is extracted according to image force, defined by gradient of the image, and internal force, defined by the curve characteristic. This method fails to extract edges at the sharp corner. Melladi *et al*. [2] introduced level set for image segmentation. Edge is extracted as the pixels with the zero signed distance value. Both active contour and level set method use intensity gradient to define image force. Estimation of this gradient is very sensitive to noise. Chan and Vese [3] defined image force as the function of the region homogeneity. Their method works well on segmenting regions with no distinct edge.

Image information alone is not sufficient for extracting organs in medical images, because the intensity variation among organs is not always distinct. In addition to image information, object shape must also be considered. Chen *et al*. [4] used mean shape of the training set as prior knowledge. The contour must minimize the sum of distance from the extracted object to the mean shape and image energy. Leventon *et al*. [5] derived shape parameters by PCA on a set of signed distance of training images. Segmentation is under the influence of image force and shape parameters estimated by MAP. The shape parameters are estimated every iteration of level set computation. Tsai *et al*. [6] also represented the model by parameters derived from PCA. Tsai method estimated the coefficients of the eigenvector and used the estimated coefficient to construct the segmentation results.

Because we cannot find all eigenvectors from the limited number of training data, error from the image reconstructed by PCA is unavoidable. However, segmenting curve from Tsai is still useful. To improve the segmentation result, fine tuning process, which can move the contour to the actual boundary, is considered. However, from our review, there is no work specific on this issue. Nonetheless, it can improve the results with very few noticeable differences on complexity.

In this paper, we propose the two-stage level set segmentation method. In the first stage, we adopted the algorithm by Tsai *et al*. to estimate and extract the object shape. In the second stage we fine tune the result by moving the edge inside the area near the estimated shape (from the first stage). In this stage, we applied the segmentation technique of Chan and Vese.

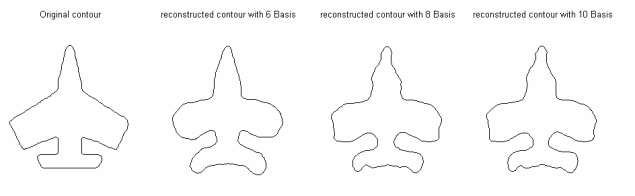
The rest of this paper is organized as follows. Section II explains how we extract the shape information and reconstructed the object shape for the given image (first stage). The fine tuning (second stage) is described in Section III. Section IV shows experimental results and discussion. We then conclude this paper in Section V.

II. SHAPE INFORMATION EXTRACTION AND SHAPE RECONSTRUCTION

A. Training Image Alignment

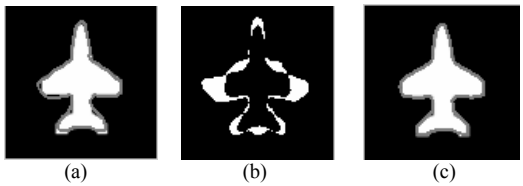
Object shapes are built from the set of objects extracted by experts. The shapes are represented by binary format with pixel value "one" inside the object and otherwise "zero". All training shapes are aligned to the same pose and scale. Following the algorithm of Tsai *et al*. we align binary images by estimating the pose parameter giving the minimum cost. The cost function is defined as follow:

$$E_{align} = \sum_{i=1}^{n} \sum_{\substack{j=1 \\ j \neq i}}^{n} \left\{ \frac{\iint_{\Omega} \left(\tilde{I}^{i} - \tilde{I}^{j} \right)^2 dA}{\iint_{\Omega} \left(\tilde{I}^{i} + \tilde{I}^{j} \right)^2 dA} \right\}, \quad (1)$$



(a) (b) (c) (d)

Figure 1. The error of shape reconstruction. (a) Original Shape. (b) – (d) Reconstructed Shape using 6, 8 and 10 bases.



(a) (b) (c)

Figure 2. (a) boundary from the first stage. (b) Active region of (a) with b=1 and k=2. (c) Segmenting curve after fine tuning.

where $\tilde{I}^i(\tilde{x},\tilde{y}) = I^i(T[\mathbf{p}][x\ y\ 1]^T)$, the i th binary image, and Ω denotes the image domain. The pose parameter, $\mathbf{p}$, consist of x-, y-translation, scale and rotation. The optimal pose parameters are found by gradient descent method.

B. Shape Representation

Signed distance function is used to represent the object shape. Pixels inside and outside the object have the negative and positive signed distance value, respectively. The magnitude of the signed distance function represents the distance of the pixel to the nearest edge. The boundary is embedded in the pixels with the zero signed distance value. The shape variation is captured via mean-offset functions $\{\tilde{\boldsymbol{\Psi}}_1, \tilde{\boldsymbol{\Psi}}_2, ..., \tilde{\boldsymbol{\Psi}}_n\}$, which are the value of n signed distance function subtracted by their mean level set function $\overline{\boldsymbol{\Phi}}$ at that position. The mean level set function is defined by,

$$\overline{\boldsymbol{\Phi}} = \frac{1}{n}\sum_{i=1}^{n} \boldsymbol{\Psi}_i, \tag{2}$$

where $\boldsymbol{\Psi}_i$ is the signed distance function of image i. Each mean offset function is stored in lexicographical order forming $N = N_1N_2$ elements vector. The n principal bases from n training curves are found by eigenvalue decomposition of $(1/n)\mathbf{S}\mathbf{S}^T$, where $\mathbf{S}$ is the $N\times n$ matrix defined by $\mathbf{S} = [\tilde{\boldsymbol{\Psi}}_1\ \tilde{\boldsymbol{\Psi}}_2\ ...\ \tilde{\boldsymbol{\Psi}}_n]$. Eigenvalue decomposition is defined by following equation:

$$\frac{1}{n}\mathbf{S}\mathbf{S}^T = \mathbf{U}\Sigma\mathbf{U}^T. \tag{3}$$

The n orthogonal bases are stored in each column of $\mathbf{U}$. We re-order the column of $\mathbf{U}$ from N_1N_2-D vector into $N_1\times N_2$ matrix, called eigenshape ($\boldsymbol{\Phi}$). The magnitude of eigenvalue shows the degree of variation among the training shapes in the direction of the corresponding eigenshape. Small eigenvalue indicates small variation from the mean value. Small variation can be ignored, so, at this eigenshape direction, the mean level set is sufficient to represent the entire set of training shapes. Thus, the shape can be represented as follow:

$$\boldsymbol{\Phi}[\mathbf{w}] = \overline{\boldsymbol{\Phi}} + \sum_{i=1}^{k} w_i \boldsymbol{\Phi}_i, \tag{4}$$

where $k \le n$ and w_i is the result of projecting image to $\boldsymbol{\Phi}_i$. By varying $\mathbf{w}$, the shape is changed. The pose of the object can be changed by adding the pose parameter into equation (4) as shown in equation (5).

$$\boldsymbol{\Phi}[\mathbf{w},\mathbf{p}](x,y) = \overline{\boldsymbol{\Phi}}(\mathbf{p}) + \sum_{i=1}^{k} w_i \boldsymbol{\Phi}_i(\mathbf{p}) \tag{5}$$

C. Segmentation Process

The segmentation follows the algorithm of Chan and Vese [3], which segments an image into two regions with homogenous intensity. This segmentation is the problem of minimizing the following function:

$$\begin{aligned} E(C) = {} & \lambda_i \int_{inside(C)} \left| I(x,y) - \hat{I}_i \right|^2 dxdy \\ & + \lambda_o \int_{outside(C)} \left| I(x,y) - \hat{I}_o \right|^2 dxdy \end{aligned} \tag{6}$$

which is equivalence to the energy function of $\mathbf{w}$ and $\mathbf{p}$ parameter defined in equation (7).

$$\begin{aligned} E(\mathbf{w},\mathbf{p}) = {} & \lambda_i \int_{\Omega} \left| I - \hat{I}_i \right|^2 H(-\boldsymbol{\Phi}(\mathbf{w},\mathbf{p}))dA \\ & + \lambda_o \int_{\Omega} \left| I - \hat{I}_o \right|^2 H(\boldsymbol{\Phi}(\mathbf{w},\mathbf{p}))dA. \end{aligned} \tag{7}$$

where

$$H(x) = \begin{cases} 1 & \text{if } x < 0 \\ 0 & \text{if } x \ge 0. \end{cases}$$

The optimal $\mathbf{w}$ and $\mathbf{p}$ are found by gradient descent method. The boundary of an object is extracted from the zero level of $\boldsymbol{\Phi}(\mathbf{w},\mathbf{p})$.

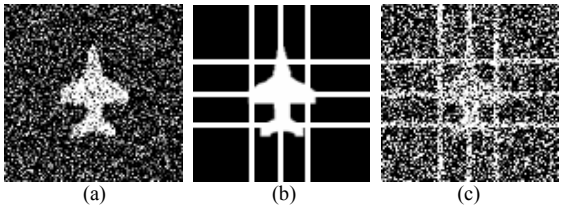
III. Fine Tuning Process

Because we use fewer bases than the available basis, the extracted boundary does not exactly match the boundary of an object as shown in Figure 1. In this Figure the error exists; although, we use all eigenshapes. Nevertheless, we found that the extracted boundary is near the actual boundary. By fine tuning the extracted boundary, it is possible to move the boundary to the actual boundary. We applied the segmentation algorithm of Chan and Vese in our fine tuning stage; however, we restrict the area that the boundary can moves. We call this area "active region" and define the area by the following function:

$$A_{Active} = \left| H(\boldsymbol{\Phi}_k[\mathbf{w}_k + b\boldsymbol{\sigma}_k, \mathbf{p}]) - H(\boldsymbol{\Phi}_k[\mathbf{w}_k - b\boldsymbol{\sigma}_k, \mathbf{p}]) \right|, \tag{8}$$

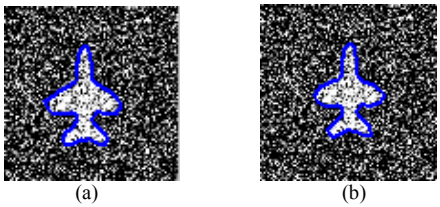
where b controls region size and $\boldsymbol{\sigma}$ is the standard derivation of the eigenshapes. A_{Active} is one in the active region and zero, otherwise. For a small b, the active region is narrow. The active region would be narrow on the region that the curve has low variation, and vice versa. To build the active region, we use only the eigenshape with large variation (large eigenvalue). Figure 2(b) shows the active region of fighter jet image boundary from first stage, as shown in figure 2(a), with b=1 and k=2.

Now, the signed distance values are changed by the following equation,



(a) (b) (c)

Figure 3 Examples of synthetic image which have been tested. (a) Fighter jet image with noise. (b) Fighter jet image with occlusion. (c) Fighter fet image with noise and occlusion.



(a) (b)

Figure 4. (a) Segmenting curve of the first stage. (b) Segmenting curve after fine tuning.

$$\frac{\partial \Phi}{\partial t} = \delta(\Phi) A_{Active} \left[\mu K + \lambda_i (I - \hat{I}_i)^2 - \lambda_o (I - \hat{I}_o)^2 \right], \quad (9)$$

where K and is a curvature of the level set function.

IV. Experiment

A. Quality Assessment

In this paper, we used two techniques, area similarity [7] and distribution of distance from reference boundary, to measure and compare the quality of our segmentation method to Tsai's method. In order to have the absolutely correct segmentation result, we used the synthetic image to assess the segmentation method.

1) Area Similarity: In this method, we compare the area of the segmented object with the reference object. Let A and A_R be the binary images of segmenting curve and the reference object templates which pixel with value "one" lies inside the object and pixel with value "zero" lies outside the object. Area similarity can be calculate by

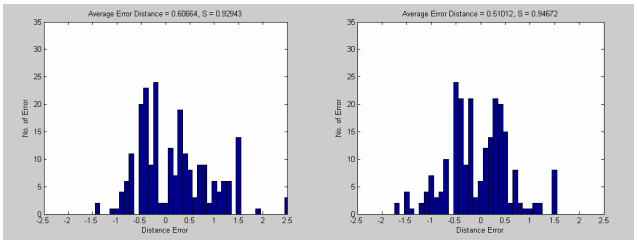
$$S_{area} = \frac{2n(A_R \wedge A)}{n(A_R) + n(A)} \quad (10)$$

where $\wedge$ is "and" operator and $n(\cdot)$ is the number of the pixel inside the object.

2) Distribution of Distance from Reference Boundary: This technique shows the number of pixels on the curve which are far from reference curve for each distance range. Let distance from any point (x,y) to curve C be

$$D(x,y) = \begin{cases} -\min\limits_{(i,j)\in C} \sqrt{(x-i)^2 + (y-j)^2}, (x,y) \text{ is inside } C \\ \min\limits_{(i,j)\in C} \sqrt{(x-i)^2 + (y-j)^2}, (x,y) \text{ is outside } C. \end{cases} \quad (11)$$

The distribution of distance from pixels on the extracted boundary to the reference boundary indicates the accuracy of the segmentation. If the distribution concentrates near zero, the accuracy of segmentation is high.



(a) (b)

Figure 5. (a) Distribution of distance from reference curve of Figure 3(a). (b) Distribution of distance from reference curve of Figure 3(b).

B. Result and Discussion

We test our proposed method with synthetic and medical image. The performance of our method is compared with Tsai's method by the proposed assessment.

1) *Synthetic image:* We used fighter jet images, which are the jet shape binary image, in this experiment. The eigenshapes were calculated from 12 training shapes. In the algorithm of Tsai *et al*., we approximated the coefficients of k eigenshapes, then we used this result as the result of the first stage in our algorithm. In this experiment, we corrupted the jet image by adding noise and occlusion which can be shown in Figure 3. The example of Tested image with noise adding is shown in Figure 3(a). Figure 3(b) shows the image with occlusion and Figure 3(c) shows the image corrupted by both noise and occlusion. In this experiment, we vary the parameter b, the size of active region, and the number of basis k. the experimental result show that our proposed method outperforms in all three cases. Increasing k does not always improve the performance of the first state but, surely, reduce the computational time because more parameters have to calculate. The segmentation performance seems always increase when we increase b and it would saturate at some point. However, in binary image with occlusion, the segmentation performance would drop when b still increase. This means that too much b would decrease the prior information. The curve from the first stage is just the good initial for the second stage but, finally, the curve would act like traditional Chan-Vese algorithm when too much b is used. Figure 4 shows the segmentation result of our proposed method comparing with Tsai's Method when we set b=1 and k=2. Figure 4(a) and 4(b) show the result of Tsai *et al*. method and our method respectively. Comparing Figure 4(a) with 4(b), we found that our extracted boundary fit more into the object than the boundary from Tsai's method. Figure 5(a) and 5(b) are the graphs showing the distribution of distance from reference boundary from the result of Tsai's method and our method, respectively. The result of our algorithm had the range of the distribution distance from -1.75 to 1.5 which is less than the range from Tsai's method (-1.5 to 2). In addition, the number of the pixels with the distance larger than +1 is less in our results. The average error distance and the area similarity of the results from the method of Tsai and our method are shown in Table 1. It is very clear that our method gave the result with smaller average error distance and higher area similarity.

(a) (b)

Figure 7. (a) Enlarged image of Figure 5(a). (b) Enlarged image of Figure 5(b).

2) *Medical Image:* In this experiment, the eigenshapes of heart were calculated from 16 training shape, extracted manually. We test the proposed segmentation method with the cardiac MRIs which are from the same source of our test images. The results of Tsai's and our method are shown in Figure 6(b) and 6(c) respectively. The initial curve is shown in Figure 6(a). These test images have low contrast, so they are hard to evaluate visually. We enlarged and increased the contrast of Figure 6(b) and 6(c) and showed them in figure 7(a) and 7(b) respectively. We found our method gave the boundary that was closer to the true boundary than Tsai's method.

V. CONCLUSION

In this paper, we propose the 2-stage level set segmentation method. In the first stage, we adopt the method of Tsai to extract the object shape. In the second stage, we fine tune our extracted shape by the method of Chan and Vese. We restrict the area that the boundary can move. After comparing our method to the method of Tsai with synthetic and medical images, we found the improvement over Tsai's method in all cases.

TABLE I

SOME COMPARISON BETWEEN TSAI'S AND OUR PROPOSED METHOD

Test Image	average error distance		Area Similarity	
	Tsai's Method	Our method	Tsai's Method	Our method
Jet	0.769	0.391	0.9323	0.9798
Jet+30dB -noise	0.773	0.603	0.9302	0.9434
Jet +Occlusion + 30 dB -noise	1.758	1.572	0.8873	0.8911

***Abstract*-This paper proposes an efficient method to improve the quality of digital image compression using Visual Pattern Image Coding (VPIC) in wavelet domain. Wavelet based compression gives higher quality of the reconstructed image with high PSNR and less amount of minimum mean square error compared to VPIC. However, its compression ratio is reasonably low. Therefore, the proposed method combines the advantages obtained from both wavelet transform and VPIC to achieve high compression ratio while preserve the quality of the reconstructed image. The proposed algorithm can be separated in to three main processes. First, wavelet transform is used to decompose the low and high frequency coefficients. Then, the LL coefficients are reserved, while one of the high frequency sub-bands (HL, LH, and HH) is selected based on its Standard Deviation (SD). The sub-band having the highest information distribution usually contains proper edge information, which could be used to improve VPIC algorithm. Finally, the LL and the selected sub-bands are decomposed to obtain the result image. The experimental results show that the proposed compression algorithm can achieve high compression ratio while still maintain good image fidelity and minimum mean square error.**

I. INTRODUCTION

Several algorithms are proposed for digital image compression such as Block Truncation (BTC), Vector Quantization (VQ) and Visual Pattern Image Coding (VPIC). BTC[1], [2] was first proposed in 1979 by Delp and Mitchell, to compress monochrome images. BTC is an efficient method for block correlated signals. It quantizes block data into two values by preserving the first moment and the second moment. The advantages of BTC are its simple computation, easy implementation and fine edge preservation. The main drawback of BTC is its high bit rate. VQ[3] was proposed in 1980 by Linde, Buzo and Gray also called "LBG" algorithm . It separates an image into blocks (4x4 pixels), which we can determine intensity vector of pixels. Drawback of this method is its high complexity coding and low quality of edge image.

BTC and VQ are similar in that the image to be coded is first partitioned into a large number of smaller sub-images or blocks. Each block is then coded either by extracting certain intrinsically high-information quantities which are transmitted in reduced form(as in BTC), or by marking a comparison between the block and a set of preordained vectors or "typical" sub-image, the index of the "closest" vector being transmitted instead of the original block(as in VQ).

VPIC[4] was proposed in 1990 by Chen and Bovik. High compression ratio with low computational complexity is the main advantage for VPIC. However, the algorithm produces higher minimum mean square error and lower PSNR compared to other techniques.

This paper is organized as follows. Section II describes the overview of proposed method. Section III presents applying of VPIC. Section IV is experimental results and the final is the conclusions.

II. OVERVIEW OF PROPOSED METHOD

In this paper, we presents the compression method applying VPIC encoding with selection of wavelet sub-bands containing 4 separated the frequency bands (LL, LH, HL and HH). Only the LL sub-band is inversed with no modification. One of the other sub-bands is selected based on maximum SD value. This sub-band is used as input to VPIC. Then, the LL sub-band and the result of VPIC are used as input to inverse wavelet transform in order to compressed information as shown in figure 1.

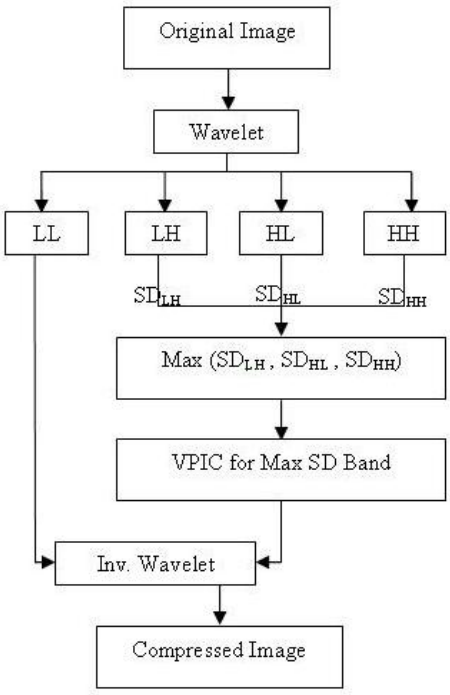

Fig.1 Show the overview of proposed method.

III. Implementation of The Proposed Algorithm

In this section, we apply VPIC to encode image information into binary blocks, and then each binary block is classified as the uniform or edge block based on its gradient magnitude in final stage.

A. Image Coding

In order to reduce the computation time, in the first stage, algorithm is initiated by separating image into sub-blocks (4x4 pixels). Then, the mean intensity of the pixel in each sub-block is calculated as shown in (1). This mean value is used to translate the intensity sub-block into binary sub-block. If the intensity value in the pixel is equal or greater than the mean intensity value, we assign the value of "1" to that pixel, otherwise assign "0".

$$Mean = \left(\sum_{i=1}^{4} \sum_{j=1}^{4} I(i,j) \right) / 16 \tag{1}$$

where $I(i,j)$ is sub-block of image.

Next stage, determine the value of $\Delta_x b_{i,j}$ and $\Delta_y b_{i,j}$ of each sub-block illustrated in (2) and (3) respectively to calculate the value of gradient magnitude and orientation $\angle \Delta b_{i,}$, which can be calculated using (4) and (5) respectively. The gradient value is used to separate between uniform sub-block and edge sub-block while the $\angle \Delta b_{i,j}$ is used to determine the direction of edge in each sub-block.

$$\begin{aligned} \Delta xb_{i,j} = {} & AVE\{ I_{n,m} : 4i+2 \le n \le 4i+3, 4j \le m \le 4j+3 \} \\ & -AVE\{ I_{n,m} : 4i \le n \le 4i+1, 4j \le m \le 4j+3 \} \end{aligned} \tag{2}$$

$$\begin{aligned} \Delta yb_{i,j} = {} & AVE\{ I_{n,m} : 4i \le n \le 4i+3, 4j+2 \le m \le 4j+3 \} \\ & -AVE\{ I_{n,m} : 4i \le n \le 4i+3, 4j \le m \le 4j+1 \} \end{aligned} \tag{3}$$

where $I_{n,m}$ is intensity of pixels in sub-block.

$$|\nabla b|_{i,j} = \sqrt{(\Delta xb_{i,j})^2 + (\Delta yb_{i,j})^2} \tag{4}$$

$$\angle \Delta b_{i,j} = \tan^{-1} \left(\frac{\Delta yb_{i,j}}{\Delta xb_{i,j}} \right) \tag{5}$$

Ultimately, we compare the gradient magnitude value $|\nabla b|_{i,j}$ with the threshold $|\nabla I|$ [1] to classify the class of sub-block. If the $|\nabla b|_{i,j} \le |\nabla I|$, that sub-block is defined as uniform block, and can go to image coding stage. Otherwise, it is defined as edge block. The edge block is compared to 28 pattern blocks to find the most similarity for the next encoding process. Figure 2 shows the 14 examples of the pattern blocks.

B. Coding Analysis

In coding stage, the binary coding is constructed based on the class of each sub-block from the previous stage. The coding information composes of 6-bit mean intensity, 6-bit gradient magnitude value, 5-bit number of pattern block and 1-bit sub-block type. Moreover, two additional bits called sub-band ID are used to identify the sub-band, whose the SD value is maximum. Figure 3 presents the data format obtained after VPIC coding. Table I shows the number of bits for each field of the information coding.

C. Decoding Analysis

At the decoder, the class of sub-block is determined from the received compressed bitstream. If the sub-block is a uniform block, a 4x4 pixel block is created and the mean intensity of each pixel is estimated. In contrast, if the sub-block is an edge block, the pattern block that matches with the information of that sub-block is applied. The mean intensity and gradient magnitude value are used to calculate low and high intensity value. The low intensity value is represented by "0" pixel, high intensity value is represented by "1" as shown in (6).

$$xH+yL=16*Mean \tag{6}$$

where x is "1" in the pattern block number
y is "0" in the pattern block number

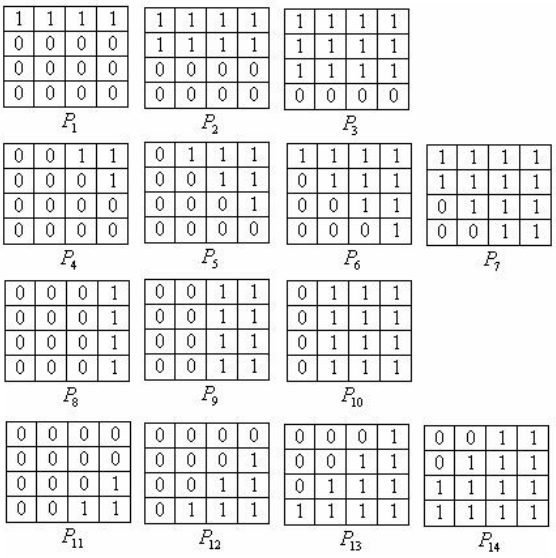

Fig.2 Show 14 examples pattern blocks (a) 90° patterns; (b) 45° patterns; (c) 0° patterns; (d) -45° patterns.

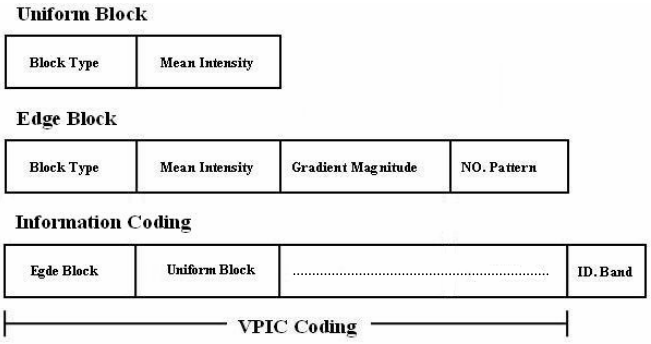

Fig.3 Coding pattern of proposed method.

TABLE I
DETAIL OF INFORMATION CODING.

	Uniform Block	Edge Block
Block type	1	1
Mean intensity	6	6
Gradient	0	6
Pattern number	0	5
Total	7	18

For example, we would like to find the low and high intensity value of pattern block P1 as shown in figure 2.

Given

$$4H+12L=16*Mean \quad (6.1)$$

From (5)

$$|\nabla b|_{i,j} = \sqrt{(\Delta xb_{i,j})^2 + (\Delta yb_{i,j})^2}$$

Where $(\Delta xb_{i,j}) = \frac{4H-4L}{8}$ and $(\Delta yb_{i,j}) = 0$

$$|\nabla b|_{i,j} = \sqrt{\left(\frac{4H-4L}{8}\right)^2}$$

$$8|\nabla b_{i,j}| = 4H-4L \quad (6.2)$$

Given (6.1)-(6.2)

$$16L = 16*Mean - 8|\nabla b|_{i,j}$$

$$L = \frac{16*Mean - 8|\nabla b|_{i,j}}{16} \quad (7)$$

Substitute L in (6.2)

$$H = \frac{16*Mean - 12L}{4} \quad (8)$$

Equation (7) and (8) can be used to calculate the low and high intensity value of P1 pattern block.

IV. EXPERIMENTAL

This section presents the experimental results of the proposed compression techniques. The experiments are conducted using the grayscale images of "Lena", "Girl", "Baboon", "Camera man" and "Woman with 512x512 pixels size. The original images are decomposed using wavelet transform. Daubechies 9 wavelet is used in this paper. The wavelet coefficients of 4 sub-bands (LL, LH, HL, and HH) are coded at 8 bits/component. Figure 3 displays wavelet coefficients for all four sub-bands of Lena image.

As previously mentioned, the LL sub-band is preserved without any modification. The VPIC coding is performed on the chosen high frequency sub-bands, which its SD value is maximum. At the decoder side, both information of the LL and the selected high frequency sub-bands are used to decode and reconstruct the result image.

For example, the SD values of all the high frequency sub-band of Lena image is presented in Table II. The sub-band having the highest SD value is the HL band. Table III shows the MSE of the reconstructed image using different combinations of LL and one of the high frequency sub-band. The minimum MSE also occurs in the case of the combination of the LL and HL sub-band information.

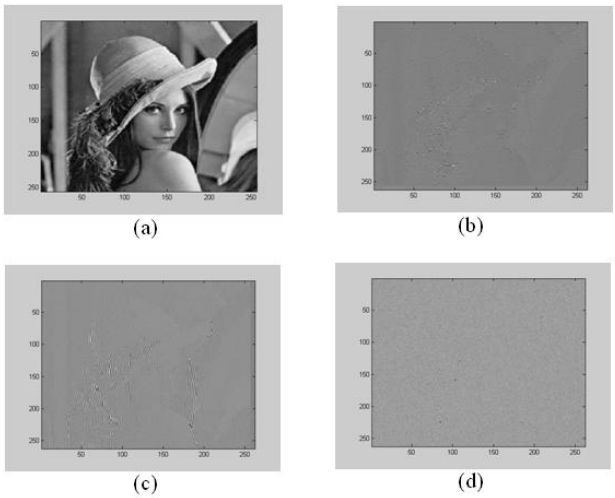

Fig.3 Result of wavelet transform of Lena
(a) LL band; (b) LH band; (c) HL band; (d) HH band.

TABLE II
STANDARD DEVIATION VALUE OF 3 SUB-BANDS OF LENA IMAGE.

Band	Standard Deviation
LH	1.7861
HL	4.7285
HH	0.2979

TABLE III
MSE OF WAVELET TRANSFORM OF LL BAND WITH OTHER BAND.

Wavelet	MSE
LL+LH	5.8584
LL+HL	1.0933
LL+HH	6.9073

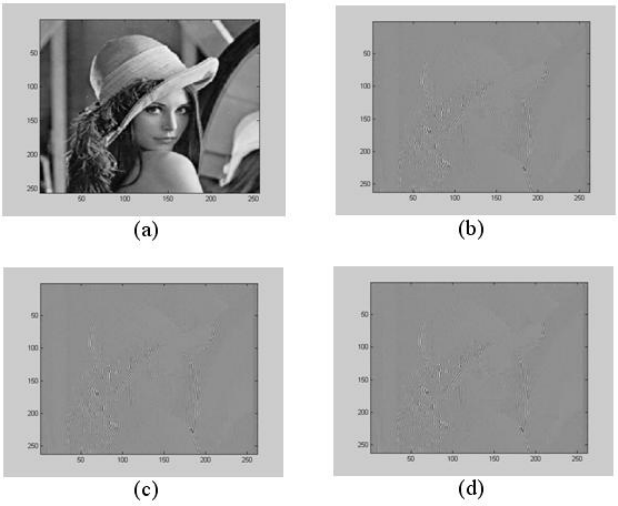

Fig. 4 (a) LL Band; (b) HL Band;
(c) gradient value =10; (d) gradient value = 30.

Figure 4 shows wavelet coefficients of the LL sub-band (a), the HL sub-band (b) of the original Lena image and those of the HL sub-band of the reconstructed image using gradient threshold = 10 (c) and 30 (d). Table IV show the results of the HL sub-band after VPIC coding with different gradient thresholds. The higher the value of the threshold, the lower the chance to find the edge blocks. As the number of the edge blocks decrease, the compression ratio will be higher.

Table V compares the MSE values of different tested images obtained from VPIC and the proposed technique (Wavelet and VPIC) algorithm with various gradient thresholds.

TABLE IV
THE INFORMATION OF LENA IMAGE IN HL BAND WITH PROPOSED METHOD.

	Gradient (threshold) = 10	**Gradient (threshold) = 30**
Edge block	55	26
Uniform block	4041	4070
compression ratios	17.9066	18.1039

TABLE V
THE MSE VALUE OF VPIC AND THE PROPOSED METHOD

Image Name	**VPIC**		**Wavelet & VPIC**	
	Gradient (threshold)		**Gradient (threshold)**	
	10	**30**	**10**	**30**
Lena	34.62	45.8	4.8	5
Cameraman	62.4613	74.7471	10.5215	10.6232
Woman	9.8507	13.2069	1.4746	1.5046
Girl	57.3144	71.5343	6.2108	6.2108
Baboon	287.5341	327.7233	53.2742	53.4756

TABLE VI
THE RELATION OF INFORMATION SIZES AND QUALITY FACTORS

Feature	**Wavelet**	**VPIC**		**Wave & VPIC**	
		Gradient (threshold)		**Gradient (threshold)**	
	LL+HL	**10**	**30**	**10**	**30**
Information size	130KB	21.1KB	16.3KB	68.7KB	68.6KB
MSE	1.0933	34.62	45.8	4.8	5
PSNR	47.7436	32.74	31.5	41.34	41.14

Table VI shows the results of information sizes and quality factors (MSE and PSNR) for three compression techniques (Wavelet, VPIC, and the proposed combination of Wavelet and VPIC). From the table V, the proposed technique offers lower size of the information while producing slightly higher MSE value compared to wavelet based technique. However, the proposed technique produces lower MSE value even though the information size is larger than that of VPIC technique.

V. CONCLUSION

This paper presents an image compression algorithm using a combination of VPIC and wavelet based coding techniques to improve compression quality factors of MSE and PSNR. The value of minimum mean square error and good image fidelity are improved by conserving the coefficients of the low frequency component (LL band) of wavelet transform which represents the smooth of image data. The coefficient of the other three sub-bands provides additional information, which is less important and can be neglected with less amount of perceptually effect. However, if some of the information from high frequency sub-bands is included in the encoded bitstream accompany with the information from LL sub-band, the quality of the reconstructed image could be improved. This paper proposed a method to choose the appropriate high frequency sub-band base on standard deviation. Then, the selected sub-band is encoded using VPIC technique. Consequently, the proposed compression algorithm can achieve high compression ratio while still maintains good image fidelity and minimum mean square error.

***Abstract* - This paper introduces the approach to check Thai banknotes by employ 2 following steps; 1. Check the invisible fibers of banknote to identify that it is legal banknote or counterfeit banknote. 2. Perform banknote recognition by using rule base for classify the types of banknote. This classification is based on the recognition of number " 1 ", " 2 " and " 5 " which appear on each banknote. In the experiment, 30 samples of 5 types of Thai banknotes (20 baht, 50 baht, 100 baht and 1,000 baht) were used to test the efficiency of this approach. While 5 samples of each type were used in the training system.**

Keywords : Thai Banknote , Invisible Fibers , Rule Base

I. INTRODUCTION

Nowadays, there are the widespread of counterfeit banknotes and the technique to produce counterfeit bank-notes is more complicated. However, the techniques for manufacturing and printing the banknote were also improved to prevent the imitation [1]. for example, adding invisible fibers on the banknote, using various fine color, using watermark, adding metal color fibers, using rare material on banknote. Therefore, these distinctive information on the banknote are useful for identify the counterfeit banknote.

There are many approaches to perform banknote recognition [2]. In this research, the invisible fibers investigation technique is introduced to identify the counterfeit banknote. Subsequently, the banknote recognition is performed by rule base approach, which analyzes the numeric numbers which appear on the banknote. There are many researches on recognition applications by using rule base technique; For example, The alphabet and symbol recognition by using Rule Base technique in [3], The number recognition from hand-writing by using the Rule Base technique in [4], and The name place recognition on Chinese language by using the Rule Base technique in [5]. All of the mentioned researches indicate the good efficiency of rule base technique.

This research describes the method to investigate the banknotes by focusing on the invisible fibers, which can be seen only under the ultraviolet (UV) light. There are 3 kinds of invisible fibers; red, green and blue invisible fibers. These fibers are able to be detected by taking the image of banknote under the UV light and using the property of color model: HSV (Hue,Saturation,Value) to detect the invisible fibers on the image. Later on, the image will be passed through the recognition step.

II. SYSTEMS

The hardware structure of this system, which appeared on figure 1, is composed of (1) ultraviolet light bulb to perceive the invisible fibers on the banknote, (2) The tested banknote (3) digital camera to take the data image of tested banknote, and (4) computer to perform image processing.

The structure of software system is displayed on figure 2, (1) the image of tested banknote is imported to the software system, (2) Identify the banknote. If it is legal banknote then performs the banknote recognition on step (3). However, if the banknote is counterfeit, the system will deny and indicate the result on output (4).

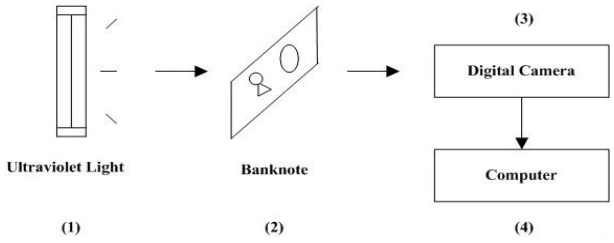

Figure 1. Hardware System

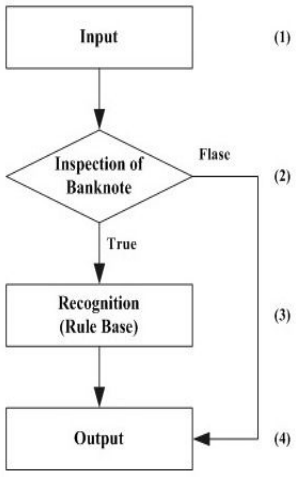

Figure 2. Software System

III. CONCEPTS

1.The invisible fiber is made from very high technological manufacturing process. It has a distinctive property; cannot be seen by human eye under the normal lighting. Hence, this is an essential point to prove the banknote.

2.Every banknote is composed of 3 types of invisible fibers which are different on features and positions

3.This research employs IF…THEN rules to perform number recognition for classify the type of banknote.

IV. ALGORITHMS

A. Characteristic of the invisible fibers

The invisible fibers, which added into the front side and back side of the banknote, are used to prevent the imitation. The size of each fiber is not similar and they are randomly distributed on the banknote also. It is difficult to imitate.

The invisible fibers are able to be detected when the banknote is illuminated by ultraviolet light. The figure 3 shows the image of banknote under the normal lighting. While the figure 4 displays the image of legal banknote under the illumination from ultraviolet bulb. The various colors of invisible fibers are appeared on the image. Whereas the figure 5 is the image of counterfeit banknote under the ultraviolet light. No invisible fibers can be detected from this image.

Because the important feature of invisible fibers are their distinctive colors. Hence, in this research, the HSV color model (Hue, Saturation, Value) is employed to detect the invisible fibers on the banknote and determine that the tested banknote is legal or counterfeit.

Figure 3. Image of banknote under the normal light

Figure 4. Image of legal banknote under the ultraviolet light

Figure 5. Image of counterfeit banknote under the ultraviolet light

Table 1
Result of inspection the banknote from Invisible Fiber.

Type of banknote	20 Baht (legal)	50 Baht (legal)	100 Baht (legal)	500 Baht (legal)	1000 Baht (legal)	Counterfeit banknote
Amount	30 items	30 items	30 items	30 items	30 items	50 items
Legal banknote	30	30	30	30	30	0
Counterfeit banknote	0	0	0	0	0	50

From the table 1, the result of inspection the banknote by detecting the invisible fiber is proved that it can separate between the legal banknote and counterfeit banknote.

B. Rule base technique

"Rule base" is one method in the expert system, which described in artificial intelligent science, and can apply to perform pattern recognition. This rule base technique employs the "If … Then" rules [6] as following.

$$R_n = IF \ldots\ldots THEN \ldots\ldots \quad (1)$$

Whereas the R_n is one of the rules, "IF" is the condition and description of that rule, and "Then" is a part of conclusion or action to be executed.

The rule bases, which are the same pattern in equation 1, will be created to describe the property of each type of Thai banknote, and used to perform banknote recognition.

V. BANKNOTE RECONITION

The banknote recognition step will prove the Arabic numbers on the front-side of Thai banknotes, which can be classified into 5 types: 20 baht, 50 baht, 100 baht, 500 baht, and 1000 baht. Figure 6 (a) shows the images of Arabic numbers from each kind of actual Thai banknotes, while the images in figures 6 (b) are the first character of each kind of Thai banknotes. The image of numbers will be passed to the thinning algorithm. The results are displayed on figure 6 (c).

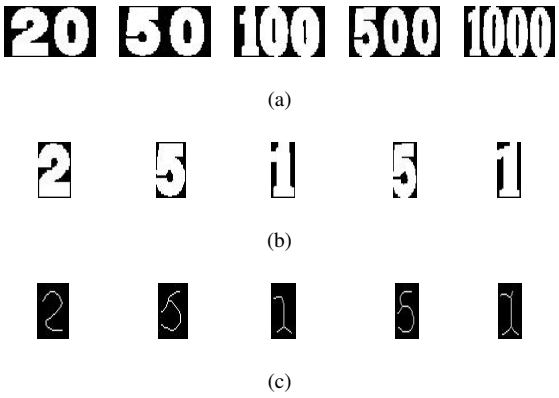

Figure 6. (a) Images of numbers from each kind of Thai banknote, (b) First number of each banknote, (c) Results after perform thinning algorithm with images from figure 6 (b).

The first step of banknote recognition is finding the histogram of the image of numbers, which appears on the tested banknotes, as shown on figure 6 (a). Hence, the software will know the coordination of first number. Subsequently, the image of the first number will be reduced by thinning method. The result is similar to images in figures 6 (c).

Finally, the thinning image of the first number will be separated into 9 regions in figures 7. The software will count the number of white pixels in each region, and compare to the standard value of each number [" 1 ", " 2 " and " 5 "] by equation (2) to find the error.

$$E = | P_n - \bar{\mu}_n | \quad (2)$$

- E is the error value.
- P_n is number of white pixels in region n.
  n is region of image (n = 1, 2, 3,…, 9)
- $\bar{\mu}_n$ is the standard value of white pixel in each region. These standard values are obtained from the learning step with 5 samples, and finding the average of these 5 samples. Hence, after finished the learning, we will obtain 3 set of $\bar{\mu}_n$ [" 1 ", " 2 " and " 5 "].

The error value, which calculated from standard value $\bar{\mu}_n$ of " 1 ", will be kept as parameter $\sum E_1$, calculated from standard value $\bar{\mu}_n$ of " 2 ", will be kept as parameter $\sum E_2$, and calculated from standard value $\bar{\mu}_n$ of " 5 ", will be kept as parameter $\sum E_5$. Subsequently, these errors will be used in rule base equations from (3)-(5), R_1, R_2 *and* R_3 are the recognition rules of each numeric character 1, 2 and 5.

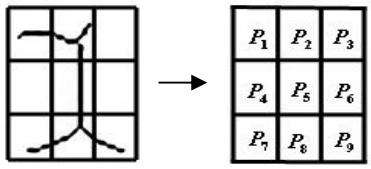

Figure 7. Separate thinning figure into 9 regions

$$R_1 : IF\ Min((\sum E_1),(\sum E_2),(\sum E_5)) = \sum E_1\ THEN\ Output = 1 \quad (3)$$

$$R_2 : IF\ Min((\sum E_1),(\sum E_2),(\sum E_5)) = \sum E_2\ THEN\ Output = 2 \quad (4)$$

$$R_3 : IF\ Min((\sum E_1),(\sum E_2),(\sum E_5)) = \sum E_2\ THEN\ Output = 5 \quad (5)$$

- By consideration on equation (3), if the minimum value among these three errors is $\sum E_1$, hence, the tested thinning image is " 1 ".
- By consideration on equation (4), if the minimum value among these three errors is $\sum E_2$, hence, the tested thinning image is " 2 ".
- By consideration on equation (5), if the minimum value among these three errors is $\sum E_5$, hence, the tested thinning image is " 5 ".

After knowing the first number of tested banknote, we will find the number of digits by using histogram, and, hence multiply the first number to the number of digit. We will obtain the actual number, which appears on the tested banknote. The proposed method is shown in figure 8.

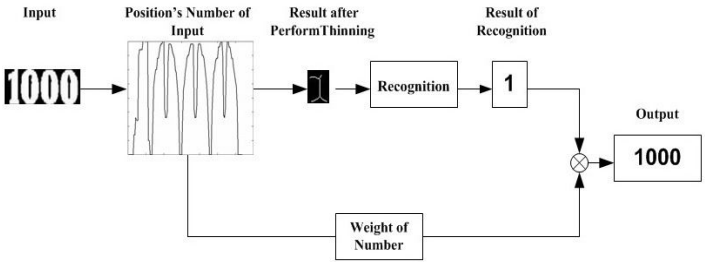

Figure 8. The Structure of System

VI. RESULT OF THE EXPERIMENT

In this testing, we used 5 types of legal Thai banknotes and counterfeit Thai banknotes as well. Figure 9 shows the images of those 5 types. The invisible fibers of each Thai banknote, which have different in features and positions, is a key feature to determine that the tested banknote is legal or counterfeit.

After the tested banknote is proved, the number, which appear on the banknote and has a certain size and coordinate, will be performed the recognition process.

The result of this testing is shown on table 2. The system indicates the 100% accuracy for separating the counterfeit banknotes from legal banknotes, and 100% accuracy to classify the types of banknotes. Except the 1,000 baht banknotes, this system gives only 96.67% accuracy to recognize this type. Because there is a complicated graphic beneath the number " 1,000 " on the banknote, as shown in figure 9 (f).

Table 2
Result of the Experiment

Type of banknote	20 Baht (legal)	50 Baht (legal)	100 Baht (legal)	500 Baht (legal)	1000 Baht (legal)	Counterfeit banknote
Amount	30 items	30 items	30 items	30 items	30 items	50 items
No. of banknotes which can be recognized correctly	30	30	30	30	29	Rejected
% Accuracy on the recognition process	100	100	100	100	96.67	n/a

The 50 samples of counterfeit banknote are use for testing the inspection, 10 samples of each type. The result of the test is it can reject all of counterfeit one.

(c)

(d)

(e)

(f)

Figure 9. Image of each type of Thai Banknotes (a) 20 baht banknotes. (b) 50 baht banknotes. (c) 100 baht banknotes. (d) 500 baht banknotes. (e). 1000 baht banknotes (f) 1000 baht banknote which has a complicated graphic beneath the number " 1,000 " on the banknote.

VII. CONCLUSION

This research proposes the method for proving the banknotes by checking the invisible fibers and performs banknotes recognition by using rule base method, which is one technique in pattern recognition application.

From the testing with 30 items of each kinds of Thai banknotes, this proposed system can give the 100% accuracy for separating counterfeit banknote from legal banknote, and 100% accuracy for recognize each types of banknote. However, the system gave the accuracy only 96.67% for recognize 1000 baht bank notes.

***Abstract*-The system of locating and reading 1-D barcodes which captured by mobile-phone's camera is studied. In this paper we still developed program and tested it on the personal computer. At first, the location of barcode in a captured image is found by using Morphological method. Finally, the code will be decoded by reading the numeric characters under barcode image. For this step, the Rule base method was employed to recognize the numeric character, 0-9, which leaning with 20 samples each character. For the experiment, various barcode of commercial products is used to test the efficiency of this work.**

Keywords: Barcode, Morphological, Rule Base

I. INTRODUCTION

In these days, almost all commercial products have barcode labels which can be read by optical scanner called barcode reader. The identity of products will be encoded to numeric and stored in the widths and spacings of printed parallel lines. The advantage of the barcodes is the safe and rapid availability of the information about product from production to shop. The standard of barcode that used in Thailand is EAN-13 (European Article Numbering).

In the recent years, a mobile phone's performance has increased rapidly and its camera also. Some of those have more than over mega-pixel range image sensor cameras. In this propose, we use a mobile phone to find and read barcode label. The consumers can read the information of goods (i.e. type, size, price, etc.) from barcode by using a camera in mobile phone.

For method for finding and reading barcode image with mobile phone can be found in [1] and [2].

In this paper, we proposed an image recognition algorithm for 1-D barcode for EAN-13 standard. At first, the barcode in image that captured by camera of mobile phone is found by Morphological method. And then the numeric under the barcode will be read by Rule base method.

This paper is organized into 5 sections. In Section II is a brief conclusion of EAN-13 barcode. Section III is proposed method for locating and reading barcode. Experimental results is given in Section IV. And conclusion can be found in Section V.

II. THE EAN-13 BARCODE

For 1-D barcode, there are many standards that used in the world. In Thailand, the barcode system follow standard of EAN that developed by European Article Numbering. The EAN-13 barcode consists of 13-numeric characters. The first-three-numeric characters are the country code which is885 for Thailand's country code. Then the next 4 characters, 4^{th}-7^{th}, are the manufacturer code. For 8^{th} to 12^{th} numeric characters are product code. And the last one is the checksum digit. Figure 1 shows an example of the EAN-13 standard barcode. More information of EAN-13 Barcode can be found in [3].

Figure 1. Example of EAN-13 barcode

III. PROPOSED APPROACH

The block diagram of proposed method, as show in Figure 2, which consists of two steps: the first step is the location of barcode. When location of barcode is found, the next step is reading numeric characters under barcode. In this paper, the input images are captured by camera of mobile phone which having resolution 1 Mega pixels as shown in Figure 3.

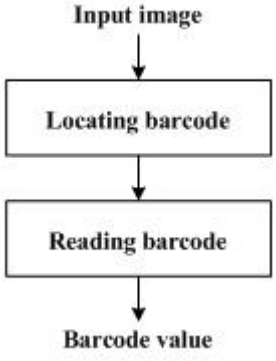

Figure 2. Block diagram of the proposed method

Figure 3. Input image captured with a camera of mobile phone

A. Locating of barcode

In locating of barcode, we use Morphological method to find the location of barcode, as illustrate in Figure 4, which explain in the following steps:

- At first, an input image as showed in Figure 3 was converted into grayscale image. Then edge of grayscale image is found by edge detection which uses the following mask.

$$\begin{bmatrix} -1 & -1 \\ 1 & 1 \end{bmatrix}$$

- After that, average value of image edge will be calculated in a horizontal line by using mask as showed below.

$$\begin{bmatrix} \frac{1}{13} & \frac{1}{13} & \frac{1}{13} & \frac{1}{13} & \frac{1}{13} & \frac{1}{13} & \frac{1}{13} & \frac{1}{13} & \frac{1}{13} & \frac{1}{13} & \frac{1}{13} & \frac{1}{13} & \frac{1}{13} \end{bmatrix}$$

- Input image is converted into binary image. Next, pixel group is classified to be an object by labeling technique. Then small size of objects will be compared with β (in this paper β = 10,000 pixels which is to obtain from experimental). The objects which have pixel numbers less than β will be removed from binary image.

- In this step, the hole inside object will be filled by using dilation in a morphological method. And the edge which connects to object will be removed, as illustrated in Figure 5.

- The last step for locating the barcode is finding top position, bottom position, left position and right position of object then the barcode region is extracted, as illustrated in Figure 6.

B. Reading barcode

After the barcode to be found, the numeric code under barcode will be read by the following steps as shown in Figure 7.

- Barcode region image is converted to binary image by Otsu thresholding technique [4]. This binary image is reduced noise which to remove object smaller then five pixels. And edge connected object is removed.

- Each bar of barcode is detected by labeling technique. After that, the first and last bars, which are standard bar of barcode, are scanned to find the width of barcode region. Then the width of standard bar will be calculated by division the width of barcode region with 95, because, in EAN-13 standard, there are 95 units per a barcode.

- The first pixel-group from labeling is determined to be the first digit of numeric code. The first digit which detected from barcode image is illustrated in Figure 9(a).

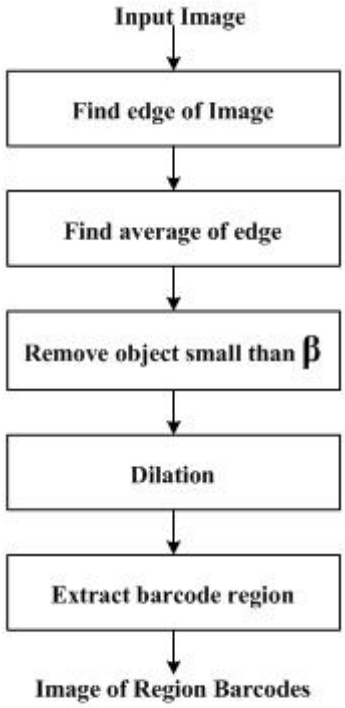

Figure 4. Block diagram of locating barcode

Figure 5. The barcode region is found by proposed locating method

Figure 6. The segmented barcode region image from input image

- 2nd – 7th digit of numeric code will be detected by referring from left-side and middle standard bar. A position of 2nd digit is left-hand side of left-side standard bar by plus double of standard-bar's width. And a position of 7th digit is middle position of middle-standard bar by minus double of standard-bar's width. For 8th – 13th digit of numeric code will be referred from middle and right-side standard bar. A position of 8th digit is middle position of middle standard bar by plus double of standard-bar's width. And a position of 13th is right-hand side of right-side standard bar by minus double of standard-bar's width. The left-side standard bar, middle standard bar and right-side standard bar positions are shown in Figure 8. The detection's results of 2nd – 7th and 8th – 13th are shown in Figure 9(b) and 9(c), respectively.

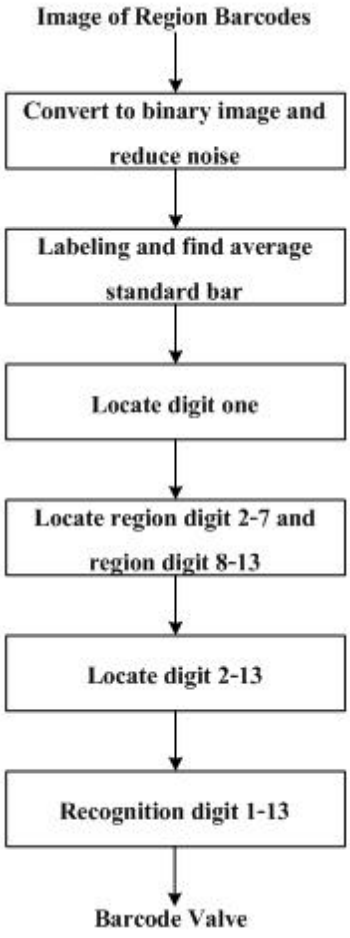

Figure 7. Block diagram of reading barcode

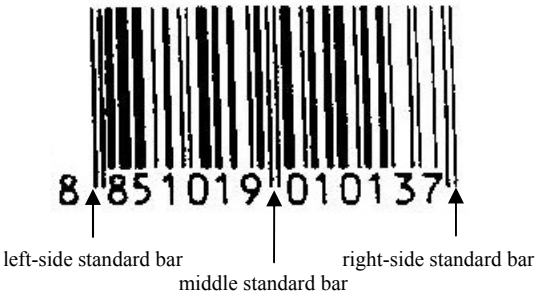

Figure 8. Left-side standard bar, middle standard bar and right-side standard bar position

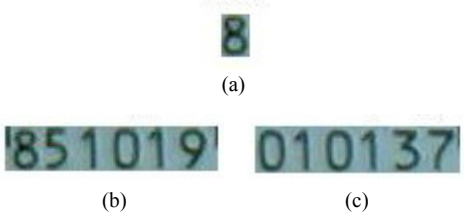

Figure 9. (a) First digit (b) second - seventh digit region (c) eighth - thirteenth digit region

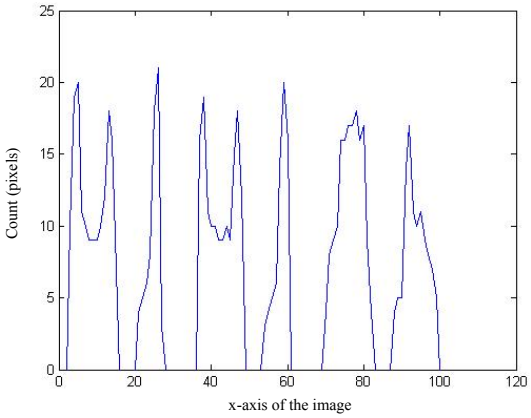

Figure 10. Histogram of 8^{th} - 13^{th} digit region image

- When 2^{nd} - 7^{th} digit region image and 8^{th} - 13^{th} digit region image were obtained, both images are completed numeric characters by dilation operation. Therefore the noise of images is reduced. Subsequently, the histograms of these images are found for cutting each numeric character at the points that have zero count. These points mean the separation of each numeric character. Histogram of 8^{th} - 13^{th} digit region image is shown in Figure 10.
- Next each digit of 1^{st} – 13^{th} numeric code is found values by Rule base method which is Artificial Intelligence system used for recognition. This rule base technique employs the "If … Then" rules as shown following in equation (1). For this step, the

images of each numeric character will be reduced by thinning method. The thinning image of each character will be separated into 9 parts. Subsequently, the software will count the number of white pixels in each region, and compare to the standard value of each numeric character, 0-9, by equation (2) to find the error (E).

$$R_n = IF \ ..... \ THEN \ ..... \quad (1)$$

Where the R_n is one of the rules, "IF" is the condition and description of that rule, and "Then" is a part of conclusion or action to be executed.

$$E = | P_n - \bar{\mu}_n \ | \quad (2)$$

Given that, p_n is number of white pixels in the n[th] part, n is part of image (n=1, 2,…, 9). $\bar{\mu}_n$ is the standard value of each part which obtained in the learning step from 20 samples per a character of 0-9 numeric characters. Finally, these errors will be used in rule base equations as shown in equation (3) - (13).

$$R_0 : IF \ Min(\sum E_0, \sum E_1 \ldots \sum E_9) = \sum E_0 \ THEN \ Output = 0 \quad (3)$$

$$R_1 : IF \ Min(\sum E_0, \sum E_1 \ldots \sum E_9) = \sum E_1 \ THEN \ Output = 1 \quad (4)$$

$$R_2 : IF \ Min(\sum E_0, \sum E_1 \ldots \sum E_9) = \sum E_2 \ THEN \ Output = 2 \quad (5)$$

$$R_3 : IF \ Min(\sum E_0, \sum E_1 \ldots \sum E_9) = \sum E_3 \ THEN \ Output = 3 \quad (6)$$

$$R_4 : IF \ Min(\sum E_0, \sum E_1 \ldots \sum E_9) = \sum E_4 \ THEN \ Output = 4 \quad (7)$$

$$R_5 : IF \ Min(\sum E_0, \sum E_1 \ldots \sum E_9) = \sum E_5 \ THEN \ Output = 5 \quad (8)$$

$$R_6 : IF \ Min(\sum E_0, \sum E_1 \ldots \sum E_9) = \sum E_6 \ THEN \ Output = 6 \quad (9)$$

$$R_7 : IF \ Min(\sum E_0, \sum E_1 \ldots \sum E_9) = \sum E_7 \ THEN \ Output = 7 \quad (10)$$

$$R_8 : IF \ Min(\sum E_0, \sum E_1 \ldots \sum E_9) = \sum E_8 \ THEN \ Output = 8 \quad (11)$$

$$R_9 : IF \ Min(\sum E_0, \sum E_1 \ldots \sum E_9) = \sum E_9 \ THEN \ Output = 9 \quad (12)$$

From (3) - (12), $R_0, R_1, R_2 \ldots, R_9$ are the recognition rules of each numeric character, 0, 1, 2…, 9. And the values of $\sum E_0, \sum E_1, \sum E_2 \ldots, \sum E_9$ are summations of errors (E) of 0-9 character image, respectively. R_0 – R_9 will be chosen from the minimum value of $\sum E_0, \sum E_1, \sum E_2 \ldots, \sum E_9$. If the minimum value equals $\sum E_1$, hence, this tested image is the "i" numeric character.

IV. EXPERIMENTAL RESULTS

In the experiment, we used 20 barcode-sample images for testing our proposed algorithm which experimental results are show in Table1. A sample images are captured by 1 mega-pixel-mobile-phone's camera. From 20 samples of barcode images, 100% of samples can be located and detected to be barcodes and 80% of samples can be read their all numeric code under them correctly.

TABLE 1
EXPERIMENTAL RESULTS

Number of barcode (patterns)	Number of correct location (patterns)	Efficiency location (%)	Number of correct reading (patterns)	Efficiency of reading (%)
20	20	100	16	80

The reason that makes the barcode locating fail is region of barcode smaller than β. And the false of reading numeric of barcode is a size of numeric is too small to read and surface of label has reflected then it is difficult to read.

For this paper, our algorithm to locate and read 1-D barcode is in the studying step then we still developed program and tested it on the personal computer. In future work, we will implement on mobile-phone system.

V. CONCLUSION

In this paper, we propose method of locating and reading barcodes form images captured by camera of mobile phone. In locating barcodes use Morphological method to locate barcode and reading barcode use Rule Base method to recognize number under barcode to read barcode value. The experimental results with 20-pattern barcodes have 100% efficiency for the locating of the barcode and 80% efficiency for the reading of numeric character.

Abstract- **In this paper, we propose an amelioration of the Principal Component Analysis (PCA) for face recognition using an ensemble method to multiresolution analysis. Indeed, the input data are first decomposed into several frequency subbands by Discrete Wavelet Transform (DWT) for representation. We consider several fusions of frequency subbands. Then, for each fusion, PCA is used in feature extraction and classification is done independently. The final decision is obtained from the majority vote of decision from each fusion. The experimental results show that our proposed method outperforms both PCA and Two-Dimensional Principal Component Analysis (2DPCA) in term of recognition accuracy rate.**

I. INTRODUCTION

Face recognition is one of the most interested pattern recognition problems which are growing in many applications. Among face recognition algorithms, appearance-based approach [1] is the most popular. This approach relies on the pixel intensity-derived features. It can be further classified in 3 categories, which are holistic matching method, featured-based matching method and hybrid method [1]. Holistic matching method is used in this work. Holistic matching method uses the whole face region as the raw input to a recognition system, therefore it is also known as appearance-based method. In this approach, Principal Component Analysis (PCA) is widely used as feature extraction technique. PCA selects components at the source resolution that are optimal for minimizing mean square error in reconstructing the original input [2]. For classification, where discriminability among classes puts an additional constraint on representations, PCA is no longer optimal.

Features utilizing multiresolution have been demonstrated to preserve discriminability better than a single scale representation. Multiresolution is widely used techniques for signal representation. Wavelet decomposition is the most widely used multiresolution technique in image processing. The components are chosen to provide good representations of the input signal at several resolutions. The full set of components provides an exact reconstruction of the original signal. In Ref. [3], PCA and wavelet transform were using to reduce computation complexity. PCA was applied to extract meaningful features from one mid-range frequency subband. Moreover, Linear Discriminant Analysis (LDA) has also been used with multiresolution to reinforce discriminant power [4]. LDA was incorporated into low frequency subimage of three-level pyramid structured wavelet decomposition. While there are 2 main motivations for representation an image in several resolutions. First, a given feature may be best observed at some scale, but the appropriate scale may not be known. Second, several features may be of interest, but no single resolution is satisfactory for all features. For example, in Ref. [5], a hybrid (local/global) model of the localized kernel feature and multiresolution feature for face representation and recognition has been presented. This approach exploited the intrinsic discriminating power of the face kernels. They were not only capable of exhibit performance comparable with other hybrid kernel methods, but also computationally efficient. In Ref. [6], the author investigated the performance of a technique for face recognition. This approach based on the computation of 25 local autocorrelation coefficients. It operated at a speed of one face per second and gave the good performance. In Ref. [7], the authors investigated the use of eigenface-like features computed on different portion of input image. They performed PCA to provide an adaptive basis for multiresolution and multiresolution provided localization to PCA. The feature extraction point of view was analyzed that projection to high dimensional spaces also enhances the chance of obtaining better feature. In Ref. [8], the authors considered an ensemble classifier working on frequency subbands similar to this work. Indeed, they first compared each individual subband. They considered the fusion of best performing subbands. It was shown that the fusion improve recognition accuracy compare to using a single subband. The studied papers of multiresolution have been demonstrated that information integrating from multiple sources is essential for reliably performing. Therefore, we also consider multiple classifier system, in which each classifier focuses on some particular resolutions, in order to improve the recognition accuracy.

The multiple classifier systems have been used in several pattern recognition works. They are powerful solutions to difficult pattern recognition problems involving large class sets and noisy input. Because, they allow simultaneous use of arbitrary feature descriptors and classification procedures. Decisions by the classifiers can be represented as rankings of classes so that they are comparable across different types of classifiers and different instances of a problem [9]. There are heterogeneous classifier ensembles and homogeneous classifier ensembles. The heterogeneous ensemble method integrates various pattern recognition algorithms as experts in a committee machine. In Ref. [10], the authors used the sum rule and RBF-based integration strategies to combine three face classifiers based on PCA, ICA, and LDA representations. This

approach could improve the performance of face identification system. However, each classifier is appropriate in different kind of database. Therefore, the dynamics face recognition committee was proposed in Ref. [11]. The authors formulated gating network to determine suitable weights for the experts. This face recognition system could combine the strong points of each representation and performed the better performance.

The homogeneous ensemble method relies on the same type of classifier in the system. It has been used in non-face and face recognition frameworks. In Ref. [12], the authors used multiresolution wavelet analysis and an ensemble of classifier for the early diagnosis of Alzheimer's disease. They performed on event related potential EEG signal which were used with the ensemble of classifiers based Learn++ algorithm. Parallel Consensus Neural Network (PCNN) in Ref. [13] is another homogeneous ensemble method that uses neural networks to satellite data classification. Indeed, each network is trained on different input full wavelet tree representations. Then, the decision is taken by class-specific weighted averages in the framework of consensus theory. However, the small size of face database makes it not suitable for applying this neural network based approach. In face recognition framework, multiresolution was applied to multiple classifier systems in the several previous works [5-8]. The experimental results of the previous works demonstrated that there was hidden information in many resolutions. They used the homogenous expert to classify and gave various decisions. Multiple classifier systems were the simple way to combine decisions and gave the better result.

In this paper, we consider face recognition from intensity images in multiresolution analysis and the homogeneous ensemble classifier. In this work, the input image is first decomposed into several frequency subbands. Four groups of frequency subbands are chosen due to their information coverage. For each group different kinds of fusion are considered. PCA is used in each group to reduce computational load while retaining meaningful features. We can further consider these 4 groups as independent classifiers in parallel classifiers system [14]. Thus new decision can be drawn from the majority vote of these 4 classifiers. Experimental results show that our proposed method outperform the classical approach of "PCA" and its recent extension of "2DPCA" [15] on the well known ORL face database.

II. BACKGROUND

A. *Multiresolution Analysis*

Multiresolution methods provide powerful signal analysis tools, which are widely used in feature extraction, image compression and denoising applications. Wavelet decomposition is the most widely used technique in image processing. Images have typically locally varying statistics that result from different combinations of abrupt features like edges, of textured regions and of relatively low-contrast homogeneous regions. While such variability and spatial nonstationarity defied any single statistical characterization, the multiresolution components are more easily handled. Wavelet transform can be performed for every scale and translation, resulting in continuous wavelet transform (CWT), or only at multiples of scale and translation intervals, resulting in discrete wavelet transform (DWT). Since, CWT provides redundant information and requires a lot of computation, generally DWT is preferred.

B. *Ensemble Method*

Ensemble method is one of the major developments in machine learning in the past decade. It finds a highly accurate classifier by combining many moderately accurate component classifiers. Bagging, Boosting, and Random Subspace methods are the most successful techniques for constructing ensemble classifier [16, 17].

There have been many previous studies on how to create the ensemble of models. The methods for constructing the ensemble of models can be categorized into five groups [16] : 1) Bayesian voting, which creates an ensemble of model by sampling them from an estimated posterior model distribution; 2) Manipulating the training examples, which creates multiple subset of training examples and trains a classifier for each subset; 3) Manipulating input features, which creates a number of subsets of the input features and a classifier is built for each subset of input features; 4) Manipulating the output targets or error-correct output code (ECOC) [18], which converts a multiple class problem into a set of binary class problems; 5) Injecting randomness, that generates ensembles of classifiers by injecting randomness into the learning algorithm.

Among the five categories, our work is closely related to the third method, which creates multiple classifiers by manipulating input features. This method only works when the input features are highly redundant. And it is optimal for multiresolution input.

C. *PCA and Eigenface for Face Recognition*

PCA was also knows as the Karhunen Loeve (KL) expansion in communication theory or Hotelling transform in image processing. It is a well-known approach for feature extraction. It is a method of identifying patterns of data, and expressing the data in a way to highlight their similarities and differences. The basic idea of PCA is to discard all redundancy existing in the original set of features thus allows representing the same object in a more compact way. Therefore the dimension of the image can be greatly reduced. In face recognition, the eigenface method is more generally called "PCA", which is used to find a low dimensional representation of face image data.

D. *Fusion*

There are 3 architectures of fusing frequency subbands [8], which are "data fusion", "feature fusion", and "decision fusion". We fuse raw pixel values of the frequency subbands in data fusion as shown in Fig. 1. The block diagram of feature fusion is shown in Fig. 2. We fuse feature vectors that exacted from the frequency subbands. For decision fusion, we fuse in classification decisions of the frequency subbands as showed in Fig. 3.

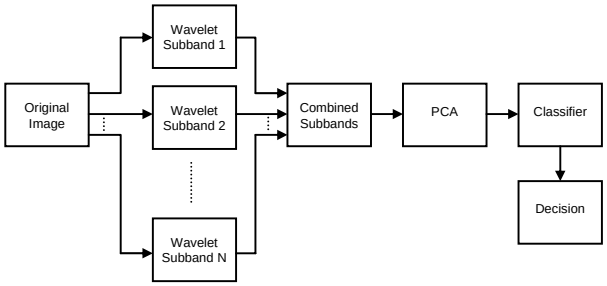

Figure 1. Block diagram of the data fusion scheme

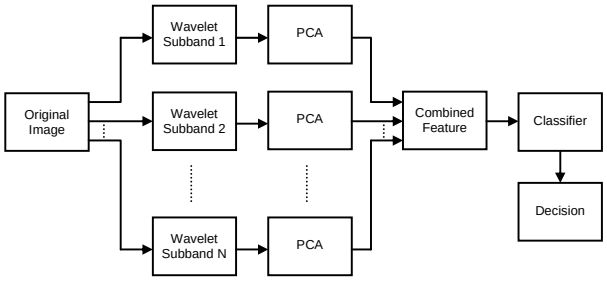

Figure 2. Block diagram of the feature fusion scheme

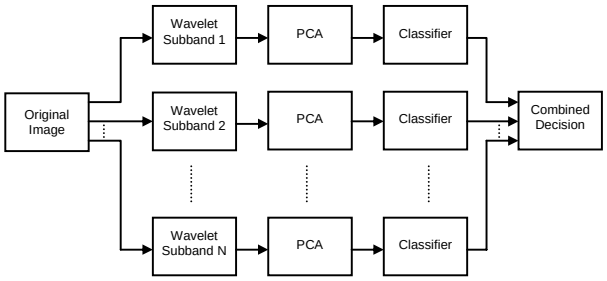

Figure 3. Block diagram of the decision fusion scheme

III. Proposed Method

There are many fusion techniques in [8] as shown in previous section. The authors proposed only trend to select group of frequency subbands for fusing. In this paper, we propose new architecture for fusing frequency subbands. We use the conception of multiple classifier systems to decide the results of each fusion again.

The schematic of the wavelet decomposition, which used in this paper is shown in Fig. 4. There is approximation (A), horizontal detail (H), vertical detail (V), and diagonal detail (D) coefficients respectively. A 128 x 128 pixels original face image is decomposed in the first level, and four 64 x 64 pixels resolution frequency subband images A1, H1, V1 and D1 are obtained. In the second level, we decompose only A1, yielding four 32 x 32 frequency subband images A2, H2, V2 and D2. And in the third level, we decompose A2 component to produce four 16 x 16 frequency subband images. In summary, we obtain 12 different subband images from the original face image and input them into the multiple classification scheme in Fig. 1-3. The octave decomposition is used in our proposed. We found that classification performance of individual H, V, and D were very low [3].

We define the group of frequency subbands in each level from octave DWT. The several frequency subbands are decomposed as Fig. 4. It consists of information from the different stage networks. Each stage has alike original input data with different time frequency resolutions. We divide the group of frequency subbands to 4 levels.

0 level : The 128 x 128 pixels of original image.
1 level : A1H1V1D1
2 level : H1V1D1A2H2V2D2
3 level : H1V1D1H2V2D2A3H3V3D3

Our proposed scheme in Fig. 5 is the fusion of fusion architecture. First, the original image is decomposed to be 3 level octave tree DWT. The frequency subbands are concatenated to 1-3 level groups of subbands. Then, we use similarly fusion scheme for fusing every level of frequency subbands. The fusion blocks in Figure 5 are three types of fusion, which are Fig. 1, Fig. 2, and Fig. 3. Finally, we combine all decision of fusion blocks together with decision fusion (majority vote). It gives the final decision. We choose Daubechies 4 wavelet for the experiments because it gave the optimum results [3, 4].

IV. Experimental Results

We tested on ORL face database in Appendix B [19]. The database has 400 pictures, which made up from 10 pictures of 40 people. The images are 112 x 92 pixels, 8 bit gray scale images. The pictures show variation in background lighting, scale, orientation and facial expression. The tolerance in scale is about 20% and tolerance for tilting is about. All of face images are scaled to 128 x 128 pixels resolution. We use first 5 images for training and last 5 images for testing. In recognition stage, we conserve 90% of energy for reducing computation.

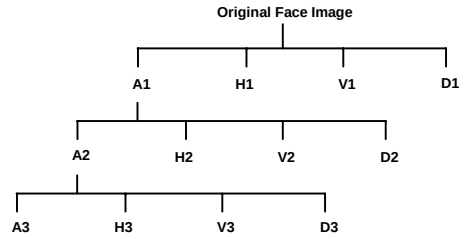

Figure 4. Wavelet decomposition tree in the study

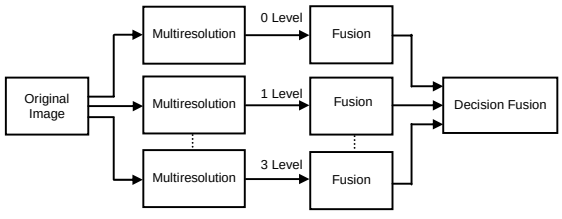

Figure 5. Block diagram of the proposed fusion scheme

The nearest neighbor classifier is chosen for classification. We evaluated comparatively three different distances namely the $L1$, the $L2$ norm, and the normalized correlation coefficient (CC). The top 3 results of PCA on single wavelet transform subband are shown in Table 1. Our proposed method's recognition accuracy rates are shown in Table 2. For example, in 1-3 level (Data Fusion), the 1 level, 2 level, and 3 level are selected to be multiresolution input and data fusion is chosen in fusion block in Fig. 5. The subbands in each level are fused by data fusion separately. After that, three level display 3 individual decision result. The decision fusion is used to combine 3 decisions and give final decision. Almost fusing several subbands levels give better accuracy recognition rate than original and single subband. It shows that manipulating the input features of ensemble method and multiple classifier systems are appropriate to our proposed method. The 0-3 level fusing subbands which first fused by decision fusion gives the best result.

Our best architecture can improve recognition accuracy rate to the ORL database. We compared our proposed method's best result to the classic PCA approach's result and the new approach of PCA which is called "2DPCA" [15] result. The size of images tested for PCA and 2DPCA is 112 x 92 pixels. The result in Table 3 indicate that our proposed give the best result which better than PCA 15.5% and better than 2DPCA 2.5%.

V. CONCLUSIONS

In this paper, a framework of ensemble frequency subbands are proposed for face recognition to be one approach to select group of fusing frequency subbands. One of the advantages of adding redundant features is good for classification problem as long as the redundant information supplied to ensemble classifiers is not harmfully correlated. But it has to spend more computation time and more complexity than 2 compared methods. If there are high speed enough CPU and large enough memory machine in the future, our proposed method will be one option.

TABLE I
TOP 3 RESULTS OF PCA ON SINGLE WAVELET TRANSFORM SUBBAND AND D3

Wavelet Subband	L1	L2	CC
A1	85.5	78	84.5
A2	86.5	80.5	83.5
A3	86.5	78.5	87
D3	53.5	59.5	69

TABLE II
OUR PROPOSED METHOD'S RESULTS

Level Fusion	L1	L2	CC
0 level (original)	85.5	78.5	85
1-3 level (Data Fusion)	75	82	93
1-3 level (Feature Fusion)	81	83	88.5
1-3 level (Decision Fusion)	79	82	92.5
0-3 level (Data Fusion)	84	78.5	91.5
0-3 level (Feature Fusion)	84	81	89.5
0-3 level (Decision Fusion)	84.5	84	**94**

TABLE III
THE TOP RECOGNITION ACCURACY COMPARISONS OF PCA AND 2DPCA

Method	PCA	2DPCA	Proposed (Best)
Accuracy (%)	78.5	91.5	**94**

***Abstract*-We propose an on-line character recognition method for Khmer numeral based on DP matching of barycenter trajectory. First, the barycenter is determined from the center point of script and two adjacent pen-point positions with respect to time in handwriting process. Then the barycenter trajectory and its direction changes are used to describe the features of handwritten characters. Finally, the numeral is recognized by calculating the dissimilarity between the features of handwritten character using Dynamic Programming(DP) matching. Character recognition experiments are performed on database consisting of 5000 Khmer numerals. As the result, the average of recognition rate was 95.9%.**

I. INTRODUCTION

Many methods for on-line character recognition have been reported[1][2][3]. In those methods, the pen-point position is used to recognize the character. It is considered that using pen-point position directly is not effective to extract the feature of the handwritten character. In this paper, the barycenter determined from the center point of script and two adjacent pen-point positions is used instead of pen-point position to extract the feature of the handwritten character. We considered that the feature of the handwritten character can be described by two features, the barycenter trajectory and its direction change. Finally, the incorporation of the barycenter trajectory and its direction changes into DP matching is used to recognize the character.

II. PREPROCESSING

It is considered that there are fluctuations depending on many factors such as age, habit, psychological and mental state, physical or practical conditions in handwriting process of writer. For instance, size, location, shape, and duration time in handwriting process of the same alphabet are never precisely the same even they were written by the same writer.

Fig.1 shows Khmer numeral 'one' written by different writers. From Fig.1, we can see that the characters are written in different sizes, locations and styles. In order to recognize the character effectively, such fluctuations of handwriting should be reduced.

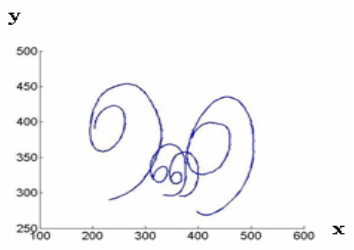

Figure 1: Khmer numeral 'one' written by different people.

It is assumed here that Khmer numerals are written on a graphical tablet to recognize the character. The horizontal and vertical components of pen-point position at a time, $t = n\tau(\equiv t_n)$, in handwriting process are denoted here as $x(t_n)$ and $y(t_n)$, respectively, where τ is a constant sampling rate.

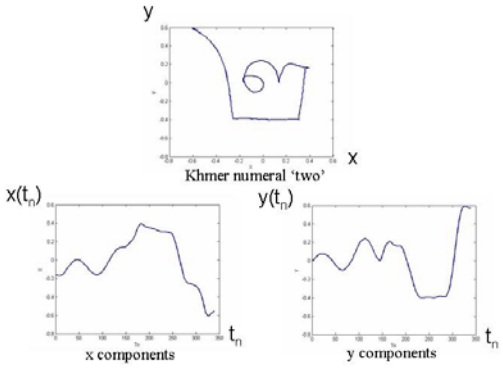

Figure 2: Khmer numeral 'two', its x components and y components (top to down , left to right).

Fig.2 shows Khmer numeral 'two' and its x, y components with respect to time in handwriting process. In order to reduce the fluctuation of handwriting, two kinds of normalization with respect to the size and location in handwriting process are performed as follows:

1) Normalization of size

The size of the script is standardized after removing the duplicated points of pen-point position. In order to make a standard size of script, the horizontal and vertical components, $x(t_n)$ and $y(t_n)$ are normalized as

$$\hat{p}(t_n) = \frac{p(t_n) - p_{\min}}{p_{\max} - p_{\min}}, \; p = (x, y), \quad (1)$$

where $p_{\min} = \min_{0 \le n \le N-1} p(t_n)$, $p_{\max} = \max_{0 \le n \le N-1} p(t_n)$, (2)

and N is a total number of sampled points of pen-point position.

2) Normalization of location

The location of the script is normalized as follows:

$$c_p = \frac{1}{N} \sum_{n=0}^{N-1} \hat{p}(t_n), \; p = (x, y), \quad (3)$$

$$\tilde{p}(t_n) = \hat{p}(t_n) - c_p, \; n = 0,1,2...N-1, \quad (4)$$

where c_p is the center point of script.

Fig.3 shows Khmer numeral 'two' before and after normalization. It can be seen from Fig.3 that the fluctuation of handwriting character can be reduced by using the normalization.

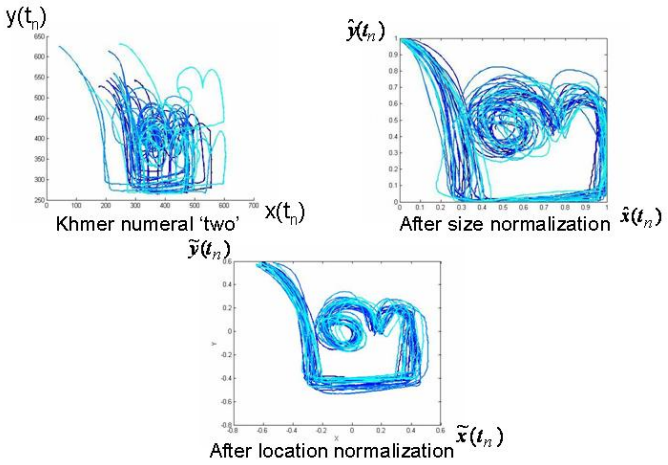

Figure 3: Khmer numeral 'two', after size normalizaton, and location normalization (left to rigth; top to down).

In order to reduce a fluctuation of pen-point movement in handwriting process, a trajectory of the barycenter determined from the center point of script and two adjacent pen-point positions with respect to time in handwriting process is used. The coordinates $(r_x(t_n), r_y(t_n))$ of the barycenter shown in the Fig.4 are calculated by the following equations:

$$r_x(t_n) = \frac{\tilde{x}(t_n) + \tilde{x}(t_{n+1}) + 0}{3},$$

$$r_y(t_n) = \frac{\tilde{y}(t_n) + \tilde{y}(t_{n+1}) + 0}{3}, \quad (5)$$

$$(n = 1,2,3..N-1),$$

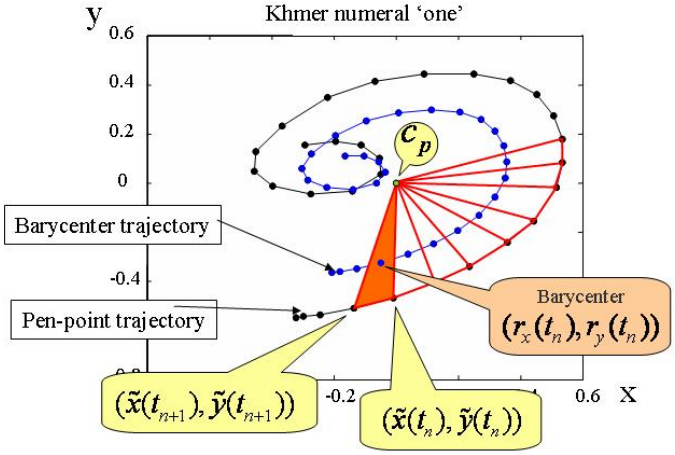

Figure 4: Khmer numeral 'one'.

III. FEATURE EXTRACTION

In this paper, we consider that the handwriting feature of Khmer numeral can be represented by two features, barycenter trajectory and its direction changes. The two features can be described as follows:

$$z(t_n) = r_x(t_n) + j r_y(t_n), \quad (6)$$

$$\theta(t_n) = \arctan\left(\frac{r_y(t_{n+1}) - r_y(t_n)}{r_x(t_{n+1}) - r_x(t_n)}\right), \quad (7)$$

where $z(t_n)$ is the complex function representing barycenter trajectory, and $\theta(t_n)$ represents the direction changes of the barycenter at the time t_n.

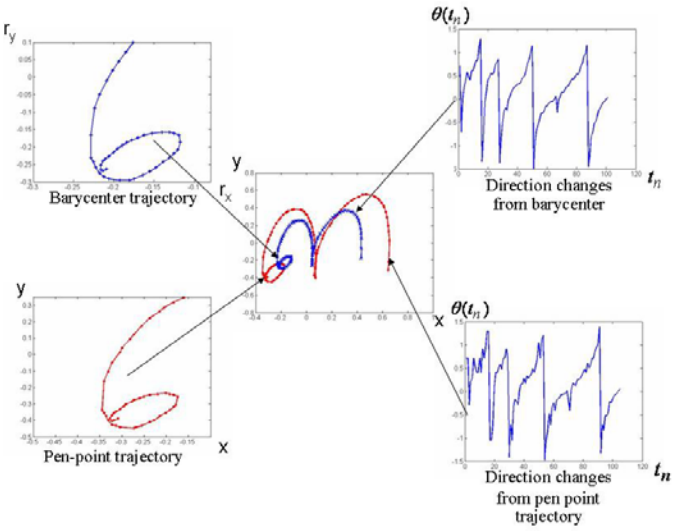

Figure 5: $z(t_n)$ and $\theta(t_n)$ obtained from the pen-point position and barycenter.

Fig.5 shows the comparison of $z(t_n)$ and $\theta(t_n)$ obtained from pen-point position and the barycenter. It can be seen from fig.5 that $z(t_n)$ and $\theta(t_n)$ obtained from the barycenter

are less sensitive than those obtained from the pen-point position.

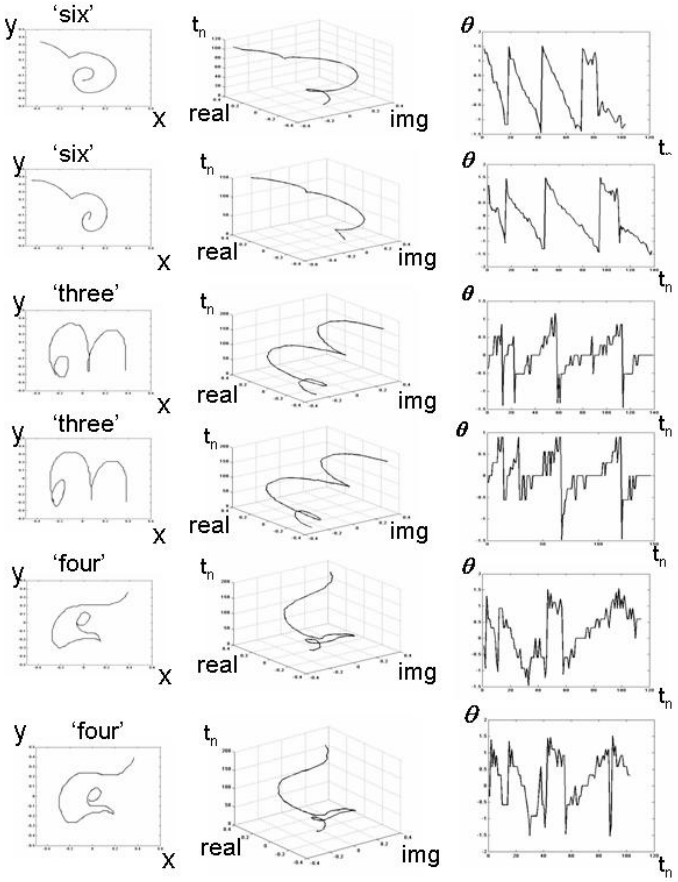

Figure 6: Khmer numerals, their complex features, and their direction changes from left to rigth.

Fig.6 shows $z(t_n)$ and $\theta(t_n)$ obtained from the same and different Khmer numerals. It can be seen from Fig.6 that $z(t_n)$ and $\theta(t_n)$ obtained from same numeral class are similar and different from those obtained from different numeral class. Therefore, we consider that the $z(t_n)$ and $\theta(t_n)$ can be used as the features of handwriting characters for Khmer numeral recognition.

IV. CHARACTER RECOGNITION

It is well known that the duration time in handwriting process obtained from the same character are never precisely the same. It is considered as the fluctuation in time-axis of handwriting character. To recognize the character effectively, Dynamic Programming(DP) matching method[4] is used to calculate the dissimilarity between the features of the reference handwriting character and a character to be recognized. With DP matching technique, the fluctuation of the duration time in handwriting process can be reduced. The DP matching can be performed as follows:

1) The feature parameter vectors of handwriting process are given by

$$\mathbf{z}^r = \left[z^r(1), z^r(2), z^r(3)..., z^r(I)\right]', \quad (8)$$

$$\mathbf{z}^t = \left[z^t(1), z^t(2), z^t(3)..., z^t(L)\right]', \quad (9)$$

$$\boldsymbol{\theta}^r = \left[\theta^r(1), \theta^r(2), \theta^r(3)..., \theta^r(I)\right]', \quad (10)$$

$$\boldsymbol{\theta}^t = \left[\theta^t(1), \theta^t(2), \theta^t(3)..., \theta^t(L)\right]', \quad (11)$$

where $z^r(t_n)$, $z^t(t_n)$, $\theta^r(t_n)$ and $\theta^t(t_n)$ are the barycenter trajectory and its direction changes obtained from preceding section, $\mathbf{z}^r$ and $\boldsymbol{\theta}^r$ are the feature parameter vectors for reference character, $\mathbf{z}^t$ and $\boldsymbol{\theta}^t$ are the feature parameter vectors for character to be recognized, and I and L are the number of elements in the feature parameter vectors for the reference character and the character to be recognized, respectively.

2) In order to obtain a good matching between the feature parameter vectors, a warping function $w(k)$ is defined as sequence

$$\mathbf{w} = w(1), w(2), w(3), ..., w(K), \quad (12)$$

where $w(k) = (i_k, l_k)$, $(1 \le i_k \le I; 1 \le l_k \le L)$, with the initial condition as $w(1) = (1,1)$, and the terminal condition as $w(K) = (I, L)$. K is the number of warping points obtained from DP matching

3) The dissimilarity between the feature parameter vectors is calculated by

$$S = \frac{1}{I+L} \min_{w} \left(\sum_{k=1}^{K} d(w(k)) g_k \right), \quad (13)$$

where

$$d(w(k)) = \left| z^r(i_k) - z^t(l_k) \right| + p \left| \theta^r(i_k) - \theta^t(l_k) \right|,$$
$$g_k = (i_k - i_{k-1}) + (l_k - l_{k-1}), \quad (14)$$

The minimum cost of matching two features are calculated by

$$h(w(k)) = \min \begin{Bmatrix} h(i_k - 1, l_k - 1) + 2d(i_k, l_k) \\ h(i_k - 1, l_k) + d(i_k, l_k) \\ h(i_k, l_k - 1) + d(i_k, l_k) \end{Bmatrix}, \quad (15)$$

Equation (13) can be rewritten as

$$S = \frac{1}{I+L} h(w(K)), \quad (16)$$

where $h(w(1)) = 2d(w(1))$, p is the weight for θ.

Fig.7 shows the warping function of matching two vectors, $\mathbf{z}^r$ and $\mathbf{z}^t$. It can be seen that timing differences between two patterns are eliminated by the warping function.

It is assumed that the reference patterns of known classes for Khmer numerals 'zero', 'one', 'two', 'three', …, 'nine' are defined by $\{C_0, C_1, C_2, ..., C_9\}$, respectively.

Then an unknown character x is assigned to a class $C_i \in \{C_0, C_1, C_2, ..., C_9\}$

$$\text{if } S_{\min}(C_i, x) = \min_l \{S(C_l, x)\},\ l = 0,1,2,...,9, \qquad (17)$$

where $S_{\min}(C_i, x)$ is the dissimilarity between the feature parameter vectors obtained from an unknown pattern x and that obtained from the reference pattern of known class C_i.

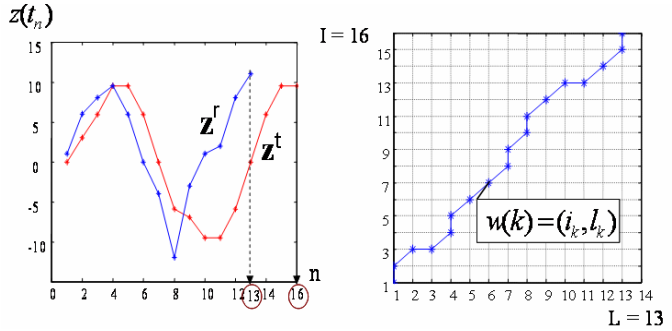

Figure 7: Reference vector $\mathbf{z}^r$, test vector $\mathbf{z}^t$ (left), and the warping function (right).

V. EXPERIMENTS

Character recognition experiments were performed on a database consisting of 5000 Khmer numerals written by 20 people. In the experiments, 100 scripts for each Khmer numeral(0,1,…,9) are selected randomly from the database and used as the test data, and the training data for each Khmer numeral consisting of 5 scripts selected randomly from the database. The examples of some Khmer numerals in our database are shown in Fig.8.

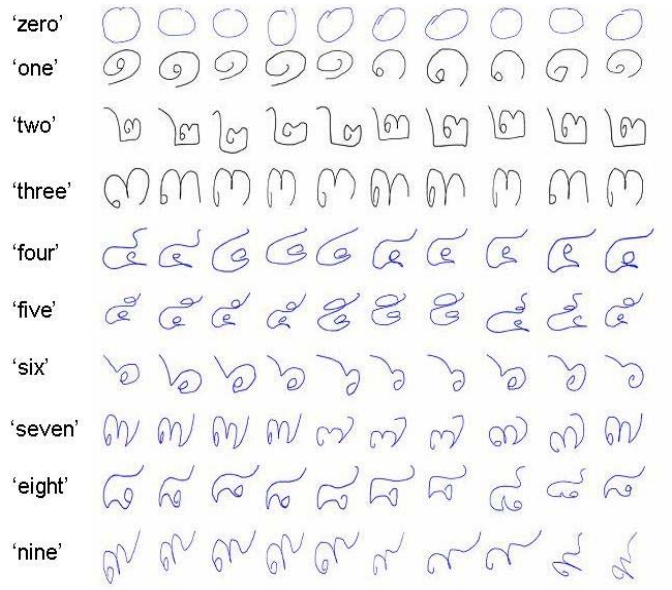

Figure 8: Some Khmer numerals in database.

The experimental results are shown in Table I. Table I shows the comparison of the experimental results of the proposed method using pen-point position and the barycenter. It can be seen from Table I that the recognition rate obtained from the barycenter is better than that obtained from pen-point position. The average of recognition rates was 95.9%, and it can be seen from Table I that the recognition rates obtained from numeral 'nine' and 'seven' are less than those obtained from other numerals because the handwriting style for numeral 'nine' and 'seven' obtained from some writers are similar. Fig.9 shows Khmer numeral 'nine' and 'seven' which were not correctly recognized.

Table I: Recognition rates of Khmer numerals.

Khmer numeral	Recognition rates (%)	
	Using pen-point	Using barycenter
'Zero'	96	96
'One'	63	94
'Two'	85	92
'Three'	98	99
'Four'	98	99
'Five'	74	92
'Six'	100	100
'Seven'	95	99
'Eight'	83	96
'Nine'	85	92
Average	87.7	95.9

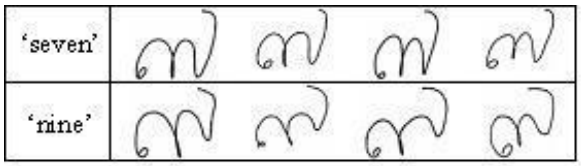

Figure 9: Numeral 'seven' (first row) , and numeral 'nine' (second row).

VI. CONCLUSION

We proposed an on-line character recognition method based on DP-matching of barycenter trajectory. The barycenter, determined from the center point of the script and two adjacent of pen-point positions, was used to reduce the sensitivity of pen-point movement in handwriting process. The character was recognized by the incorporation of the barycenter trajectory and its direction changes in DP matching. The experimental results show that the proposed method is useful for on-line character recognition for Khmer numeral.

The Use of Context-free Grammars in Isolated Word Recognition

C. Chirathamjaree

2 Bradford Street
Mt. Lawley, WA 6050 AUSTRALIA

***Abstract*-A method using non-recursive context-free grammars is presented for the recognition of isolated words. Some form of 'training' is required to combat problems of variations in speech. In the training mode, one grammar for each word in the vocabulary is constructed directly from a set of sample strings of 'features' represented by symbols. In the recognition mode, an incoming string is analyzed to determine which grammar, if any, could have generated it. The word corresponding to such grammar is then said to have been recognized.**

I. INTRODUCTION

An isolated word recognition (IWR) system is one which can recognize human utterances. Short pauses are required before and after utterances to be recognized. Following the common practice in the filed of pattern recognition [1], an IWR system can be considered to consist of a feature extractor (FE) or a pre-processor of some sort followed by a recognizer or classifier (Figure 1). The FE transcribes the input speech signal into strings of symbols representing various parameters extracted from the signal. A decision is made by the recognizer on this simplified representation as to which word in the vocabulary, if any, has been spoken.

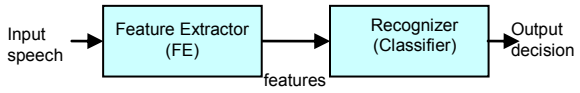

Figure 1. An isolated word recognition system.

The classical decision-theoretic methods [1,2] from the filed of pattern recognition have commonly been used to produce recognizers for processing strings of symbols generated by the FE. Another promising approach, which stemmed from the fields of mathematical linguistics and computer science, is to make use of the techniques of formal language theory [3]. The essence of this method is the use of formal grammars to model a FE and to classify a pattern by determining which of a number of formal grammars [4] or sets of rules could have generated it. This paper presents the application of linguistic methods to the modeling of a FE and the recognition of isolated words from a limited vocabulary.

II. THE FORMAL GRAMMARS IN ISOLATED WORD RECOGNITION

In general, a person does not always speak the same word in the same way. This may be due to the emotional and physical states of the speaker, the ambient noise level of the surrounding and free variation from trial to trail. Hence, some form of 'training' is usually required in order to combat problems of variations in speech. This is done by having the user speaking each word in the vocabulary a number of times until the representative rules for the construction of each word are formed.

In IWR systems, words are spoken in isolation with short gaps between utterances. This leads to the following assumptions:-

(a) Only a finite number of symbols are generated by the FE and only one symbol can be represented at a particular time.

(b) Each word uttered results in a sequence of symbols of some finite length.

The problem of designing a recognizer in an IWR system can be broadly divided into two areas: the construction of models based on formal grammars, known as grammar inference [5,6,7], to represent characteristics of the symbol-generating source and the search for suitable decoding methods for efficiently analyzing the strings from the source using rules or grammars of the models previously created.

In outline, the basis of the linguistic method is simply explained (Figure 2). In the training (learning) mode, a user repeats each word in the vocabulary a number of times. Each time the same word is spoken, a similar but not necessarily the same string of symbols is produced by the FE. Grammar-based models, one for each word in the vocabulary, are then automatically constructed and stored in the system memory for future use. In addition to producing all the strings in the sample set, each model is also capable of predicting other similar strings. Model building is considered to be the encoding of strings. In the recognition mode, an incoming string is processed using suitable decoding algorithms to determine which model, if any, corresponds or nearly so to the word spoken. If the most compatible model is found, the corresponding word is then indicated as to have been recognized. Otherwise, the recognition fails and the word is rejected.

In IWR systems, unlike many applications of grammar inference where the class of grammars to be inferred is precisely defined, it is not clear what types of grammars best represent the FE. In principle, regular or finite-state grammars (FSG's) would be adequate since each training set can consist only of a finite number of finite-length strings. The FSG approach is simple, offers well-established characteristics and its sequential nature is similar to that of the string symbols. In addition, many efficient computational techniques are known for the FSG methods. This paper presents a method using non-recursive context-

free grammars (CFG's) for the recognition of isolated words. The CFG approach is selected because it enables useful complexity to be generated without requiring inordinate computing power. In addition, a CFG may have fewer nodes and/or links than a finite-state grammar using the same data. Another motivation behind the use of the non-recursive CFG approach is to determine whether there is any advantage from the use of a more powerful grammar in isolated word recognition.

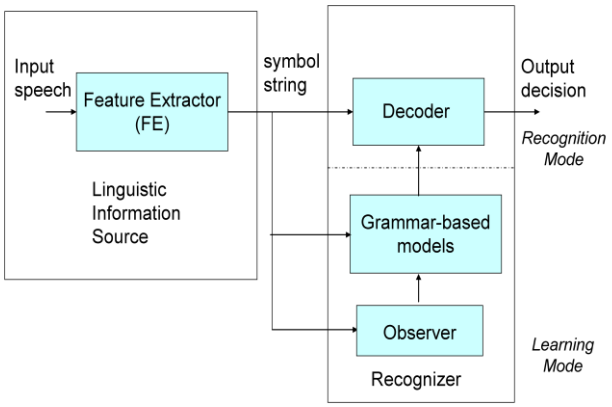

Figure 2. A grammar-based IWR system.

Some notation and terminology are now introduced. Precise and complete definition of context-free grammars (CFG's) are available elsewhere [3,4,8].

A CFG consists of:

1. A finite set of *non-terminals* $A_1, A_2, \ldots, A_r$;
2. A finite set of *terminals* $b_1, b_2, \ldots, b_s$;
3. A set of *rewriting rules* (or just *rules*) of the form $A \rightarrow \beta$; where A is a non-terminal and β is a non-empty string of terminals or non-terminals, or both;
4. A *start symbol*, which is one of the non-terminals.

Any CFG can be transformed into an equivalent Chomsky normal form [4] in which the rules are of the following forms only:

Bielement rules: $A \rightarrow BC$
Terminating rules: $A \rightarrow a$

where A, B and C are non-terminals and a is a terminal.

III. Computation of the Minimization Matrix

Before the inference method can be given, it is necessary to describe the minimization matrix, M, which forms the basis of the inference process of the CFG's.

For a given CFG in Chomsky normal form and for a string, S, the minimization matrix, M, (M-matrix) is a 3-dimensional, n x n x r matrix where n is the length of S and r is the number of non-terminals in the grammar. Let a_j represent the j^{th} symbol of S. Element m_{ijk} of M denotes the minimum number of symbol alterations (insertions, deletions or substitutions) required if the length-i substring of S, whose first symbol is a_j, is to be generated by the grammar from A_k, the k^{th} non-terminal.

M-matrix can be computed iteratively by the following procedure.

Part 1: Terminating rules

m_{1jk} = 0, if and only if $A_k \rightarrow a_j$ is a rule of the CFG

m_{1jk} = 1, otherwise.

For i=2,3,…,n:

$$m_{ijk} = \max\left[(i-1), \sum_{u=j}^{j+i-1} m_{1uk}\right].$$

Part 2:Bielement rules

$$m_{1jk} = \min_{p,q \in P_k} \left\{\min\left[m_{1jp} + H(q), m_{1jq} + H(p)\right]\right\}$$

where P_k is the set of ordered pairs (p,q) such that $A_k \rightarrow A_pA_q$

For i=2,3,…,n:

$$m_{ijk} = \min_{p,q \in Pk} \left\{\min\left[x, \min_{1 \le u < i} (m_{ujp} + m_{i-u,j+u,q})\right]\right\}$$

where $x = \left[m_{ijp} + H(q), m_{ijq} + H(p)\right]$

IV. Inference Procedure

In the learning mode, a learning algorithm is employed to automatically construct one grammar for each word in the specified vocabulary. The inference process produces rewriting rules directly from the observed sample strings in response to the words spoken. Rule or production probabilities are also estimated during the learning process.

Inference algorithms of the CFG's are based on the criterion of maximizing the similarity between various strings of the same word. The basis of the inference process is now explained. The first grammar, called the *skeleton grammar* G_1, is constructed from the first string in the sample set such that G_1 can generate only that string. Other strings are then individually processed in the search for incompatibility between each string and the current grammar. If the nth observed string, S_n can be derived from the $(n-1)^{th}$ inferred grammar G_{n-1}, then $G_n = G_{n-1}$ and no augmentation of G_{n-1} is required. Otherwise, G_{n-1} is augmented such that G_n is produced which can generate the present string. For the CFG approach, the matching process between an incoming string and a CFG involves the computation of the *M-matrix* whose elements reveal the shortcomings of the grammar in relation to its ability to generate the string.

V. Recognition Scheme

In the recognition mode, each unknown string presented to the recognizer is classified or decoded using the rules obtained in the learning mode. The recognition process consists of three main levels of operation in terms of the complexity involved. The recognition always starts at the lowest level (level 1). A higher level is applied only if the previous one fails to classify a string according to some criteria.

Level 1: In this simplest level of the recognition process, an incoming string is tested by means of a parsing algorithm to determine which grammar, if any, could have generated it. If the string is accepted by one grammar only, the corresponding word is indicated at the output. For unsuccessful matching, the method of level 2 is applied to decode the string. When two or more grammars can generate the string, it is necessary to employ a stochastic algorithm to find one 'best word' that is most likely to have produced the string. If two or more such words are possible, the string is rejected.

Level 2: In this level, a technique is utilized to determine the 'closest match' for the string i.e. the grammar that could nearly have generated the string. It is basically a dynamic programming method of optimizing the similarity between two functions.

Level 3: This is the highest and most complicated level of the recognition process where the operations in the two lower levels have to be performed in order to reach level 3. It is applied when there exist two or more closest-matched words corresponding to the string. Another stochastic algorithm is employed to select the most likely closest-matched word. The string is rejected if two or more such words are found.

The foregoing recognition scheme is not too restrictive in the sense of immediate rejection of an erroneous string but rather trying to find a grammar that could most likely have generated the string. This can be very useful in many applications involving noisy strings.

VI. Results and discussion

The experimental IWR system has been constructed based on the use of the CFG's outlined in this paper to model the FE. The vocabulary consists of ten digits 'ZERO' to 'NINE' uttered by a single speaker. The speech signal of the spoken digits is of telephone-grade quality. This is obtained from a normal telephone set via a circuit representing two local lines. Ten of CFG's for the recognition of the spoken digits 'ZERO' to 'NINE' were generated from a total of 100 strings, of average length 3.6 symbols. The testing set consists of 500 strings in total with 50 strings for each of the ten digits spoken. The average length of testing strings is 3.4 symbols per string.

The non-recursive CFG approach yields the average recognition rate of 72.8% using the training and testing set as described above. In another experiment using FSG's approach, the recognition rate using the same training and test set as above gives an average recognition rate of 73.4%. From the results obtained, it seems that the use of FSG's and CFG's to model a FE offers comparable recognition performances with less than 1% variation between them. This, in a way, is to be expected since the learning algorithms for the inference of both types of grammars are based on a similar criterion of maximizing the similarities between strings in the sample set.

It appears that there is no advantage gained for the use of non-recursive CFG's over that of FSG's, as far as recognition performance and computational requirement are concerned. This may be because only an isolated word, and not a sentence, needs to be recognized and this does not require the information of the syntax of the words concerned. There are, however, other situations where there may be an advantage for using a CFG approach. One example is the recognition of connected speech.

The previous sections have described an incremental method for the construction of non-recursive CFG's. This is appropriate for applications such as the recognition of isolated words, where finite-length strings only are involved. The method presented is guaranteed to yield non-recursive CFG's that are capable of producing all the given strings, irrespective of the order in which they are presented. Any other strings generated by the grammar will resemble those in the training set. The method also produces compact grammars having a near-minimal number of rules and non-terminals.

The representation of strings by a set of rules of formal grammars instead of direct storage of strings make possible the 'generalization' of strings in the training set. This reduces the size of the training set needed compared with the approach of using template matching techniques in order to cover the same number of strings. Extension of the method to the construction of stochastic CFG's, by counting the frequency of use of rules, is straightforward. Future work on the recognition of words in connected speech is planned.

VII. Conclusion

Techniques of formal language theory or the syntactic methods provide a useful approach to the solution of classification and description in an isolated word recognition system where only a finite number of features (represented by symbols) are generated for each utterance. The method presented for the generation of grammars from sample strings enables grammars of useful complexity to be generated without requiring inordinate computing power. Comparison with an approach using DTW (Dynamic Time Warping) is planned for futture work.

***Abstract*- Lao handwritten characters can naturally be represented as a sequence of curve in clockwise and counter clockwise directions. This paper proposed the use of this curve sequence as a main feature in Lao handwritten character recognition system. Since, there can be variation and noise in a handwritten that usually generates small curve segment. Also, some curve segments when written in fast speed can be decreased to small curve segment. Hence, it is hard to distinguish between real curve and noisy curve. To overcome this problem, small curve segment is treated as both real curve and noise curve. The noise curve segment is omitted from the sequence while the real curve is remained. Each uncertain curve segment causes two possible representations. So, instead of single curve sequence, a tree of curve segment is form and use as a main feature in recognition. The proposed method can recognize different handwritten Lao character very well in comparing to the conventional method such as elastic matching.**

Keywords- *feature tree, curvature feature, distinguish feature, handwritten Lao character, Lao recognition.*

I. INTRODUCTION

Many methods for online character recognition have been proposed [1]. However a few methods for Lao character recognition have been proposed [6,7]. In this paper, a new method for unconstrained Lao handwritten recognition is proposed. Fig 1. shows the example of Lao characters and Fig. 2 shows the unconstrained Lao handwritten, where characters are written out of proportion and varied in amount of rotation (slant) and writing style. Most zone features [1] are less effective due to the out of proportion since some characters will have big, small or omitted head.

The proposed method will be compared with elastic matching which provides a very good recognition rate and has been widely used since the early [2] and recently handwritten recognition research [3,4]. The elastic matching can be used to performed matching the unknown writing with the prototype character and the unknown writing is recognized as the character with the closest match.

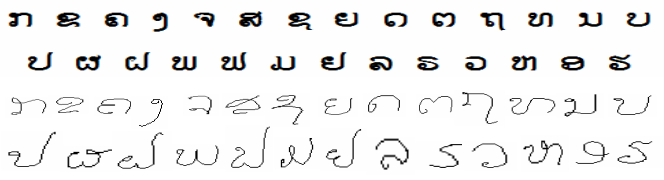

Fig 1. Example of Lao isolated handwritten and printed characters

Fig 2. Variation of Lao handwritten.

The elastic matching by finds the optimal alignment distance among all the n points of both matched characters by summing distance of all the matched points. The disadvantage of elastic matching is the overall shape matching of character which has also been observed by other researcher [3]. This is a problem in Lao handwritten as shows in Fig. 3, where the overall shape matches to the wrong character and miss the small curvature in the top. The elastic matching misses dominant point due to equally treatment of all the point in the matching.

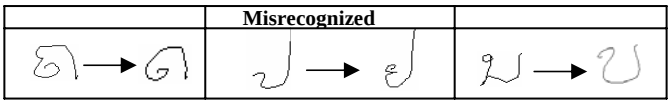

Fig 3. Misrecognized characters by elastic matching method.

Handwritten Lao character is usually continuous drawing of curves (mostly single stroke). It is naturally to represent handwritten Lao as a sequence of curve segment with clockwise and counter clockwise direction as the main feature. Even though this feature quite coincides with the way writers learn to write Fig. 4, it may consist of noisy curves. Usually, the noise curve segment can be distinguished from the real curve by the high amount of curvature of the real signal. But when the written speed is fast, the curvature is reducing close to the noisy curve as shown in Fig. 4. These noisy curves are hard to distinguish with normal noise reduction technique such as Fourier expansion or Fourier descriptor due to the similarity in frequency and amplitude.

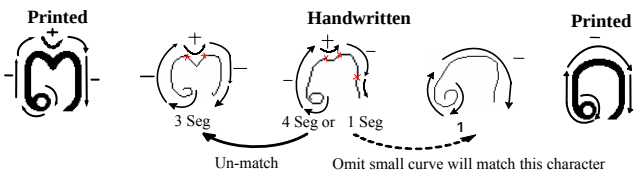

Fig 4. Uncertain segment with small curvature.

In order to successfully use the curvature sequence in the recognition, one may have to identify real curvature from the noisy one. As shown in Fig. 4, the character ๆ consist of three curvatures in sequence. If all small curvature is treated as noise and omitted. It will match to another character ๅ that has one clockwise curvature. On the other hand, if treated all curvature as real curve the character will have 4 curvatures and can't match to the correct character with three curvature segments. So in the proposed method, we classify curve feature into three groups, noise, real and uncertain segments. The noise group consists of the noise curves that can be identified and are ignored. The uncertain group consists of noise and real signal that can't be distinguished. The real group has high curvature enough to be certain as a real signal. A binary tree of curve sequence is formed, the branch in the tree represents uncertain curve segment. So the feature of a handwritten character is not just a single sequence of curve but a tree of curve segments. The noisy curves are discarded and the real curves still remain in the tree. In other word, we discard the certain noise out but keep all possibility of the uncertain and real curve segment and form them in the tree. For detail of tree generation will be descript later in section three.

Since all possible segments still remain in the tree, we postpone the determination of the uncertain segment until we compare with another character. So in order to find a similarity (or dissimilarity) with another character, it is liked comparing two trees for all possible representation of curve sequence of both characters. Since this method needs to compare between two characters in order to select the closet representation of the two characters, this technique is suitable for similarity based pattern recognition.

The tree representation guarantees to have one correct sequence of curve, but also contains a lot of other noisy sequences. Hence, more additional curve features are added in order to make noisy curve dissimilar enough to make the correct sequence pair the most similar. In order to show the effectiveness of this approach, the comparison of the recognition results obtained from the proposed method using the curvature tree and the elastic matching are given.

II. CURVATURE SEQUENCE EXTRACTION OF LAO HANDWRITTEN

Lao handwritten is input as a sequence of X,Y coordinates samples from input device with the rate of 100 samples per second. In order to extract curvature sequence, the following steps are performed: 1) Translate the X,Y coordinate sequence into the direction sequence and the length sequence. 2) Translate the direction sequence into the angle sequence by subtracting the current direction from the next direction in the sequence. 3) Find segmentation points and then curvature sequence is defined by adding the angle between consecutive segmentation points.

The direction of pen trajectory is represented as real number call directional code [5]. Examples of the directional code calculation are shown in Fig. 5. The 45-degree means one unit (360-degree is 8 units). The directional code can be calculated

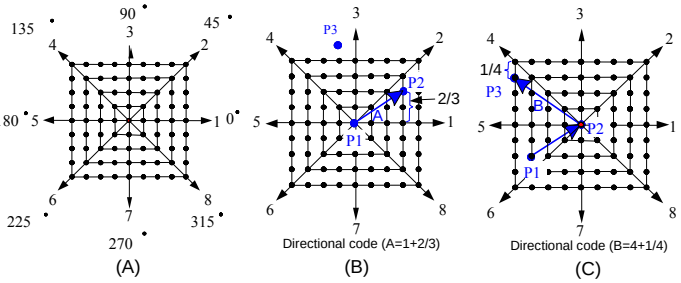

Fig 5.The directional code calculation,(A) The directional code,(B)Directional code calculation of vector A, (C) Directional code calculation of vector B.

as a real number. As shown in Fig. 5, the directional code of vectors A and B are given as 1 + 2/3 and 4+1/4, respectively.

The angle between two consecutive segments of pen trajectory is defined as the difference between the corresponding directional codes, the current directional code minus the previous one. With the above angle, the directions of pen trajectory, counter clockwise and clockwise can be represented as positive and negative angles, respectively. The angle of a curve segment represented as the sum of the angles of the consecutive segments and the length of curve segment is represented as the sum of the length of the segments in the curve segment. It can be seen that the angle for curve segment is rotation invariant and shape invariant. As shown in Fig.6, the directional code for the rotation of any counter clockwise 90 degree turn is 2.0 and the directional code for whole circle 270 turn is 6 independent of exact shape. In the following the whole character is represented as the sequences of curve segments with clockwise and counter clockwise directions.

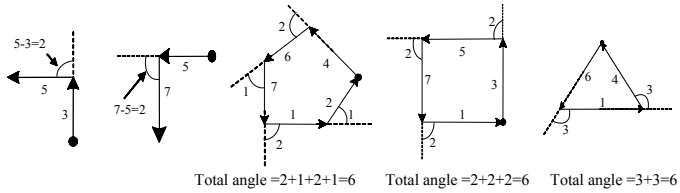

Fig 6. Rotation invariant and shape invariant.

Consecutive segments with the same direction of clockwise or counter clockwise are treated as one angle. A point separating pen trajectory into two curve segments with clockwise and counter clockwise directions is defined here as a segmentation point. In other words, a segmentation point is the point changing the direction of pen trajectory from the clockwise to the counter clockwise and vice versa. Some researchers [5] have used the dominant point or point where the pen trajectory turns the direction quickly. We consider the segmentation points in the pen trajectory of Lao handwritten by improving the above dominance point in the literature [5]. In order to represent Lao handwritten with segmentation points effectively, the noise such as small variation or fluctuation in the pen trajectory should be removed. In this paper the noise cancellation is made as show in Fig. 7(A) and 7(B). When the direction of pen trajectory is not in alignment but in zigzags (clockwise and counter clockwise curve segments with small equal angle), the zigzags is considered as a straight line. In other words, the pen trajectory with the zigzags segments is

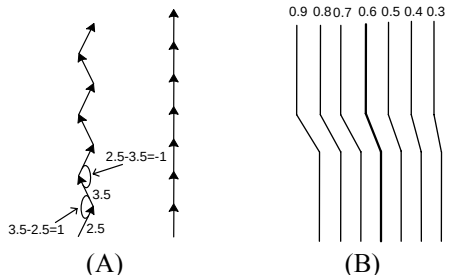

Fig 7. (A) Quantized noise cancellation, (B) The threshold 0.6 curvature

considered as a straight line if sum of the angles of curve segments between the consecutive segmentation points is equal to zero. As show in Fig. 7(B), a pen trajectory has a noise such as small and quick change of curvature. In this case pen trajectory is considered as a straight line or zigzag line according to the amount of the angle of the curve segments between two segmentation points. That point is not considered as the segmentation point if the angle is less than a selected threshold angle. In the example in Fig. 7(B), pen trajectory is considered as straight line if amount of the angle of the curve segments is less than threshold value (0.6), otherwise a zigzag line. It can be seem that the direction of pen trajectory is determined using the angle of curve segment in the trajectory. However some Lao characters such as ถ and ฦ have same clockwise direction of pen trajectory. In this case we can not recognize two characters as different using the angle. Thus we introduce the change of the x, y coordinates and the length of the curve segment of pen trajectory as other features of handwritten Lao character.

III. CURVATURE TREE REPRESENTATION

This section explains construction of curvature tree for all possible uncertain segments. The sequence consisting of clockwise and counter clockwise curve segments is used to construct curvature tree using the following steps:

1) Classify each curve segment as one of the following segments, noise, uncertain and real using length and angle of the segment. Then discard the noise segment by merging noise segment with the previous segment and subsequent segment.

2) Re-classify each merged segment as one of the following segments, uncertain and real. If any adjacent uncertain segments has the same amount of angles but different signs (-clockwise,+ counter clockwise), then both uncertain segments are treated as a noises with zero angle and merge both adjacent segments as mentioned above.

Construct binary tree of curve segments consisting of the real and uncertain segments.

The noise of segment can be reduced using the combinations of the angle of the curve segment and the length of the segment. The real curve segment should have high curvature and significant size. Some noise segments may have high curvature with short length or small curvature with long length, but not both. Hence, the noise segment can be classified here using angle-length feature, the angle multiplied by the length (the ratio of the length over the summation of the entire segments length). If the angle-length feature is less than a threshold value (0.017) then the segment is considered as a noise segment. If it is between 0.017 and 0.4, then it is considered as an uncertain segment and furthermore if it is greater than 0.4, then it is considered as a real segment. These threshold values 0.017 and 0.4 got from our handwriting database. Since our database is from 18 writers and we have rotation invariant feature, this threshold should be suitable for other writer. The segment contaminated with noise is removed from the pen trajectory and then the angle and the length of segment are added to both adjacent segments (previous and subsequent segments). After noise removal, the angle and the length of the merged segment change due to the addition. The noise classification of the merged segments is repeated until this classification results in only uncertain and real segments without noise. Up to now the curve sequence has been represented by a sequence of clockwise and counter clockwise curve segments with some uncertain segment. In the next step a binary tree of all possible representation is formed, where each uncertain segment can be treated as a noise or real segment and forms the binary branch of the tree. When uncertain segment is treated as a noise segment, the adjacent segments (three segments) are merged together, as shown in Fig. 8. The figure also shows the tree representation of character ถ. Each node of tree consists of sum angle and sum length. As mentioned in the introduction, the purpose of feature tree is to keep all the possible representations of a character. At this moment, we still don't know which the real curve sequence is because of some uncertainty. But, the real representation can be identified by comparing with the other characters.

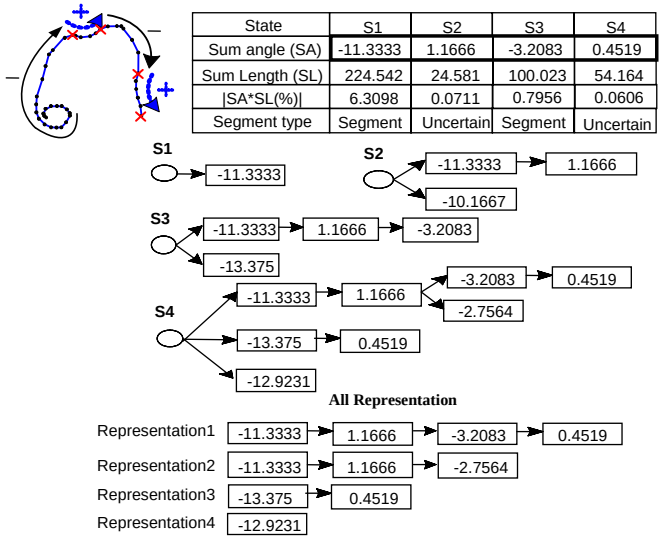

Fig 8. Curvature tree representation and merge of uncertain segment treated as a noise.

IV. RECOGNITION USING PROTOTYPE MATCHING

It is assumed that the character to be recognized has some segments, and the prototypes are prepared in each segment. For the convenience of explanation, it is assumed the character to

be recognized has p segments and the number of character classes with p segments, is s_p. Then the character X is represented as

$$X \equiv X_{p=} (\xi_{1,}\ldots,\xi s_p)^T \quad (1)$$

X_p is corresponding to the branch of the alternate curvature tree for the character X then the character X is recognized as follows (Fig. 9)

(Step.1) calculate the distance between prototype P_k and X as

$$d\left(X_p, P_k\right) = \left\| X_p - P_k \right\| \quad (2)$$

where $d\left(X_p, P_k\right)$ is the Euclidean distance between X_p and prototype P_k of the *k*th character class with p segments.

(Step.2) calculate the minimum distance as

$$\underline{d}_{s_p}(r) = \min_{1 \le k \le s_p} d\left(X_p, P_k\right) \quad (3)$$

(Step.3) character x is recognize as $X \in C_r$ (The *r*th character class)

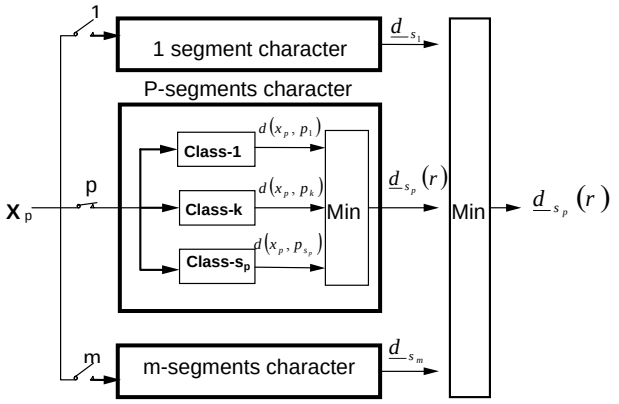

Fig 9. Lao handwritten recognition system

V. EXPERIMENTAL RESULTS

The proposed curvature tree and the elastic matching method are compared. In experiment we used PC with 1.4 GHz Pentium 4 and using our database consisting of 24321 handwritten Lao characters belonging to 27 classes. The prototypes of characters consisting of 3729 handwritten Lao characters. The recognition rates of each method are shown in Table I

TABLE I
COMPARISONS OF RECOGNITION METHODS

Method	Recognition Rate (%)	Average Time (s)
curvature tree	96.78	0.0204
Elastic Matching	94.05	1.2356

Some of characters misclassified by our method and elastic matching method in the experiment are shown in Fig. 10.and Fig.11, respectively. It can be seem from Fig.10 that it is rather difficult for out method to recognize some of characters having small loop or curve, but it easy to recognize curve segment with clockwise or counter clockwise direction in pen trajectory. While it can be also seem from Fig.11 that the elastic matching method can not recognize a curve segment with clockwise or counter clockwise direction in pen trajectory but it is easy to recognize a character with similar shape except for the direction, clockwise or counter clockwise of pen trajectory.

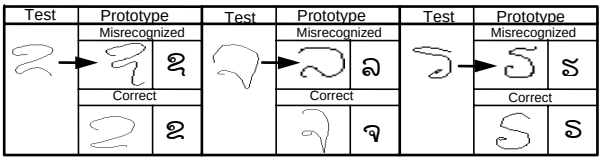

Fig 10. Example of misrecognized in our method.

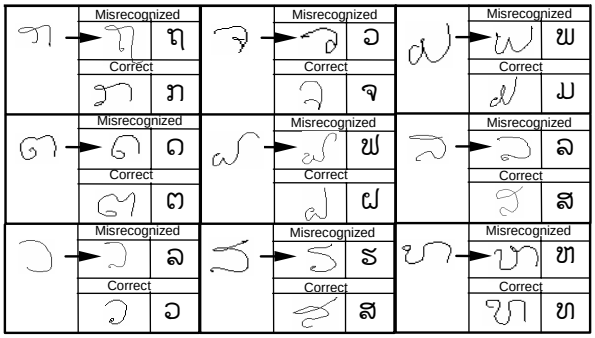

Fig 11. Example of misrecognized in elastic matching.

VI. CONCLUSIONS

This paper proposed an unconstrained isolated Lao handwritten recognition method by using curvature tree. In the proposed method, as unique features of Lao handwritten, different characters with similar shapes having small or large curve segments with clockwise and counter clockwise directions, were take into account. The proposed method can recognize correctly Lao handwritten with above features though the elastic matching method having been used widely can not do this. It was found from our experiments using our data base that the recognition rate of our method was higher than that of elastic matching method and average time requited to the recognition of our method is faster than elastic matching method.

Combination of Self-Organizing Map and Fuzzy C-Means algorithms for project performance segmentation in Agricultural Technology Transfer and Service Centers

Sasithorn Mongkolsripattana, Anongnart Srivihok
Department of Computer Science, Faculty of Science,
Kasetsart University, Bangkok, Thailand
Email: {g4764238, anongnart.s}@ku.ac.th

***Abstract*- Currently, there are more than six thousands Agricultural Technology Transfer and Service Centers (ATSC) which conduct training to target groups in Thailand. Project performance measurements are significant for management and strategic planning for ATSC. Therefore, the assessments of their performances are not simple since all data are enormous and stored in huge database. This study aims to introduce a new tactic in segmenting ATSC performances. Clustering and ranking data set are two key steps in this approach. Firstly, apply two data mining techniques: SOM (Self-Organizing Maps) and Fuzzy C-Means algorithms to cluster ATSC data related to their project performances. SOM algorithm is used to calculate the appropriate number of clusters. Three measurement indices: SD validity index, DB and PBM index are used for SOM. Later, the same ATSC data set is clustered by Fuzzy C-Means algorithm. Secondly, data are ranked on their project performance scores. There are four levels of project performance: high, above average, average and low. Results revealed that ATSC can be clustered in six groups. The majority of ATSC project performances are in average and low levels, whereas some are in above average and no center is in high level.**

I. INTRODUCTION

Data mining is an integral part of knowledge discovery [1], which is the process of discovering useful knowledge in large database. Many industries [2] including finances, public health, education, and engineering have applied this method in their business. Clustering [1] is one of the most useful tasks in data mining. The main objective of the clustering algorithm is to find groups of closely related objects.

A. Previous Work

In case of using two-stage method to cluster data is certainly not new. Kuo et at. [3] proposed a two-stage method which is a combination of the SOM and K-Means algorithms for Market Segmentation. And then results were compared with the conventional two-stage method by Wilk‘s Lambda for measuring. The results indicate that the proposed method is better than the conventional two-stage method. Weng and Liu [4] used a combination between SOM and K-Means algorithms for one to one market recommendation system. The results show that the optimal number for clustering was 9 groups which have the best CV (Coefficient of Variance) values. Chaimeun and Srivihok [5] proposed the principles of data mining to cluster Thai handicraft customers by using a hybrid algorithm including SOM and K-Means algorithm. Mongkolsripattana and Srivihok [6] purposed the approach in clustering Technology Transfer Center performances by using two steps: clustering and ranking data set. First two data mining techniques (SOM and K-Means algorithms) used to cluster data according to their project performances. Second, project management efficiency scores (p score) were calculated for ranking TTC according to their management performances. The disadvantages of this research is that data set used in experimenting is small.

The above literatures have applied two-stage methods including SOM and K-Means algorithms. The majority used SOM algorithm to find the optimal number of clusters because K-Means algorithm requires an input which is a predefined number of clusters, k. Fuzzy C-Means algorithm is an extension of K-Means algorithm (it also requires an input which is a predefined number of clusters). It allows an object to partially belong to multiple clusters because of it has a membership function. Fuzzy C-Means algorithm is frequently used in many fields including pattern recognition, image processing and data mining. Albayrak and Amasyali [7] used unsupervised clustering method to developed medical diagnostic system by using Fuzzy C-Means algorithm. This algorithm was used for classification Thyroid patients and then compared performances with K-Means algorithm. Results reveal that Fuzzy C-Means algorithm give better results than K-Means algorithm in correct classified samples. Mingoti and Lima [8] presented the comparisons of clustering performance among SOM, Fuzzy C-Means, K-Means algorithms and Agglomerative Hierarchical. The results show that Fuzzy C-Means algorithm has the best performances in all cases and is stable in the presence of outliers and overlapping. And other methods are affected by the amount of overlapping and outliers. From this research Fuzzy C-Means algorithm has better performance, we will propose two-stage methods which combine SOM and Fuzzy C-Means algorithms for clustering ATSC data.

B. *Agricultural Technology Transfer and Service Center (ATSC)*

The policy for ATSC was established in Thailand in 1999. In these days, there are more than six thousands centers in each subdistrict (tumborn) of Thailand. ATSC provide services and training in agriculture to inhabitants in the neighborhood areas. Examples of a variety of trainings include training on rice cultivation, mango plantation and others. On monthly basis, ATSC have to report their progresses for planning and work practices on the provided web site.

II. CLUSTERING METHOD

Clustering is a division of data into clusters of similar objects. Each cluster consists of objects that are similar between themselves and dissimilar to objects of other clusters.

A. *Self-Organizing Maps (SOM)*

SOM [9] is one of the popular and powerful neural network algorithm which is unsupervised learning. Clustering using the SOM technique consists of six steps described below [10].

1) Initialize the weight vectors (*w*)
2) Calculate Distance: Calculate equation (1)

$$D(j) = \sum_{i=1}^{n} \left(w_{i,j} - x_i \right)^2 \quad (1)$$

Given *i* is input data, *j* is number of clusters as final result, *D*(j) is the distance between instance data and center of cluster, *x* is attribute of data.

3) Compare *D(j)* from each cluster
4) From step 3 we calculate cluster that least value by (2)

$$w_{i,j}(new) = w_{i,j}(old) + \alpha \left(x_i - w_{i,j}(old) \right) \quad (2)$$

When *w(new)* is a new weight, *w(old)* is an old weight

5) Decrease α
6) Go to step 2 and recomputed until *D(j)* has not change.

B. *Fuzzy C-Means (FCM) algorithm*

FCM is a clustering technique which allows one piece of data which belongs to two or more clusters with different membership function between 0 and 1. This method developed by Dunn [11] and improved by Bezdek [12]. The steps of the Fuzzy C-Means algorithm are given below [7].

1) Choose *c* initial centroids, *c* is the number of cluster.
2) The membership matrix (*U*) is randomly initialized

$$U_{ij} = 1 \Big/ \left(\sum_{k=1}^{c} \left(\frac{d_{ij}}{d_{kj}} \right)^{\frac{2}{(m-1)}} \right) \quad (3)$$

Where d_{ij} is the Euclidian distance between i_{th}, centroid (c_i) and j_{th} data point, *m* is a weighting exponent, and u_{ij} is between 0 and 1.

3) Calculate centroids (c_i)

$$C_i = \left(\sum_{i=1}^{n} U_{ij}^{\ m} x_i \right) \Big/ \left(\sum_{j=1}^{n} U_{ij}^{\ m} \right) \quad (4)$$

4) Compute dissimilarity between centroids and data points. Stop if its improvement over previous iteration is below a threshold

$$J(U, c_1, c_2, \ldots c_c) = \sum_{i=1}^{c} J_i = \sum_{i=1}^{c} \sum_{j=1}^{n} U_{ij}^{\ m} \left\| c_i - x_j \right\|^2 \quad (5)$$

5) Compute a new *U* using Equation 3. Go to Step 3.

III. EVALUATION OF CLUSTERING

Three indices are used for evaluating the efficiency of data clustering. The first index was proposed by Halkidi et al. [13], they reported that SD validity index proposed an optimal number of clusters. The second method, Davies-Bouldin (DB) index [14] is well-known for cluster validity. And the last index is PBM-Index, the new validity index proposed by Pakhiraa [15]. In this paper, three indices used to evaluate the optimal number of clusters.

IV. RESEARCH METHODOLOGY

A. *Research Design*

The framework for this study includes three steps; it is depicted in figure 1.

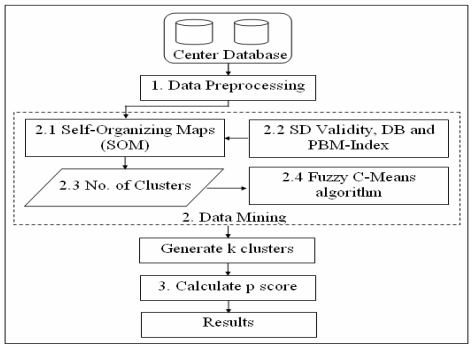

Figure 1. System Framework for the study

1) *Data Preprocessing*: We selected transaction data from ATSC including Center Profile and Activity Profile from tables in database were retrieved from Sending Activity Table, Committee Meeting Table and Sending Report Tables. In order to get the complete data set, incomplete data, noise and duplicate observations were discarded.

2) *Data Mining*: In this phase, two data mining techniques: SOM and Fuzzy C-Means algorithms used to cluster ATSC data.

Step 1: SOM is used to group data into 2-10 groups and then SD validity index, DB and PBM-Index were applied to find the optimal number of clusters which is the output of this phase. The lower index value reveals the better power of clustering for SD validity and DB index. On the order hand, the bigger value of PBM-Index is the better performance of cluster.

Step 2: Fuzzy C-Means algorithm is used for clustering ATSC data. The number of cluster or k value is derived from step 1. In this step ATSC data are segmented based on their work performances.

3) *Calculate p score*: After clustering have finished, p score in each group is calculated according to six attributes of project management which include (1) number of trainings (*Activity*), (2) number of participants in each training (*Target*), (3) the different between actual and planning technology transferred projects (*PE*), (4) the different between actual and expected participants (*TE*), (5) number of committee meetings (*Meeting*) and (6) number of submitted report (*Report*). The

real value of each attribute is adjusted in level ranged from 1 to 5. The p score of group is calculated from the sum of the average value of each attribute in that group, it was defined as

p score = sum score of (Activity + Target + PE + TE + Meeting + Report) (6)

From Table III, Cluster 1 includes the mean score of *Activity*, *Target*, *PE*, *TE*, *Meeting* and *Report* equal to 2.14, 2.06, 3.02, 3.02, 2.00 and 3.00 respectively. Thus, p score is 15.24 (2.14+2.06+3.02+3.02+2.00+3.00 = 15.24).

To rank ATSC, their performances are divided in 4 levels and the total p score is 30 points.

1) High: p score is ranged from 24 to 30 points.
2) Above average: p score is ranged from 18 to 23 points.
3) Average: p score is ranged from 15 to 17 points.
4) Low: p score is less than 15 points.

V. Experiment and Results

A. Experiment data

In this study, 68,281 transactions (in year 2005) obtained from working data of ATSC in Thailand. Center Profile and Activity Profile are the components of data set. Center Profile consists of general data of ATSC, such as Sub district ID, District ID, Province ID, Zone and other. Activity Profile is work practices of ATSC in each month. Clustering attributes in Activity Profile including

1) Technology Transfer Activity (*Activity*) is the numbers of technology transferred activity are organized in one ATSC. They are divided in 5 groups.

G1: No activity G2: 1 activity G3: 2 activities
G4: 3 activities G5: More than 3 activities

2) Agriculturist Target (*Target*) is the number of participants attending at each training. It is divided in 5 groups.

G1: No person G2: 1-50 persons G3:51-100 persons
G4:101-150 persons G5: More than 151 persons

3) Project-Expected (*PE*) is the different between actual technology transferred projects and planning. They are divided in 5 groups.

G1: Less than -1 G2: -1 G3: 0
G4: 1 G5: More than 1

4) Target-Expected (*TE*) is the different between actual and expected participants attending in each training. They are divided in 5 groups.

G1: Less than -50 G2: -50 to -1 G3: 0
G4: 1 to 50 G5: More than 50

5) Committee meeting (*Meeting*) is the meeting provided at ATSC in one month. They are divided in 5 groups.

G1: No meeting G2: 1 times G3: 2 times
G4: 3 times G5: More than 3 times

6) Report submission (*Report*) is the total number of reports sends to the head quarters by the web site. It is divided in 5 groups.

G1: No report G2: 1-5 reports G3: 6-10 reports
G4:11-15 reports G5: 16-20 reports

B. Results

Table I. depicts the results of clustering ranging from 2 to 10 clustered by using SOM algorithm. At the number of cluster equals 6 has the minimal value of SD validity and DB index. In part of the PBM-Index has the maximum value in clusters numbers equal 9. Thus, we choose cluster numbers equal 6 for the next step because two indices that give the same results.

TABLE I
CLUSTERING BY SOM ALGORITHM USING DIFFERENT INDEX FOR MEASUREMEN

No. of clusters	Validity Index		
	SD	DB	PBM
2	1.893	1.384	1.651
3	1.683	0.844	20.637
4	1.808	0.689	2.373
5	1.791	0.678	0.067
6	**1.677**	**0.622**	0.670
7	2.220	0.706	0.213
8	2.144	0.646	0.927
9	2.646	0.662	**33.633**
10	2.641	0.661	0.004

This phase, Fuzzy C-Means algorithm is applied for ATSC data segmentation in 6 clusters. Results are depicted in Table II. Characteristics of each cluster are as follows:

Cluster 1: It is the smallest cluster (10.77%). Technology transfer and Committee meeting in this cluster are about 1 activity and 1 time respectively. The number of participants in training is about 1-50 persons. Report submission is between 6-10 reports per month. P score is 15.24 which is average level. In order to improve the performances, ATSC in this cluster should increase numbers of activities, participants and meetings.

Cluster 2: It is the second largest cluster (19.05%) and has the smallest p score, 12.21 which is the low level. This group has neither Technology transfer and nor participants in training. Committee meeting is 1 time per month. To improve their performances, they should increase numbers of technology transfers, participants and meetings in each month.

Cluster 3: This cluster contains 10,407 transactions (15.24%), Technology transfer in this cluster is about 1-2 activities. The number of participants in training is about 1-150 persons. Committee meeting is 1 time per month. Report submission is between 1-5 reports per month. P score is 13.87 which is low level. In order to improve the performances, ATSC in this cluster should increase numbers of all attributes.

Cluster 4: It is the largest cluster (22.64%). Technology transfer is about 1 activity. The number of participants in each training is 1-50 persons. Committee meeting is 1 time per month. Report submission is 11-15 reports. P score is 16.28 which is average level. In order to improve the performances, ATSC should increase the numbers of training, participants and meetings in each month.

Cluster 5: This group has the maximum p score, 19.26 which is in above average level. Technology transfer activity is about 1-3 activities or more. The participants in training is more than 51 persons. Committee meeting is 1 time per month. Report submission is 11-15 reports. In order to improve their

performances, ATSC should increase committee meeting. It has 11,022 transactions (16.14%).

Cluster 6: It is the third largest cluster (16.22%). This group has Technology transfers and participants in training for this month about 1-2 activities and 1-100 persons respectively. Committee meeting is 1 time per month. This group has the maximum number of report submission, 16-20 reports. P score is 16.87 which is average level. To improve their performances, they should increase all attributes except number of report submission.

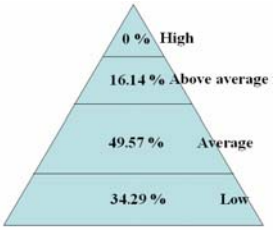

Figure 2. Ranking ATSC according to their practice work scores (p score).

VI. CONCLUSION

This study introduces a new method in segmenting ATSC performances. Clustering and ranking data set are two key steps in this method. Using SOM algorithm and three measurement indices, SD validity, DB and PBM, results show that data set should be segmented in six clusters. Then ATSC data set is clustered by using Fuzzy C-Means algorithm. The characteristics of majority ATSC include the number of technology transfers are about 1-2 activities and 1-50 participants per month. The different between number of proposed and actual projects is zero. In the same way, the different between number of proposed and actual participants is zero. Majority committee meeting is one time per month. Lastly, the number of report submission is about 1-20 reports.

This study suggests the project measurement by using performance scores (p score) to segment ATSC management. The majority of the centers are in average and low levels, whereas some are in above average and no center is in high level. When applying data clustering and p score ranking, the administrator can evaluate ATSC operations by comparing with other centers in the same or different clusters. This method will provide advantages for the manager to increase the productivity and services in their Centers by accentuating on the attributes which have low p score.

***Abstract*- We designed and implemented a robot capable of mopping smooth floor. The robot mechanism consists of two main parts: the motor driving part and the cloth cleaning part. The driving part has two rear wheels combining with a mop-head wheel in the front with cloth for mopping rolled around it. The cloth cleaning part has a brush mechanism within the cleaning chamber to remove dirt from the cloth rolled into it. We designed the navigation algorithm using the behavior-based structure to cover a working area as much as possible without wetting the floor too much. The effectiveness of the algorithm was tested on simulation and a real robot.**

I. INTRODUCTION

Thai households usually have no floor-carpet due to hot and humid weather. Therefore, the most common method to clean a floor is to mop with a damp cloth. Therefore, instead of vacuum cleaning, we designed a floor mopping robot to clean a smooth floor. The robot imitates the mopping action on the floor by using a cloth to clean the floor combining with a cloth cleaning mechanism. We proposed a navigation algorithm that is suitable for mopping in that the robot should be efficient but not wetting the floor too much. With this bottom line, the robot has to cover as large area as possible while minimizing repeatedly mops the same area.

II. RELATED WORK

Yong-Joo and Yoshio Watanabe[1] implemented a vacuum robot cleaning in households. Their design was based on the idea that good cleaning robots must have small size and light weighting order to use a small amount of energy for cleaning large areas and save time. It defined navigation algorithms for moving to be three patterns as 1.random, 2.zigzagging, 3.rectangular as shown in Figure 1.

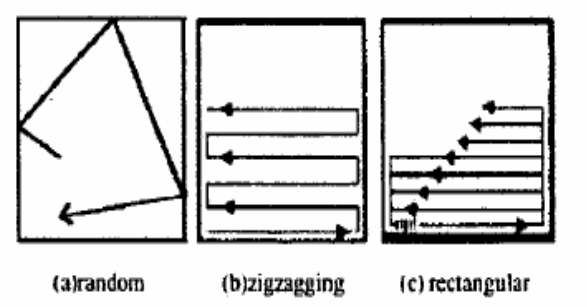

Figure 1. The navigation way

We utilized the idea of navigation algorithm from this research and used as a tested with our robot

Joon, Yoon and Jin [2] proposed a navigation algorithm for a floor-cleaning robot by using a triangular cell map. The experiments were made to compare it with the rectangular cell map to the cell map at to be triangular patterns. It can move in twenty directions around itself. While the rectangular pattern will move in eight directions. The navigation method used for both patterns are.

First: To follow side walls continuously until it moves around the room and gathers information by using templates with seven patterns.

Second: To search the uncleaned areas by visiting the closet unexplored area.

III. ROBOT HARDWARE

A. Cleaning system for the robot

The main function of the cleaning part is to wash cloth that is used for cleaning floor. Figure 2. shows the structure of the cleaning mechanism. It includes a tank for containing clean water. Inside the cleaning mechanism, there are rollers to rotate the cloth used mopping the floor and to take a cloth to a tank for cleaning a cloth. Which the system of rollers will have one roller at cleaning a cloth.

When: "1" is the knob of cloth.

"2" is the cleaning roller.

"3" is the rollers for feeding the cloth.

"4" is the outlet for draining.

"5" is the inlet for filling water.

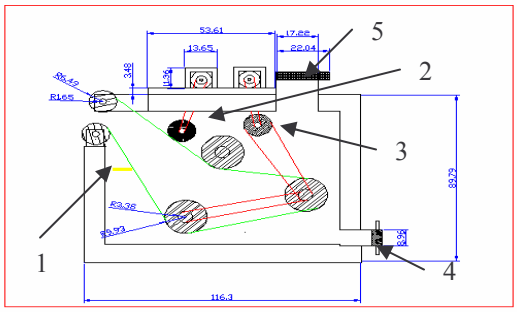

Figure 2. The cleaning mechanism

The operation of the cleaning system is as follows. Motors which are attached to the front rollers will rotate a cleaning cloth and rub it with the floor. After that, the cloth will be fed into the rollers inside a tank for cleaning.

In that moment, the rollers will pull the other part of the cloth out to clean again. The inner of the cleaning tank is filled with clean water and bristled brushes. The brushes is continuously rolled in order to whisk dirt out of the cloth while the clean water inside a tank will help dispel dirt out of the cloth. (This is similar to operation in a washing machine.) In the next step, when a cloth is readily clean, it will continually move out following the rotation of the rollers, while there is a squeezing knob that removes excessive water from the cloth and makes it ready to be used again.

B. The structure of the robot

The robot will move into many areas depending on the navigation program using the occupancy grip method.

The driving mechanism includes two wheels and two motors controlled by a microcontroller. We utilized PID controllers to control motors on the wheels. It controls both wheels that make same speed of the both wheels. Which controller will receive values from encoders on the both wheels of the robot and it send into the both wheels. It has one roller to rotate cloth into the cleaning mechanism. It also has two rollers to adjust cloth tightness. Which it want a face cloth to touch the floor for to increase the efficiency of mopping.

The sensor system includes infared distance measuring sensors and front bumping sensors. When the sensors detect obstacles, it will invoke a program to avoid the obstacles. The safe avoiding distance was calculated depended on the distance measuring from the infared sensors and the front bumper sensors.

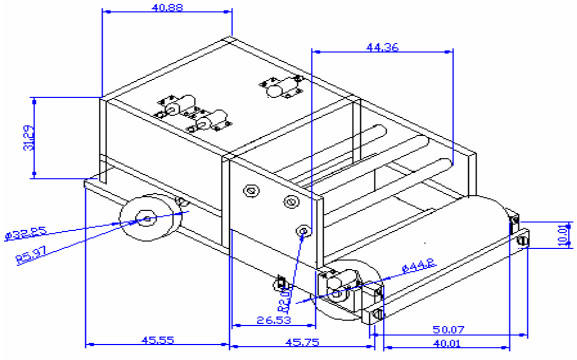

Figure 3. The complete structure of the robot

Figure 3, 4 shows the drawing and the construction of the real robot. It includes with the moving system and the cleaning system.

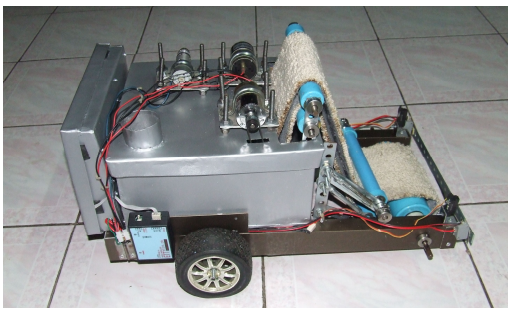

Figure 4. The floor-mopping robot

IV. NAVIGATION ALGORITHM

Behavior-based [4] approach is utilized to control the robot in a working area. We designed the control behaviors as follows .

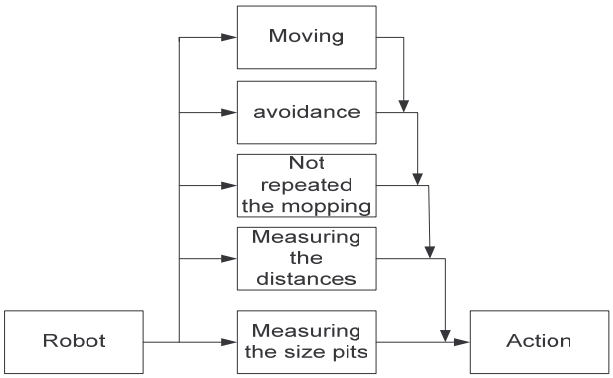

Figure 5. Behavior-base for the mopping robot

- *Moving* is the behavior for the moving of the robot from one place to another. By moving around, the robot build map according to the data from its sensors. It records the position of detect obstacles and the places that already visited and use that information to decide the place to go next. When there are many uncleaned areas to visit, it random the place to go based on four directions: left, right, up, down.
- *Avoidance* is the behavior to avoid obstacles such as wall, bed, and etc. It uses sensors to detect obstacles and keeps data into the map model.
- *Not repeated the mopping* is the behavior to avoid going to the same places that already been visited.
- *Measuring the size pits* is the behavior to search for free spaces in the map model (free space is still not keep into map model). The robot will try to go to the largest space that has not been visited.

  We calculate the largest free space from the current map by using the Component Labeling [3] that is four components. We will label the value at to be zero to put in Array. Therefore, we compare the space size and prepare a sequence by large space to equal 1 at spaces small than

first to equal 2 and decreasing a sequence. It use for to calculate to find the moving way.

- *Measuring the distances* is the behavior to measure for to find the closet free space that has not been visited by referring to the map model. The robot will try to go to the closet space that has least repeated visit. The way is to distribute out to four directions (four zones include Left, Right, Up, Down) as Figure 6. by to keep in such the value of distances by keeping values in map model continuously until to meet zero and ten values and to calculate best distance into its zone. Which will take best distance in four zones to calculate the best distance into this four zone . Formula used to find the distances as equation (1) is.

$$Distance_N^Z = \sum_{begin}^{End} value\ in\ Map\ Model \qquad (1)$$

When: N is the number of the line for to distribute into four directions.

Z is the number of the line in each zones.

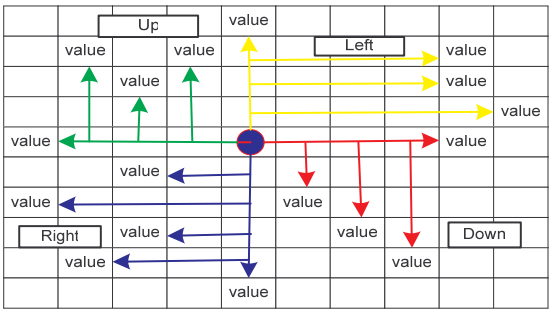

Figure 6. To show the way for finding distance in map model

To calculate for to find the best distance

To find the best distance for moving into the not cleaning area at the case is the center among the ready mopping area to find as equation (2) is.

$$Scores_n = best\ distances_n + best\ spaces_n \qquad (2)$$

When: n is the number of zone in four zones

When we obtain the ready value of four zones and to find best distances for to control the robot to move the target.

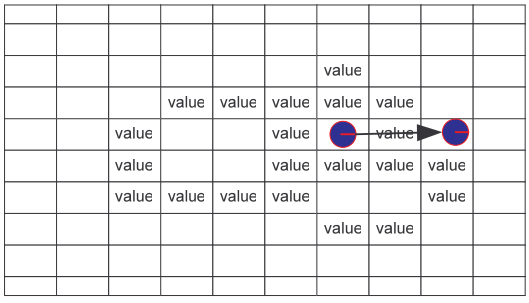

Figure 7. The case of robot searches a exit.

V. Simulation Results

In Beginning the robot will move randomly inside the map. The beginning value of the map will be all zero.

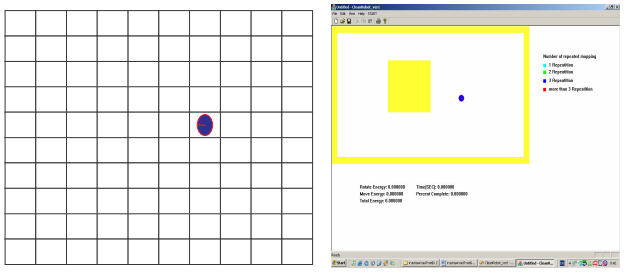

Figure 8. Show to begin simulation and map model

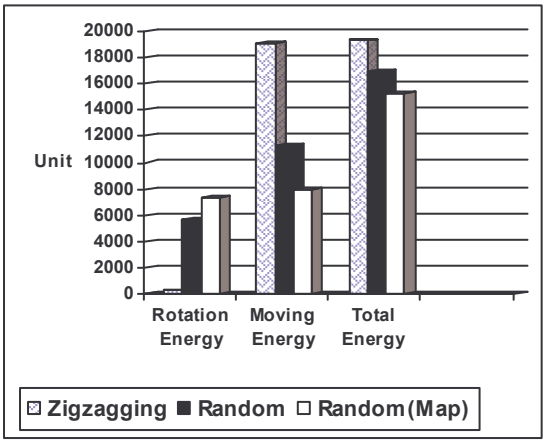
In simulation, we measured the efficiency of the robot which includes the rotation energy as the indication of energy in the rotation of the robot, moving energy as the indication of energy in the moving of the robot, total energy is to sum between rotate energy and moving energy. All energy is "Unit" for energy.

The indication of time in cleaning as time has that unit is second, The indication of cover area at cleaning as percent complete has that unit is percent (%).

Besides, we still have the indication of repeating number to divide four color that include sky-blue as one repeating , green as two repeating, blue as more than two repeating.

This experiment will made at 120 sec. By we divide two experiment that have obstructs and not obstructs. Such experiment include zigzagging, random, random (map) by moving so that.

1. Zigzagging will move from left to right and button to below .
2. Random will move not sure directions to depend on to rand for to select directions
3. Random has map model that will move to like normal random but it will add map model for using the navigation and not repeating.



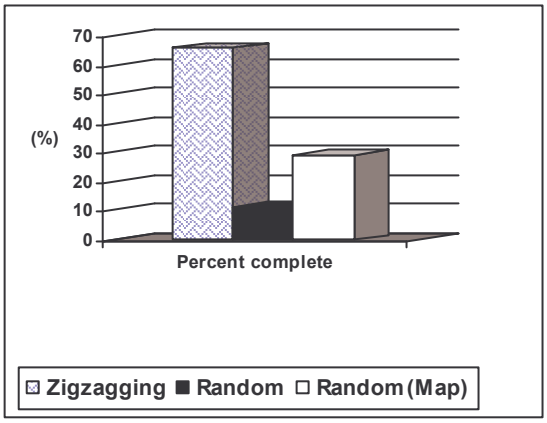


Figure 9. The energy and complete percent having no obstacles

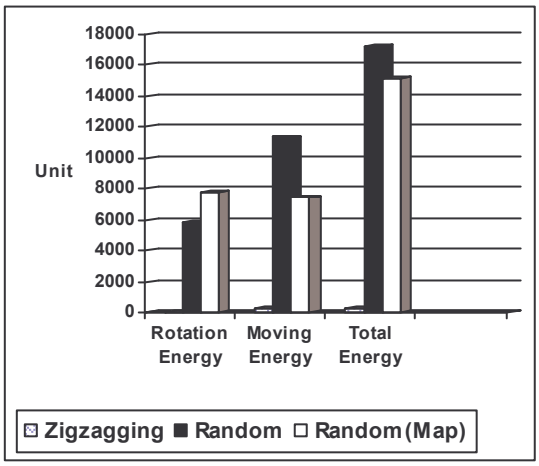

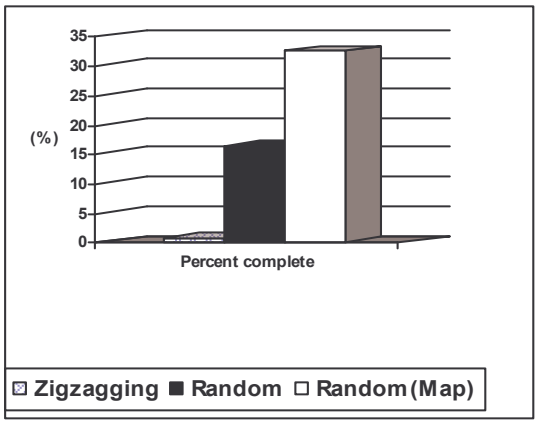

Fig ure10. The energy and complete percent having obstacles

VI. Real Results

In experimentation, we define the area to test the Automatic Floor-Mopping Robot. By we define as the square room and we can define inside room to have the number, position and size obstructs to want. From experimentation, we appear that in case having a lot of obstructs will use the many energies, many mopping numbers and in case having little obstructs will use the little energies, many mopping numbers. Again factory is to put the position obstructs and the size obstructs. It still has other factory to effect with energies of the robot such as sundry error to happen the robot. The mopping experimentation appears that sufficiency in cleaning. It will goodly clean the floor. It depend the dirty that adhere the floor. It adheres many or little on floor. It have many or little for the number of dirty.

VII. Conclusion

We implemented a floor-mopping robot. Its effectiveness was measured using three navigation algorithms: zigzagging, random ,random (map). We discovered that when there were not much obstacles the energy of zigzagging use the most energy but the completeness of the area is best. The total energy of the random (map) algorithm uses little energy, while the percent completeness of random (map) was less than zigzagging but it is more than random.

In the area is much obstacles the total energy of random (map) use the energy less than the random and the completeness of the area is best. The total energy of the zigzagging algorithm uses very little energy and completion because the robot detained much obstacles.

We conclude from three pattern that zigzagging appropriate with the area having no obstacles and the random (map) appropriate with the area having obstacles

In real experimentation, we appear that clean the room satisfactorily. It can avoid obstacles fairly.

Abstract

Today the World Wide Web has become widely accepted as the world's largest information resource. These information are generally available for users who have accessible Internet connection. However, the problem known as digital divide still exists among people who live in rural areas, especially of developing countries. To alleviate this problem, we have developed a search engine tool called Sansarn Offline with the purpose of managing, archiving and retrieving contents obtained from the Internet. Sansarn Offline is designed to accommodate two main tasks: content administration and content retrieval. For the first task, content administrator will use the tool to collect, manage and index Web pages obtained from the Internet. These contents are then organized into some predefined categories and recorded into some removable media such as CD-ROMs and DVDs. The second task involves user entering query through the interface and the tool looking up from the index and returning search results to the user. Since the contents and their indexes are stored on the removable media, the retrieval process can be done without the Internet connection. Another advantage is that the tool could yield search results which are more focused than those from regular search engines because the Web contents are selected and filtered by the administrator to match the real information need of the users.

1 Introduction

Due to the enormous growth of the Web contents available online, the Internet is now considered as the world's largest information and knowledge resource. Internet usage and applications are extremely varied and could range from e-mailing to online shopping. One of yet another important applications is to use the Internet as a public library to search for information and knowledge. Some of the interesting projects include, for example, Wikipedia [8] and Google Book Search's Library Project [6]. Wikipedia is a free well-known online encyclopedia. The outstanding feature of Wikipedia is the use of collaborative concept in which each user is allowed to edit and share the definitions and contents of the posted articles. Currently there are over *1,600,000* articles available in English and many in other languages. Google's Library Project has collaborated with many universities in order to scan and export contents of many books into digitized format. Users are then able to search and retrieve the book contents which match their interests. Besides these examples, there are many other Web sites which provide great information and knowledge and are publicly available.

These information and knowledge are however only accessible by users who could connnect to the Internet. Today, the problem known as *digital divide* still exists among people who live in rural or remote areas, especially of developing countries. The digital divide problem can be generally described as the lack of computer equipments, network infrastructure, and knowledge in IT. Therefore, one of our main goals is to bridge this gap for the users who have difficulties in accessing the Internet and the Web. To accomplish this goal, we have developed a search engine tool called *Sansarn Offline* which could be used to manage, archive and retrieve contents obtained from the Internet.

The process of using Sansarn Offline consists of two main tasks: content administration and content retrieval. For the first task, content administrator will use the tool to collect Web pages from the Internet. The tool currently supports many different document

formats such as *html*, *pdf* and *txt*. We will extend the tool in the next version to support the collection of images and other types of multimedia contents. Once a Web page is retrieved, each word token appearing on the page will be extracted and indexed using the widely adopted *inverted file* technique [4]. All contents with the index are then organized into some predefined categories and recorded into some removable media such as CD-ROMs and DVDs. The second task involves user entering search query through the interface. The tool then looks up from the index and returning search results to the user. Since the contents and their indexes are stored on the removable media, the retrieval process can be done without the Internet connection. Therefore, this tool could alleviate the problem of inaccessible Web contents. Another advantage is that the tool could yield search results which are more focused than the ones obtained by using regular search engines. This is because the content administrator would select, filter and collect only high quality Web contents which match the users' information need.

Our second goal is to provide and distribute the tool to interested users without any licensing fee. Therefore, our project will be based on the open-source software concept. With the thorough survey of the open-source Information Retrieval (IR) libraries and tools, we found *Lucene* to be a suitable choice for implementing our IR platform. *Lucene* is one of the most widely used IR library currently maintained under the Apache project [7]. Lucene provides the core indexing and searching functions which are very efficient and scalable [1]. The key success to the high scalability is the intelligent algorithm in managing the inverted index files between the memory and the secondary storage. The users may set the number of index segments and their sizes according to the system specification in order to optimize the indexing and searching performance. Lucene library, however, only comes with the support of English language. To extend the library to support other languages, developers must add language-specific analysis package into the library. Integrating and extending Lucene library is very simple and easy, since its creator has designed the framework via the object-oriented programming concept of Java [2]. This object-oriented feature is another reason that makes Lucene a very attractive choice for implementing our platform.

To make Sansarn Offline support both English and Thai texts, we have developed a Thai-language analysis package, *ThaiAnalyzer*, which could be integrated seamlessly within the Lucene framework. In addition ThaiAnalyzer, our tool includes two other functions which support the content administrator and general users. We have designed our the interface to be user-friendly so that users with little or no programming skill could use the tool with ease.

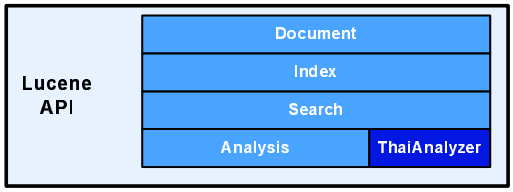

Figure 1. Lucene layer with ThaiAnalyzer package.

To demonstrate the usage, we will use Sansarn Offline tool to collect and index some useful Web pages and then distribute them among high schools in rural areas of Thailand where Internet connection is slow or not available. Students can search for useful information on CD-ROMs as if they are connected to the Internet. Our first prototype includes contents related to subjects taught among high school classes in Thailand.

The remainder of this paper is organized as follows. In next section, we give some details on Lucene library and the implementation of ThaiAnalyzer package. Section 3 gives the discussion on the system design and architecture of Sansarn Offline. Section 4 gives the conclusion.

2 Lucene Library with ThaiAnalyzer Package

Lucene was designed and implemented based on the object-oriented programming framework of Java. Figure 1 illustrates the *Lucene* API which is organized into the following four packages.

- *Document*: In Lucene, a text is organized as a document which represents a collection of fields. Before a text document could be indexed, it must be created by constructing a new instance of *Document* class. The seach results are also returned in the form of *Documents*.

- *Index*: Index contains many different classes responsible for indexing process. *IndexWriter* is the main class whose task is to create a new index and add documents into an existing index.

- *Search*: Search contains classes related to search operations. *IndexSearcher* is the main class whose task is to search within the given index directory for matching documents.

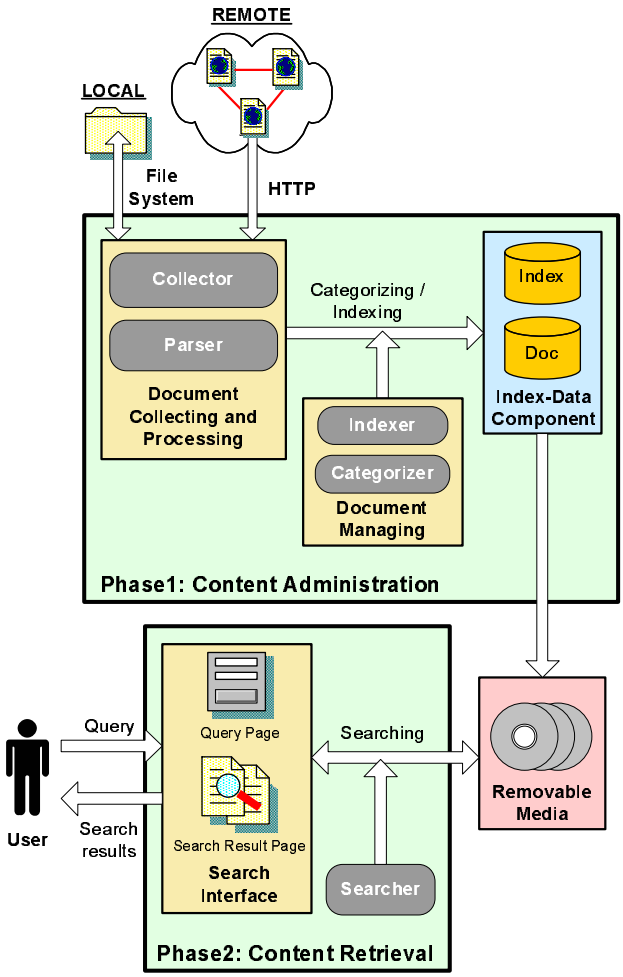

Figure 2. Sansarn Offline: System functionalities.

- *Analysis*: Analysis contains classes for performing the text processing. Different *Analyzer* classes are provided for various specific tasks such as stopword removal and stemming which are suitable only for English language. To make the analysis applicable to Thai language, we developed *Thai-Analyzer* package whose basic task is to tokenize Thai texts into a set of words [3].

3 Sansarn Offline: System Architectural Design

Figure 2 illustrates the overall architecture of *Sansarn Offline*. The system consists of two functions: *content administration* and *content retrieval*. For the first function, there are four important modules which support the content administration function.

- *Collector*: To provide flexibility, the *Collector* module contains various classes for collecting documents from either remote servers or local file system. For remote documents, i.e., Web pages, the collector functions exactly as a Web crawler.
- *Parser*: This module contains classes for removing HTML tags or pre-specified XML tags.
- *Indexer*: This module contains classes which perform indexing functions. Indexer package contain higher-level classes which make use of the *Index* package from Lucene library.
- *Categorizer*: This module contains classes which perform automatic categorization of collected contents into predefined subjects or categories. This module will be implemented and added into the tool in the next version.

The outputs from the first phase are data contents with the index which are then recorded into some removable media such as CD-ROMs or DVDs. The second *content retrieval* function consists of two modules which support the retrieval of contents for the users.

- *Searcher*: This module contains classes which perform searching functions. *Searcher* contain higher-level classes which make use of the *Search* package from Lucene library.
- *Search Interface*: This module provides a GUI-based interface which connects to the searcher module in order to pass the query from the users and to return the search results back to the users.

Sansarn Offline is implemented in Java by using Eclipse tool [5]. Using Java offers several advantages including platform-independent and open-source development. Our first application of Sansarn Offline is to collect useful and related Web pages from the Internet which are related to the class materials taught in high schools. The contents and the tool could enhance the teaching and learning outside classes. The CD-ROMs containing the contents, indexes and tool will be distributed to many high schools in Thailand. This project is a part of a main project whose goal is to use IT to develop schools in rural areas of Thailand.

We have collected the contents related to many subjects such as astronomy, physics, biology and chemistry. These contents were obtained from many educational Web sites. Figure 3 shows parts of table of contents which we have collected. Users are allowed to browse according to the organized subjects and click on

Figure 3. Example: Table of contents.

the links to read the full Web page. Besides browsing, another retrieval mode is the keyword search. Users can enter query of one or more keywords to search for Web pages. The returned search results show the snippets with the highlighted terms similar to typical search engines. User can click on the link to view the full page content. Since the retrieval process is done on the controlled Web pages which are stored on the CD-ROM, the results are more focused than using general search engines. Another advantage is that the response time depends only on the I/O activity of the computer which is generally more reliable than the network. Our tool also allows the users to set some configuration such as the color used to highlight the terms in the results and number of results shown per page.

4 Conclusions

We proposed a search engine tool called *Sansarn Offline* with the purpose of managing, archiving and retrieving contents obtained from the Internet. Sansarn Offline is a free open-source software which has been developed by using *Lucene* IR (Information Retrieval) library. However, Lucene doesn't support retrieval of Thai texts. Therefore, we have developed a Thai-language analysis package called *ThaiAnalyzer* whose task is to segment Thai written texts into word tokens. Sansarn Offline consists of two main functions which directly support two user groups: content administration and content retrieval. The first function is used by content administrator whose task is to collect, manage and index Web pages obtained from the Internet. The second function is carried out by general users who need the information. Sansarn Offline allows searching for information stored on the removable media, therefore the retrieval process could be done offline or without connection to the Internet. As part of our project, we have planned to distribute the contents and the program to some high schools in rural area where Internet connection is not available. Future works of this project include the automatic categorization of contents and other intelligent search features such as search result clustering which could organize and represent search results into meaningful concepts. For example, search results returned from the query "gravity" could be organized into clusters such as "definition", "experiments", "history" and "Isaac Newton".

***Abstract*- This paper proposes a combination of simulated data adaptation and piecewise linear transformation (PLT) for robust continuous speech recognition. The original PLT selects an appropriate acoustic model using tree-structured HMMs and the acoustic model is adapted by the input speech in an unsupervised scheme. This adaptation can improve the acoustic model if the input speech is long enough and is correctly transcribed in the adaptation process. Indeed, an incorrect transcription can drastically degrade the acoustic model. Our proposed method increases the size of adaptation data by adding noise portions from the input speech to a set of pre-recorded clean speech, of which correct transcriptions are known. We investigate various configurations of the proposed method. Evaluations are performed with additive noisy continuous speech. The experimental results show that the proposed system reaches higher recognition rates than MLLR and PLT.**

I. INTRODUCTION

It is commonly known that a speech recognition system trained by speech in a clean or nearly clean environment cannot achieve good performance when working in noisy environment. Research on robust speech recognition is then necessary. Gales [1] has classified the techniques of robust speech recognition into 4 approaches: 1) robust feature approach, 2) clean speech estimation approach, 3) robust model approach, and 4) combination of three previous approaches. This paper focuses on the model-based approach, which has achieved good recognition results [1]. The model-based approach aims to create or to adapt the acoustic model in specific environments. Several techniques of model adaptation have been proposed such as maximum likelihood linear regression (MLLR) [2], maximum a posteriori (MAP) [3], parallel model combination (PMC) [4], and piecewise linear transformation (PLT) [5].

In this work, we are interested in the adaptation technique of piecewise linear transformation with model selection based tree-structured cluster (MSTC) [5, 6], proposed by Zhang, Sugimura and Furui [5]. This technique is based on unsupervised acoustic model adaptation using the incoming speech. It was proven to be efficient in both the recognition accuracy and computational cost. However, a problem of the PLT is that the acoustic model may not be well adapted if the incoming speech is very short. Moreover, in the unsupervised adaptation, a wrong transcription strongly degrades the adapted model. These 2 problems can be solved by a recently proposed technique called simulated-data adaptation [7]. Indeed, the simulated-data adaptation process aims to increase the data used in adaptation by adding the background noise extracted from the current input signal to existing clean speech. Since correct transcriptions of the clean speech are known, using the simulated-data is supervised adaptation.

This paper presents a new adaptation scheme which applies simulated-data adaptation to piecewise linear transformation (called S-PLT hereafter). S-PLT combines the strength of both techniques; PLT allows selecting a good initial acoustic model while simulated-data adaptation enlarges the size of the adaptation data. S-PLT uses the MLLR adaptation technique. The proposed method is compared with other model adaptation techniques.

The proposed system was evaluated in 3 groups of environments. The first group contained a clean environment and 9 types of noisy environments that have been trained in the system. The second group contained isolated-words. The third group contained continuous-speech. Noisy speech of second and third group were prepared by adding noise signals from an exhibition in Thailand (NAC 2005) to the clean speech taken from NECTEC-ATR Thai speech corpus [8] at various SNR (0, 10, 15 dB).

We will review the PLT in the next section. Section 3 reviews the simulated-data adaptation. Section 4 describes our proposed models. Section 5 describes the data used in these works and experimental results are reported in Section 6. Section 7 concludes this paper with future works

II. PIECEWISE LINEAR TRANSFORMATION (PLT)

The PLT method is composed of 2 main steps namely MSTC [5, 6] model selection and MLLR adaptation [2]. In the training step, a wide variety of noise data were collected and classified into noise clusters using hierarchical clustering. The root node includes all noises and all SNR conditions and each leaf node consists of only one noise at one SNR condition. Intermediate nodes in this tree contain similar noises from different environments and from different SNR. A noise-added speech HMM is constructed for each node. Using this tree structure, an unknown noise environment which is similar to combination of known environments should be handled by

non-leaf HMM. The resulting tree-structured HMM allows representing both known and some unknown noises. In the recognition phase, the noise-cluster HMM which is best fitted to the input speech was selected and adapted by the input speech itself using the MLLR method.

III. SIMULATED DATA ADAPTATION

A. *Noise portion extraction*

Simulated-data adaptation begins with identifying silence parts which are supposed to be background noise of the current input signal. We assume that there are short periods of silence at the beginning and the end of the input signal. A phone-based HMM is used to segment the input signal into speech and silence portions. In this work, we use 64 HMMs of Thai phonemes including a special phoneme of silence "sil", form a speech recognizer. Fig. 1 illustrates this HMM structure. Noise portions are the signal regions labeled with silence "sil".

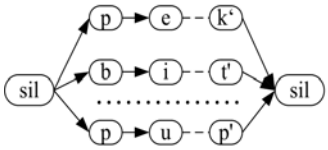

Figure 1 HMM architecture for noise extraction.

B. *Background- noise addition*

Given noise portions extracted from the input signal, several issues need to be considered in adding background noise to the pre-recorded clean speech. First we concatenate noise portions extracted from the input signal. There are two noise-only regions in the input signal, at the beginning and at the end of the signal as shown in Fig. 2. These noise portions are duplicated and concatenated so that the duration of noise signal is equal to the duration of clean-speech being added.

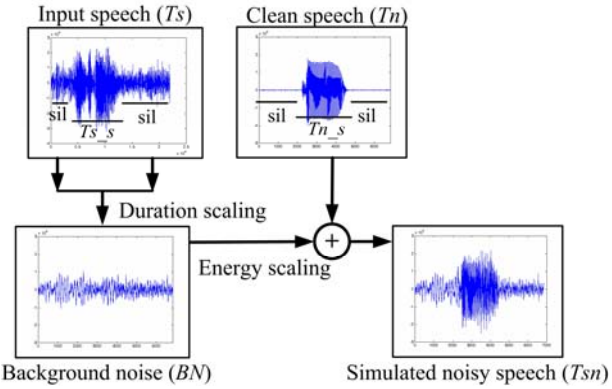

Figure 2 Background-noise addition.

Second, simulated speech for adaptation should have a similar SNR to the input speech. However, estimation of SNR is not trivial and remains unsolved. The simulated-data adaptation relies on a simple signal-energy scaling. Let "Train-S" be a set of pre-recorded clean speech, of which correct transcriptions are known. We denote by Tn and Ts the current input signal and a clean speech in the Train-S set. Tn_s and Ts_s is the speech portion of Tn and Ts and Tn_sil and Ts_sil is the silence portion of Tn and Ts. First, a scale_factor is calculated as follows:

$$EngS = sum(abs(Ts_s))/length(Ts_s) \quad (1)$$

$$EngC = sum(abs(Tn_s))/length(Tn_s) \quad (2)$$

$$scale_factor = EngC/EngS \quad (3)$$

where |T| denotes the energy of a signal T. EngS and EngC is respectively the energy averaged over all Ts_si and Tn_si extracted from Ts and Tn. Next, the background noise, BN, given by the noise-portion extraction step, is multiplied by the scale_factor and added to Tn, resulting in a simulated noisy-speech Tsn as shown in Equation (4). The signal Tsn is then included in the adaptation set.

$$Tsn = BN*scale_factor + Ts \quad (4)$$

C. *Adaptation-data preparation*

Adaptation data set is a key element in our robust speech recognition system. Two variations of the proposed method are considered. The first one uses only the pre-recorded clean speech with known transcription. This is called supervised adaptation. The second variation includes the input speech in the adaptation set with its label transcribed automatically. This second variation is called semi-supervised adaptation.

Beside these two variations, other important parameters including the selection of speakers and lexicon in the Train-S data are required to adjust. Basically, we selected speakers and words that can be correctly recognized by our clean speech model. Moreover, selected words should cover all phones presented in the system.

IV. COMBINED SIMULATED DATA ADAPTATION AND PLT

Combined simulated-data adaptation [7] and PLT [5], called S-PLT is shown in Fig. 3.

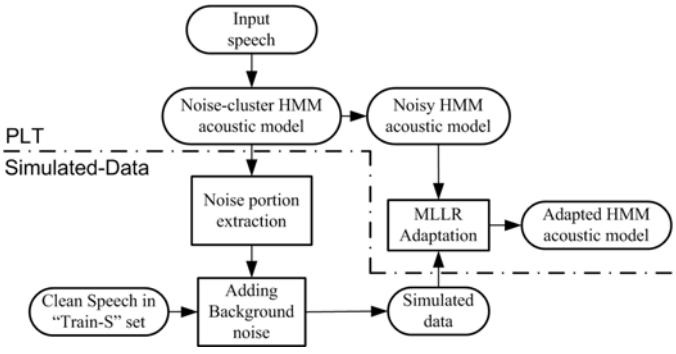

Figure 3 Combine simulated-data adaptation and PLT process (S-PLT) for HMM adaptation.

The basic idea is to adapt the model selected from the tree-structured cluster using the adaptation data prepared by the simulated-data process either in supervised or semi-supervised

mode. The adapted HMM is then used to recognize the incoming signal.

V. Experimental Setting

Our domain is continuous speech recognition using monophone-based HMMs representing 64 Thai phones. The aim of using context-independent phone model is the flexibility to add any word in the recognition lexicon. Each monophone HMM consists of 5 states and 16 Gaussian mixture per state. 12 MFCC, 1 log-energy, and their first and second derivatives are used as recognition features. The clean model is trained by phonetically-balanced utterances read by 32 speakers. The total number of training utterances is 32,000. In all experiments, clean-speech data are taken from the NECTEC-ATR corpus [8].

D. Noise data for training

Eight kinds of noise from JEIDA, including crowded street, machinery factory, railway station, large air-condition, trunk road, elevator, exhibition in a booth, and ordinary train, and one large-size car noise from NOISEX-92 are considered. All noises and the clean speech are preprocessed by resampling to 8 kHz. Noisy speech is prepared by adding the noise from JEIDA or NOISEX-92 to the clean speech of the NECTEC-ATR corpus at various SNRs (5, 10 and 15 dB).

E. Noise data for testing

Two test sets, "Test-1" and "Test-2", are used in evaluation. Test-1 contains 3,200 utterances from 640 words uttered by 5 male speakers. Test-2 contains 1,950 utterances from 390 sentences uttered by 5 male speakers.

An exhibition (NSTDA Annual Conference S&T in Thailand) recorded over four days in March 2005, are added to clean-speech utterances at three SNR levels: 0, 10 and 15 dB. This test set represents speech with different noise from the training set.

F. Simulated-data for adaptation (Train-S set)

In order to constitute the Train-S set for model adaptation, speakers and lexicon are selected from the NECTEC-ATR corpus. For speaker selection, we limited to male-speakers with clear speech and randomly selected speech signals of four speakers are used in the experiment, denoted as "MIX" speaker.

For word selection, the selected lexicon should cover all 64 phones presented in the system. According to these criteria, two sets of train-s are prepared. The first set (Train-S1) contains 22 words and the second set (Train-S2) contains 10 sentences, both are the minimum set of isolated-words and continuous speech that cover 64 phones used in the recognizer

VI. Experimental results

In this section we investigate various settings of S-PLT and compare them to other robust speech recognition techniques. Subsection A evaluates different settings of our system. Subsection B compares our proposed system to conventional methods.

A. Effects of type MLLR adaptation and type Train-S in simulated-data adaptation

In our experiments the acoustic model before adaptation can be either a clean-speech model or the model selected by the MSTC algorithm. For each model, we test adaptation in both supervised and semi-supervised modes. Semi-supervision means that the input speech is also included in the adaptation data. Table I defines four systems varying on the supervision made of adaptation and the initial acoustic model

Table I Definition of comparative systems

	Initial AM	
	Clean	MSTC
supervised	S-MLLR1	S-PLT1
Semi supervised	S-MLLR2	S-PLT2

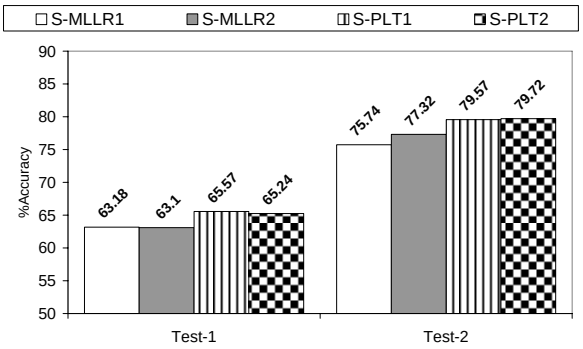

Figure 4 Recognition accuracies of S-MLLR and S-PLT evaluated by Test-1 and Test-2.

Fig. 4 shows the experimental results from various settings using the Train-S1 set in adaptation. According to these results, using the MSTC algorithm to initialize the acoustic model gives better accuracy than using the clean model. As expected, since the MSTC-selected model is closer to the real environment than the clean model and hence give the higher performance. For semi-supervised adaptation, results show that it rather suit for continuous speech (Test-2) than for isolated word (Test-1). This may be due to the fact that for the isolated word case, the signal is too short and no useful information can be automatically and reliably extracted. It is then better to rely only on assured transcription as in supervised adaptation. On the other hand, for continuous speech the signal is long enough to compensate the incertitude concerning the transcription thus make it useful for model adaptation.

Next, we investigate the use of continuous speech as adaptation data. For this propose, we ran the experiment on the Test-2 set with the Train-S2 adaptation data. Fig. 5 summarizes the results from this experiment. We can see that using the Train-S2 outperforms the use of Train-S1 in every case. This is due to the increasing in the size of the adaptation data. However, the computational time unavoidably increases as a drawback.

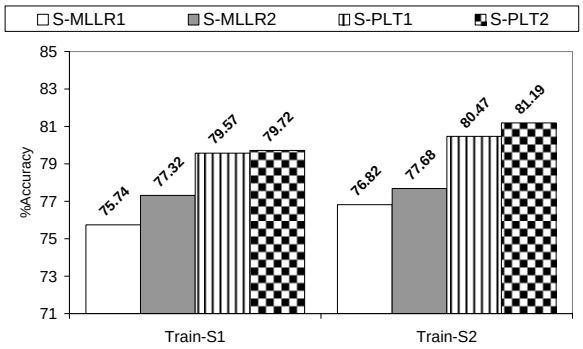

Figure 5 Recognition accuracies of S-MLLR and S-PLT with different Train-S evaluated by Test-1.

B. Comparison with conventional methods

In this subsection, several robust speech recognition techniques including ours are compared. The first one is a baseline system without any implementation for robust speech recognition. The second system, denoted as "MLLR", uses online acoustic-model adaptation based on the well-known MLLR approach. The third system, called "MSTC", uses model selection based on the tree-structured cluster model without any adaptation. The forth system called "PLT" uses the PLT method (see section III). The fifth and the sixth systems are S-MLLR2 and S-PLT2. The Train-S2 is used in adaptation.

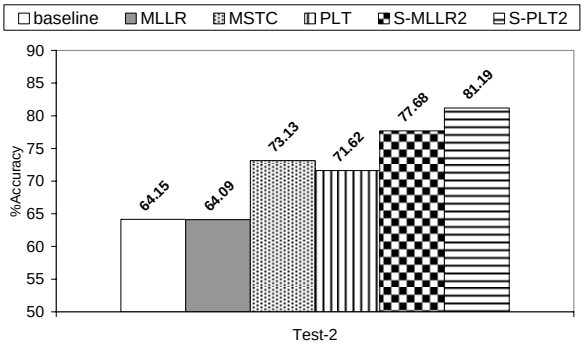

Figure 6 Comparison of baseline, MLLR, MSTC, PLT, S-MLLR2 and S-PLT2 systems evaluated by Test-2.

Fig. 6 shows comparative results. According to the results, it is obvious that our proposed methods, S-MLLR2 and S-PLT2, outperform other conventional methods. In the case of S-MLLR2 we gain approximately 14% improvement of recognition accuracies over the conventional MLLR model. S-PLT2 achieves approximately 10% improvement of recognition accuracies over the PLT-based method. Moreover, the PLT's accuracy is lower than that of the MSTC but both systems perform worse than the S-PLT2. We believe that the continuous speech signal is not long enough, so that purely unsupervised adaptation can always improve the initial acoustic model. This underlines the benefit of using clean speech with known transcription in simulated-data adaptation.

VII. CONCLUSIONS AND FUTURE WORK

This paper proposed combined simulated-data adaptation and PLT in acoustic-model adaptation. The approach solved limitations of the conventional unsupervised MLLR adaptation in the PLT method. The adaptation data were increased by adding a noise-signal extracted from the input signal to a pre-recorded set of clean speech. Since correct transcriptions of simulated-data are given, adaptation is more effective than using only the input speech with unknown transcription. Experiments showed that our technique achieved over 10% improvement of recognition accuracy comparing to the original PLT.

Future works include an evaluation of the proposed model by a larger set of speech from various real environments. Further improvement of noise extraction and noise addition in simulated-data adaptation will also be investigated.

***Abstract*-This paper presents naturalness improvement in Thai unit-selection text-to-speech synthesis (TTS) based on prosody modeling. Although several modeling approaches of prosodic parameters in Thai speech have been proposed, they have not been proven to provide a promising performance when practically assembling in a synthesizer. In this paper, two learning machines for phrase break and phoneme duration prediction are integrated in a Thai unit-selection TTS system. Evaluations focusing on the naturalness improvement are conducted both subjectively and automatically. The listening test gives 0.47 MOS improvement from the baseline system and the objective measures obviously show the better quality of the proposed system.**

I. INTRODUCTION

Text-to-speech synthesis (TTS) has been widely implemented in many kinds of applications. It is particularly important for people with disabilities. At present, there are some developed systems for Thai, which almost present in the way of unit-selection algorithm. There exist some TTS systems developed based on the demisyllable-unit concatenation algorithm with prosody modification. However, automatic controlling of prosodic parameters is still far from natural human sounds.

To improve the naturalness of synthetic speech in Thai, several components need to be considered, including word segmentation [9]-[11], sentence boundary detection [12], and grapheme-to-phoneme conversion [14]-[16]. Prosodic prediction often employs intelligent learning machines or statistical models trained by a large prosody-annotated speech corpus. Given the predicted parameters, modifying speech signals can be performed efficiently by Time Domain Pitch Synchronous OverLab-Add (TD-PSOLA) [4].

At present, Vaja [1], a Thai speech synthesizer developed by NECTEC in Thailand, is utilizing the unit-selection technique on a well-organized speech corpus named TSynC [6]. The current version, treated as baseline system in this paper, incorporated a simple rule-based phrase breaking model and had no prediction of phoneme duration. This paper presents the improvements by objective and subjective tests on a modified system, where in a machine-learning based phrase break detection and a linear-regression based duration model are incorporated. The next section will describe two Thai prosodic-parameter prediction algorithms, including phrase breaking and duration modeling. Section III presents experiments, and results. Conclusion and future works are given in Section IV.

II. PROSODY-MODIFIED THAI TTS SYSTEM

Recently, modeling of two prosodic parameters, phrasal pauses and phoneme durations for Thai, has been extensively researched [2, 3, 7, 8]. This section reviews proposed algorithms, which will be integrated in the baseline TTS system. Figure 1 shows an overall structure of our TTS system with the two additional modules for phrase breaking and phoneme duration prediction. An example of intermediated outputs is given beside.

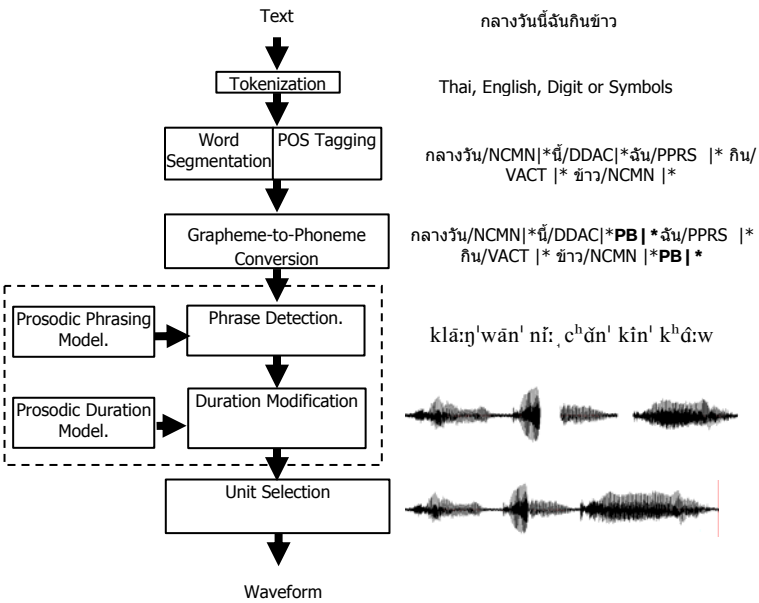

Figure 1. A structure of baseline Thai TTS system.

To predict prosodic parameters, a set of information (features) is extracted from an annotated speech corpus as shown in Table I. P and D denotes the task of phrase break and phoneme duration prediction.

TABLE I
FEATURES USED FOR PROSODY PREDICTION

Feature	Description	P	D
POS	Part-of-speech (POS) of four contextual words	✓	✓

Feature	Description	P	D
NSyl	The number of syllables between the previous phrase break and the current juncture	✓	
NWrd	The number of words between the previous phrase break and the current juncture	✓	
SylRatio	The ratio of *NSyl* and the total number of syllables in the previous phrase	✓	
WrdRatio	The ratio of *NWrd* and the total number of syllables in the previous phrase	✓	
Phone	Five phonemes including the current phoneme and four contextual phonemes		✓
PosWrd	Position in word (begin, mid, end)		✓
PosPhr	Position in phrase (begin, mid, end)		✓
Tone	Tone of the current syllable (five Thai tones)		✓

A. *Phrase break prediction*

In this section, we describe a practical approach for phrase detection. In literatures [7, 8], five candidates of the learning methods; for Thai POS sequence model, CART, RIPPER, SLIPPER and neural network, were used in prosodic phrase-break prediction. Experiments mostly showed that CART gave almost the highest performance. Since CART can be simply implemented and consumes a small processing time, this paper uses CART to predict phrase breaks.

Some features related to sentence boundaries proposed in [7, 8] are difficult to incorporate in the practical system due to unsolved problems of Thai sentence boundary detection. Not only an unreliable result, but also a high computational time is required by the current sentence breaking module. Therefore this paper ignores such features and proposes a new set of features independent of sentence boundaries as shown in Table I.

B. *Phoneme duration prediction*

Duration modeling for Thai speech synthesis is dominated by control factors (*Phone*, *PosWrd*, *PosPhr*, *Tone*), which depend on the structural design of Thai syllables, positional difference in phrase and syllable, and syllabic tones as shown in Table I.

Prediction is done by statistical linear regression based on the quantification theory as shown in the following equation.

$$\hat{y}_i = \bar{y} + \sum_f \sum_c x_{fc}\delta_{fc}(i) \quad i = 1,2,3,...,N \qquad (1)$$

where N represents the total number of data,

$\hat{y}_i$ represents the predicted phoneme duration of the i-th sample,

$\bar{y}$ represents the average duration of the phoneme,

x_{fc} represents the regression coefficient, and

$\delta_{fc}(i)$ represents the characteristic function [3] producing 0 or 1 corresponding to affected factors.

The predicted duration is exploited as the first criterion for speech unit selection in TTS. It serves later as a target value for waveform duration modification if the duration difference between the selected unit and the target value exceeds a threshold value. Duration modification is based on Time-Domain Pitch Synchronous OverLap-and-Add (TD-PSOLA) [4].

These trained models and wave-form modification technique are integrated into the baseline system resulting a new naturalness improved Vaja system.

III. EXPERIMENTS

Experiments are performed in two approaches, an objective and subjective test. Each test used different data sets and measurements as described in two following subsections. The last subsection shows experimental results.

A. *Experimental Data*

The TTS system uses a Thai speech corpus named TSynC [6], containing 2,644 paragraph, 15,716 phrase breaks, 5,200 utterances, 5,089 unique words and 30,096 tonal syllable patterns, varied on 89 Thai phonemes. Every paragraph was manually tagged with sentence-end markers, word and phrase breaks, and word POSs, by linguists. The data were divided into five subsets and performed cross-validation. Each of five cross-validation experiments utilized a training set of 2,115 paragraphs and 12,639 phrase breaks in average and a test set of the remaining data. Average results of those five sets are reported.

B. *Experimental Measurement*

Both objective (automatic) and subjective (listening) tests are performed to reflect the improvement of the system.

- *Objective evaluation of phrase breaking*

Missing or misplaced phrase breaks can distort the meaning of utterances, as well as the naturalness of synthetic speech. To measure the quality of phrase detection automatically, we compute

$$Precision = \frac{t_B}{t_B + f_B} \qquad (2)$$

$$Recall = \frac{t_B}{t_B + f_{\neg B}} \qquad (3)$$

$$F - measure = 2\frac{Precision\ Recall}{Precision + Recall} \qquad (4)$$

where t_B, f_B and $f_{\neg B}$ denote correct acceptance, false acceptance, and false rejection rates of phrase break prediction.

- *Objective evaluation of duration modeling*

Fluctuation of phoneme duration in a syllable conveys a different meaning of the whole word in an utterance. Differences between the predicted duration and the targeted duration observed from an actual human speech are shown as

an average duration error (in ms), which is calculated by the following equation.

$$\text{Average duration error} = \frac{\sum_{i=1}^{N} |D_{pi} - D_{ti}|}{N} \quad (5)$$

where D_{pi} is the predicted duration of the i-th phoneme,

D_{ti} is the targeted duration of the i-th phoneme,

N is the total number of phonemes in the test set.

- *Subjective evaluation*

A listening test using the MOS scale [5] is conducted. The values 1 to 5 in the MOS scale rank the quality of speech utterance from the worst to the best. Three test cases (S1, S2 and S3) were set up in an office room using 45 test utterances (3 cases * 15 sentences/case). The three cases are as follows.

- S1 contains 15 utterances of natural speech.
- S2 contains 15 utterances generated by the baseline TTS system.
- S3 contains 15 utterances generated by the prosody-modified TTS system.

The test is performed by prompting three versions of each of 15 sentences to a listener, starting by S1 followed by S2 and S3, which can be shuffled. The listener gives scores to each version based on the question "how natural is the utterance?" and steps to the next sentence.

The experiment is done by 20 subjects, who are NECTEC staffs aged between 22 – 38 years old (27.9 years in average). Seven of them are females and thirteen are males.

C. Experimental Result

According to the objective and subjective tests, results are presented as follows.

- *Objective Test*

This subsection shows results averaged from the five cross-validation data sets. Phrase detection in the several research works revealed that the accuracy was varied by the different features. In real situation, some features such as *POS*, *NSyl*, and *NWrd* are not precise since the previous modules; word segmentation, POS tagging, and grapheme-to-phoneme (G2P) conversion are not perfect.

TABLE II
RESULTS OF FOUR PHRASE BREAKING MODELS.

Model	Feature	Precision	Recall	F-measure
Baseline	*Rule based*	33.2	34.6	33.9
1	*POS*	77.8	65.9	71.4
2	*POS + NSyl*	74.1	70.2	72.1
3	*POS + NSyl + NWrd*	73.8	70.8	72.3
4	*POS + NSyl + NWrd + SylRatio + WrdRatio*	74.2	69.4	71.7

Table II compares four models of phrase breaking with different input features. All features are base on perfect word segmentation, POS tagging, and G2P conversion.

The results show that using *POS*, *NSyl* and *NWrd* achieves the best performance. Adding more features, e.g. in the 4th model, is noisy and hence lowers the overall accuracy.

Our word segmentation with POS tagging yields 66.6% accuracy, whereas our G2P module achieves 87.2% accuracy when the input text is perfectly segmented into words. We also compute F-measure of the phrase break prediction model when working with such imperfect word segmentation and G2P conversion. Results are illustrated in Figure 2. In the case of using actual word segmentation and G2P conversion (white pieces), which is the real situation, results show that using *POS* and *NSyl* gives the highest accuracy. Interestingly, no matter what perfect or imperfect G2P is used with the ideal word segmentation, only little changes of accuracy are obtained. The reason is that both still produce the similar number of syllables, which is one of a key feature in the phrase breaking module.

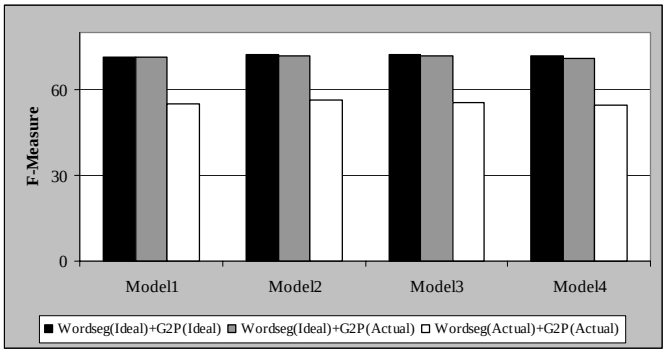

Figure 2. F-measure results of 4 models based on ideal and actual word segmentation and G2P modules.

The graph in Figure 2 obviously shows that the accuracy of phrase breaking can be significantly improved if a better word segmentation is obtained. Improving the word segmentation module can be done by a carefully treat of abbreviation, numbering, and special symbols in the input text.

In the same way, evaluations of duration modeling were also set up using five cross-validation training and test data sets. The average duration error achieves 21.4 ms and 22.9 ms given ideal and actual phrase breaks respectively. Comparing to the baseline TTS system where average duration errors are 24.9 and 25.5 ms for the ideal and actual phrase breaks, 3.5 and 2.6 ms error reductions are obtained. To express more detailed results, we count the number of phonemes, whose predicted durations lie in a $\pm t$ interval from their targeted durations. Figure 3 plots the relative counts with respect to the value of t.

We can observe that durations of over 80% of phoneme samples are well predicted, i.e. less than 20 ms average duration error. In Thai, the phoneme duration plays a critically important role on the vowel length. Short and long vowels in Thai carry different meanings and have been designed as separated units. Therefore, the system must be able to generate

at least the distinguishable durations of these two vowel groups. Hansakunbuntheung [3] showed that short and long vowels differ at approximately 50 ms in average. We then set a threshold to modify the phoneme duration by TD-PSOLA if the duration difference between the unit selected from TSynC and its targeted value exceeds 40 ms.

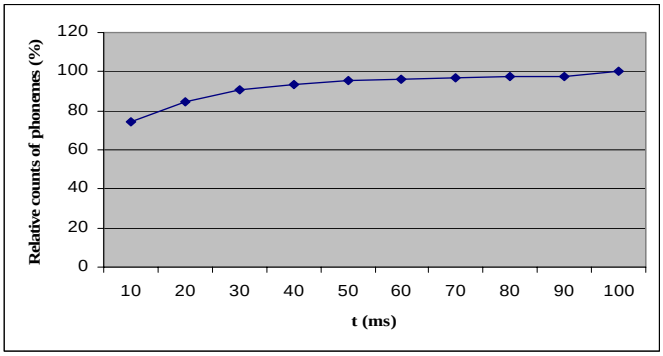

Figure 3. Relative counts of phonemes whose durations lie in $\pm t$ distance from their targeted values.

- *Subjective Test*

Table III reports MOS results of the listening test described in Section II.

TABLE III
MOS OF THREE TEST CASES

Case	Source	Naturalness score
S1	Natural speech	4.85
S2	Synthetic speech from the baseline system	2.14
S3	Synthetic speech from the prosody-modified system	2.56

The results show that a 0.42 improvement of MOS is obtained by the prosody-modified TTS system comparing to the baseline system. A major reason of the improvement comes from better phoneme durations predicted by the intelligent duration model. It is noted that some subjects gave a lower score to some prosody-modified utterances, which contain unnatural false-breaks. Such false-breaks happen more in the proposed phrase-break detector, where breaks are determined at every word juncture; while the baseline system considers only at white-spaces.

IV. CONCLUSION AND FUTURE WORKS

In this paper, phrase-break and phoneme-duration prediction modeling were optimized the practical use in a Thai unit-selection TTS system. In phrase-break improvement, a new set of features was proposed as an input to CART. To predict appropriate phoneme durations, a linear regression model was developed and TD-PSOLA was applied to modify speech signals. These proposed models were evaluated by an objective test and gave 73.8% precision, 70.8% recall and 72.2% F-measure. Moreover, duration prediction gave 3.5 and 2.6 ms reduction of average duration errors for ideal and actual phrase-break detection. A subjective test reported that the prosody-modified TTS system achieved 0.42 MOS improvement of naturalness over the baseline system.

Although the implemented system reaches an acceptable quality, there are several issues of naturalness, which can improve for example, G2P conversion of hardly literate words such as named entities, word segmentation, and other prosody information includes tonal information etc.

ACKNOWLEDGMENT

We would like to thank the members of HLT and IMG laboratory of NECTEC who spent their valuable time to join our subjective test.

***Abstract*-It is well-known that acoustic feedback causes a howling phenomenon in an audio amplifier system. This problem not only annoys hearing but also can damage an amplifier system. The adaptive howling suppressor (AHS) in an audio amplifier system is thus proposed in this paper. The algorithm employed in adaptive process is achieved by using the variable momentum least mean square (VMLMS). With this algorithm, the performance improvement and higher convergence rate can be success. The proposed AHS, which is placed between a preamplifier section and a power amplifier section, acts as a notch filter whose frequency characteristic can reduce the howling spectrum. The simulation results show good improvement in the howling suppression of the proposed algorithm. Moreover, the proposed suppressor provides faster rate when has compared with the LMS and NLMS algorithms at the same environment condition.**

I. INTRODUCTION

An amplifier system often encounters with the problem such as whistling or howling which is caused by the acoustic feedback of a loudspeaker to a microphone. This problem does not only cause hearing annoyance but also can damage the amplifier system.

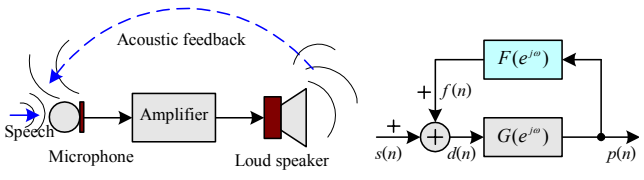
In literatures, many researchers attempt to mitigate the howling effect in amplifier systems with various techniques. The frequency shift method [1] is one of the proposed techniques but it has complicated in the modulation device. Later, the adaptive feedback cancellation (AFC) [2] which employs an adaptive finite impulse response (FIR) filter to identify the impulse response of the acoustic feedback is proposed. By using this technique, the unwanted feedback signal (howling) is estimated and subtracted from the microphone signal (speech signal). Unfortunately, this method requires large number of coefficients (>1000). Correspondingly, a simple least mean square algorithm (LMS) is not suitable employment because it leads to slow adaptation and can not completely eliminated the howling effect. For this reason, literature [2] used recursive least square (RLS) for adaptation algorithm but its disadvantage is high complexity. Nevertheless, the AFC method is usually employed to reject a howling phenomenon in a hearing aids system such as [5], [6]. This is because of short impulse response requirement in the AFC and the simplicity of the algorithm such as the LMS or normalized least mean square (NLMS) is still suitability for the work. The adaptive howling suppressor (AHS) methods [3], [4] are proposed. The AHS requires low number of coefficients (about 100) of the system and performs as notch filter characteristic in order to cancels a howling spectrum. This method can also reduce the howling effect in an audio amplifier system.

Because of, both LMS and NLMS algorithms are often used in the AHS system due to its simplicity. They are well-known that the convergence rate is directly proportional to the adaptation step size. When the step size is large, not only the convergence rate is increased but the excess mean square error (MSE) as well. To eliminate this drawback, the variable momentum least mean square (VMLMS) algorithm [8] is proposed. Therefore, it is applied for the AHS system which can provide both high convergence rate and low excess MSE is thus employed in the proposed system.

The paper is organized as follows. The howling in an audio amplifier system is described in section II. In section III, the adaptive howling suppressor is discussed. The simulation results are illustrated in section IV. Finally, conclusions are then given in section V.

II. THE HOWLING IN AN AUDIO AMPLIFIER SYSTEM

The acoustic feedback in an audio amplifier system is generally occurred when an audio signal produced by a loudspeaker travels back to a microphone either directly or being reflected from the walls, floor or ceiling (see Fig. 1(a)). This feedback system is modeled as shown in Fig. 1(b) where the $s(n)$ and $f(n)$ represent a speech signal and a feedback signal (howling), respectively, and n is discrete time index.



a). System b). Model

Figure 1. The acoustic feedback in an audio amplifier system

In this block diagram, $G(e^{j\omega})$ and $F(e^{j\omega})$ is the amplifier transfer function and the acoustic feedback transfer function respectively. The loudspeaker output signal $p(n)$ is fed back and passed through $F(e^{j\omega})$ to be the howling signal $f(n)$ to the microphone again. Then the composite signal $d(n) = s(n) + f(n)$ is amplified in $G(e^{j\omega})$ before being sent to the loudspeaker. The closed loop transfer function of the system model can be written as

$$T(e^{j\omega}) = \frac{G(e^{j\omega})}{1 - G(e^{j\omega})F(e^{j\omega})} \quad (1)$$

As can be seen, the system will become unstable if a frequency component of the feedback signal produces the $|G(e^{j\omega})F(e^{j\omega})| > 1$ and $\angle G(e^{j\omega})F(e^{j\omega}) = m2\pi$ (where m is an integer). For this condition, the oscillation phenomenon will occur. In case that the oscillation signal has the frequency in the audible range of human hearing, it is called a howling signal.

To eliminate this howling signal, the AHS that which performs as notch filter is proposed in this paper. With frequency reject characteristic of the notch filter, the howling signal is thus suppressed. The proposed system is discussed in the following section.

III. Adaptive Howling Suppressor

A. Principle of the AHS system

The proposed AHS system can be depicted in Fig. 2. The AHS inserted between a preamplifier section and a power amplifier section of the audio amplifier system. The structure of the AHS is illustrated in Fig. 3. This structure is based on an adaptive periodic noise canceller, and is modified from a well-known adaptive line enhancement (ALE) [7]. The signals $d(n)$ and $e(n)$ shown in Fig. 3 represent input and output of the system, respectively.

When the oscillation occurs, the input $d(n)$ is composed of a speech signal $s(n)$ and a periodic howling signal $f(n)$. Thus, from the point of view of an adaptive filter, the speech signal may be considered as broadband while the howling signal considered as narrowband where $s(n)$ is uncorrelated with $f(n)$ [3]. Both signals are passed through the delay unit (Δ sample) that causes delay about 1 ms (16 sample at 16 kHz sampling rate) which is sufficient to make $s(n - \Delta)$ and $s(n)$ uncorrelate each other but there is still a strong correlation of periodic component between $f(n - \Delta)$ and $f(n)$ [4]. The adaptive FIR filter attempts to adapt the system to minimize mean square error $e(n)$.

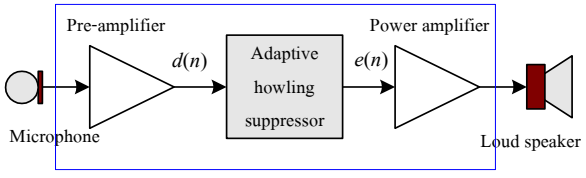


Figure 2. The adaptive howling suppressor implemented in audio amplifier

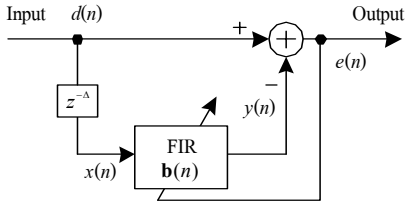

Figure 3. The structure of adaptive howling suppressor

After that, the adaptive FIR filter has reached to the optimum estimate of the periodic component. Thus, after subtraction we are left with mainly the speech component and it is a desirable signal.

B. Notch characteristic

From Fig. 3, let us consider the output equation of the AHS system as follows

$$e(n) = d(n) - \sum_{k=0}^{N-1} b_k(n)x(n-k) \quad (2)$$

or

$$e(n) = d(n) - \sum_{k=0}^{N-1} b_k(n)d(n-k-\Delta) \quad (3)$$

where $b_k(n)$ are coefficients of the N^{th} order FIR which are adjusted by the VMLMS algorithm. By assuming that adaptation of the FIR filter has converged, hence $b_k(n) \rightarrow b_k$. The AHS transfer function can then be obtained by

$$\frac{E(e^{j\omega})}{D(e^{j\omega})} = H(e^{j\omega}) = 1 - e^{-j\Delta\omega}\sum_{k=0}^{N-1} b_k e^{-jk\omega} \quad (4)$$

As shown in (4), it is seen that when the adaptive algorithm has converged thus, the transfer function of the AHS system is notch filter characteristic.

C. VMLMS algorithm

The VMLMS algorithm which is employed for the coefficient adaptation of the adaptive FIR filter is given by [8]

$$\mathbf{b}(n+1) = \mathbf{b}(n) + \mu e(n)\mathbf{x}(n) + \alpha(n)\big(\mathbf{b}(n) - \mathbf{b}(n-1)\big) \quad (5)$$

where

$$\mathbf{b}(n) = \big[b_0(n)\ b_1(n)\ b_2(n)\ \cdots\ b_{N-1}(n)\big]^{\mathrm{T}} \quad (6)$$

$$\mathbf{x}(n) = \big[x(n)\ x(n-1)\ \cdots\ x(n-N+1)\big]^{\mathrm{T}} \quad (7)$$

or

$$\mathbf{x}(n) = \big[d(n-\Delta)\ d(n-1-\Delta)\ \cdots\ d(n-N+1-\Delta)\big]^{\mathrm{T}} \quad (8)$$

It is noted that $\mathbf{b}(n)$ and $\mathbf{x}(n)$ are a coefficient vector and an input vector, respectively. In addition, $e(n)$ is a scalar of error signal (output of the AHS system), μ is a constant step size of

the algorithm that controls the convergence rate and the algorithm stability [7], [8] and $\alpha(n)$ is a scalar of momentum factor which bounded as $0 \le \alpha(n) < 1$ [8]. Also, $[\cdot]^T$ denotes the matrix transpose.

In equation (5), the last term is a momentum which the acceleration of convergence is controlled by the momentum factor. It is adjusted to large value in transient state in order to obtain high convergence rate and contrarily to be small value in steady state for low adaptation speed. Thus, if the step size of the algorithm can be accomplished a very small value and the low excess MSE is obtained. The adjustment of the momentum factor can be given by

$$\alpha(n) = \gamma\alpha(n-1) + \rho e(n)\mathbf{x}(n)^{\mathrm{T}}\left(\mathbf{b}(n-1) - \mathbf{b}(n-2)\right) \qquad (9)$$

which it can found in [8]. In the above equation, the algorithm is updated under a past difference of coefficient vector, a past momentum factor, a current input vector, a current error signal scalar, a constant γ and ρ, respectively where $0 < \gamma < 1$ and $\rho > 0$ [8]. The adaptation of momentum factor is bounded as the condition which is given by

$$\alpha(n) = \begin{cases} \alpha_{\min} & ;\ \text{if}\ \ \alpha(n) < \alpha_{\min} \\ \alpha_{\max} & ;\ \text{if}\ \ \alpha(n) > \alpha_{\max} \\ \alpha(n) & ;\ \text{otherwise} \end{cases} \qquad (10)$$

where $\alpha_{\min}$ and $\alpha_{\max}$ are lower and upper bounds of the momentum factor, respectively. The constant $\alpha_{\max}$ is normally selected near unity while the value of $\alpha_{\min}$ is chosen near or equal to zero. The initial value $\alpha(0)$ is usually taken to be $\alpha_{\max}$.

IV. Simulation Results

In this section the computer simulations are performed to examine the performance of the proposed AHS system. The adaptive 100th order FIR filter and the delay unit (Δ = 16 samples) are used where the sampling rate is at 16 kHz. For the environment set up, the amplifier system is set to oscillate at 1.6 kHz. The tested input signal of the AHS thus comprise of a speech signal and a 1.6 kHz howling signal. The speech signal is artificially generated with a speech-shaped noise using zero mean and unity variance white Gaussian noise signal through a 12th order auto regressive (AR) filter [6].

With the above set-up environment, the proposed algorithm is implemented with the parameters μ = 0.0001, γ = 0.999, ρ = 0.9, $\alpha_{\max}$ = 0.7 and $\alpha_{\min}$ = 0. The normalized power spectrum of an artificial speech with a howling signal (input of the AHS system) illustrated in Fig. 4. It is seen that the sine signal to broadband signal ratio (SBR) [7] is about 20 dB.

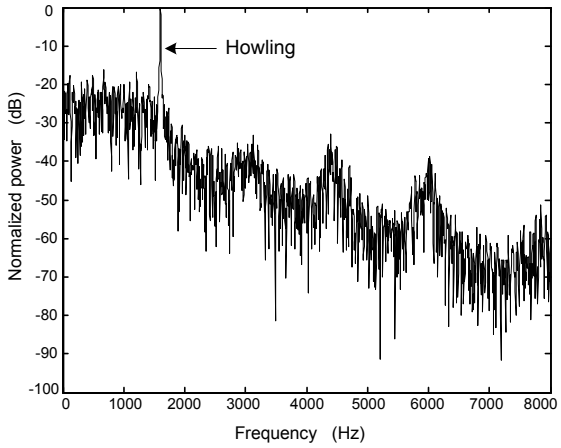

Figure 4. Power spectrum of AHS input with howling signal

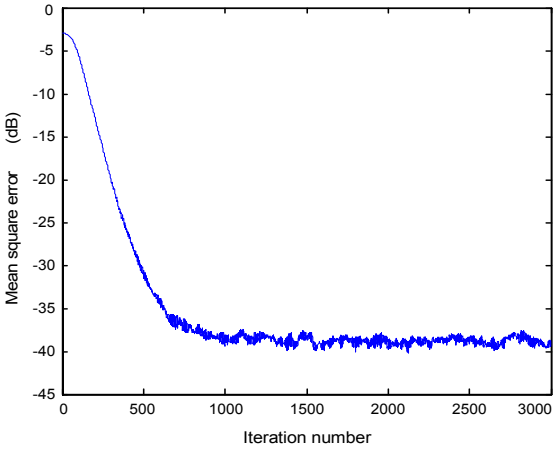

Figure 5. Convergence of AHS system using VMLMS algorithm

Fig. 5 shows the convergence behavior of the proposed algorithm where the MSE approaches the steady state about 500 iterations. As can be seen, the howling signal is almost completely suppressed after 500 iterations. When the algorithm approaches the steady state, the transfer function and output normalized power spectrum of the AHS system can be demonstrated in Fig 6 and Fig. 7, respectively. In Fig. 6, the magnitude response illustrates the notch filter characteristic of the AHS system where its depth is 1.6 kHz. Thus, the howling spectrum has been reduced as the result magnitude given in Fig. 7.

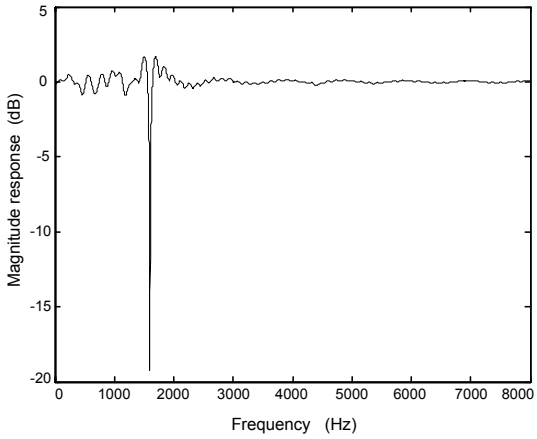

Figure 6. Transfer function of AHS system

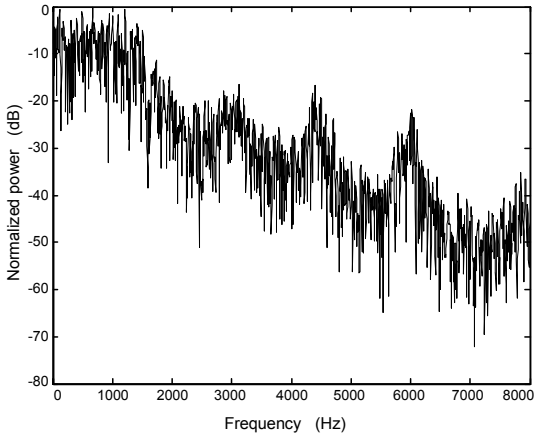

Figure 7. Power spectrum of the AHS output without howling signal

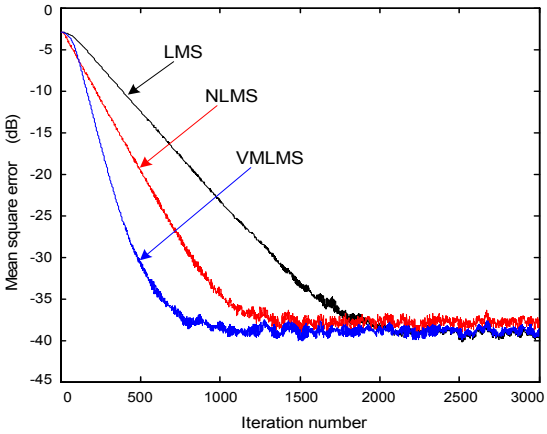

Figure 8. Comparison of convergence behavior

The convergence behavior of the proposed algorithm has been also compared with both LMS and NLMS algorithms where the parameter μ is set to be 0.0001 and 0.01, respectively. These algorithms are then performed in the same environment setup as previous discussion. As results shown in Fig. 8, the MSE convergence behavior of the proposed algorithm is superior to both LMS and NLMS algorithms.

V. CONCLUSIONS

An amplifier system often encounters with a howling problem due to an acoustic feedback of a loudspeaker to a microphone. The system will become unstable if a frequency component of the feedback produces larger than unity open loop gain and the loop phase is a multiple of 2π where the howling effect is occurred. The adaptive howling suppressor in an audio amplifier system using the VMLMS algorithm is thus proposed in this paper. The simulation results of the proposed algorithm show good result in howling suppression. Moreover, the comparison shows that the proposed algorithm provides faster convergence rate than the LMS and NLMS algorithms which are performed in the same environment.

ABSTRACT

The propose of this investigated was to implement military vehicles sound recognition by using Ergodic Hidden Markov Model (EHMM) pattern recognition system. The system used real cepstral coefficient and normalization of cepstral coefficient as feature vectors and used wavelet transform as front-end process. Real cepstral coefficient gave a good result when using small database but the recognition rate decreased when using more type of vehicles. Cepstral coefficient normalization cannot improve the recognition rate, so this method was unsuitable for military vehicles sound recognition. Using wavelet transform and real cepstral coefficient gave the best recognition rate comparing with using only real cepstral coefficient as feature extraction. In conclusion, Wavelet transform could improve the recognition rate up to 97.77% (increased 14.44% when compared with the real ceptral coefficients).

Keywords: Military Vehicles Sound, Errgodic Hidden Markov Model, Real Cepstral Coefficient, Normalization of Cepstral Cofficient, Wavelet Transform.

1. INTRODUCTION

Generally, Speech recognition system is performed by the pattern template matching as shown in Fig. 1 [1]. In order to improve recognition rate (or robustness), Many works have been shown those techniques such as pre-processing algorithm, feature normalization, recognizer improving [2]. So, most of researchers are focus into two fields of automatic speech recognition (ASR) system; feature extraction and recognizer. Nowadays, HMM recognizer is accepted be good method for good recognition rate. It applies the statistical method to making template of speech references.

A great deal of efforts has been paid in developing new feature vector extraction techniques for automatic speech recognition (ASR) system. In the last two decade, several methods were proposed which used pattern features in HMM-based speech recognition. As a result, the Cepstral coefficient of speech waveform became a standard feature set for speech recognition system.

For the system which apply cepstral coefficient as feature vector, the cepstral mean normalization is the simply method to increase the recognition rate and robustness. The papers[3][4] have been shown the improving recognition rate by the two new feature normalization, i.e. Cepstral Max Normalization (CMN) and Cepstral Standard-Score Normalization (CZN), in addition to Cepstral Mean Normalization (CMN). The normalized feature vector is changed the mean values to the zero mean for distinguishing the difference of different feature to similar feature.

Though of military vehicles sound signal don't look like speech signal. Real cepstral coefficient and normalization of cepstral coefficient as feature vectors of military vehicles sound signal doesn't accepted be good method for HMM recognition. Therefore this paper proposed developing feature vectors together wavelet Transform and Cepstral Coefficient for HMM recognizer.

This research to try analysis military vehicles sound spectral make to feature vector, and it mean of "Real Cepstral". The coefficient reduced by FFT military vehicles sound signal, and after that the feature vector to import process EHMM recognition for produce reference military vehicles sound model, And it matching for test recognition rate.

In this paper presents the review of military vehicles in next section. The recognition is simulated by EHMM algorithm. In section III, the results are presented comparing the effect of real cepstral and normalization of cepstral as feature vectors and used wavelet transform as front-end process to the recognizers in clean sound. Finally, in section IV a conclusion of this research work is given.

2. MILITARY VEHICLES

Military vehicles incorporate all forms of wheeled and tracked vehicles including the full range of body types found in commercial vehicles. However, there are also bodies and equipment that are unique to military operations. They include all types of trucks, tractors, truck tractors, personal carriers, tanks, self-propelled guns, motorized and mechanized special purpose

equipment, trailers, vans, and special purpose towed vehicles.

The principal distinction between these vehicles and their commercial counterparts is that military vehicles are specifically designed for military purposes. This includes combat operations and the transportation of cargo, personnel, or equipment; towing other vehicles or equipment; and operations, both cross country and over roads, in close support of combat vehicles and troops. They are designed and constructed to endure the rigors of the military environment ant to continue to operate at, or above, a prescribed minimum performance level in this environment. They have excellent cross-country performance capabilities over all types of terrain where tactical or combat operations can be conducted. This includes snow and ice, rocky terrain, swamps, and desert sands. In order to negotiate water barriers with a minimum of preparation, all sensitive equipment is either permanently waterproofed to prevent damage by immersion, or designed to function underwater [5].

3. EXPERIMENTAL DETAILS AND RESULTS

3.1 Performance evaluation

The performance of the algorithm proposed herein was investigated by implementation using the Borland c++ builder programming language and Matlab. For testing and evaluating the proposed algorithm, military vehicle sound cited from Armored car V150; Truck, Utility: ¼ Ton 4x4, M151 Series; Truck, Utility: Armament Carrier, Armored, 1 ¼ Ton, 4x4, M1025 (HMMWV); Cargo truck 2 ½ Ton KM 250; Truck, 10 Ton, 6x6, MB2028 and Carrier, Personnel, Full-Tracked, Armored, M113.

The simulation, 6 military vehicles sound are collected each with 5 samples for 5 seconds at the clean sound. The sounds have been recorded from the front and back of the vehicles was approximately one meter.

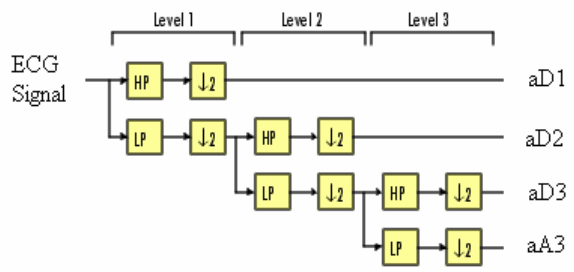
3.2 Wavelet Transform

Wavelet Transform represents the next logical step: a windowing technique with variable-sized regions. Wavelet analysis allows the use of long time intervals where we want more precise low-frequency information, and shorter regions where we want high-frequency information.

Dyadic analysis filter banks are constructed from the following basic unit. The unit can be cascaded to construct dyadic analysis filter banks with either a symmetric or asymmetric tree structure.

Each unit consists of a lowpass (LP) and highpass (HP), followed a decimation by a factor of 2. The filters are halfband filters with a cutoff frequency of Fs/4, a quarter of the input sampling frequency. Each filter passes the frequency band that the other filter stops.

The unit decomposes its input into adjacent high-frequency and low-frequency subbands. Compared to the input, each subband and has half the bandwidth (due to the half-band filters) and half the sample rate (due to the decimation by 2).



HP = highpass filter with fc=1/4 of fs.

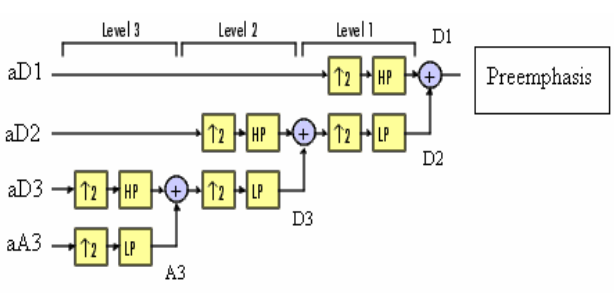
LP = lowpass filter with fc=1/4 of fs.

aA3 = approximation coefficient.

aD1, aD2, aD3 = detail coefficient

Fig. 2 *Wavelet decomposes 3 layers.*

Synthesis filter banks are constructed from the following basic unit. The unit can be cascaded to construct dyadic synthesis filter banks with either a asymmetric or symmetric tree structure as illustrated in the figure3. The unit consists of a lowpass (LP) and highpass (HP).



D1, D2, D3 = detail coefficient reconstruction.

A3 = approximation coefficient reconstruction.

Fig. 3 *Wavelet Synthesis 3 layers.*

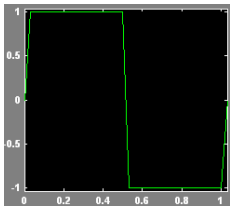


Fig. 4 *Haar Wavelet function used in this paper.*

3.3 Feature Normalizetation

The principles of the 3 techniques of feature vectors normalization which use in this paper are described.

3.3.1 Cepstral Mean Normalization (CMN)

The sequence of feature vector of a speech signal is given by

$$\mathbf{A} = \boldsymbol{a}(0)\boldsymbol{a}(1)\kappa\ \boldsymbol{a}(I-1) \quad (1)$$

where $\boldsymbol{a}(i) = (a_{i1}, a_{i2}, \text{L}\ , a_{ip}, \text{L}\ , a_{iP})^T$, I is the number of frames in each word. P is cepstrum dimension. The average value of whole coefficients in each dimension of feature vectors is obtained by

$$\mu_j = \frac{1}{I}\sum_{i=0}^{I-1} a_{ij}, (j = 1,2,...,P) \quad (2)$$

The normalization of Eq.1 by Eq.2 can be represented by

$$\tilde{\mathbf{A}} = \tilde{\boldsymbol{a}}(0)\tilde{\boldsymbol{a}}(1)\text{L}\ \tilde{\boldsymbol{a}}(i)\ \text{L}\ \tilde{\boldsymbol{a}}(I-1) \quad (3)$$

where $\tilde{\boldsymbol{a}}(i) = (\tilde{a}_{i1}, \tilde{a}_{i2}, \text{L}\ , \tilde{a}_{ip}, \text{L}\ , \tilde{a}_{iP})^T$ and $\tilde{a}_{ij} = a_{ij} - \mu_j$.

3.3.2 Cepstral Mean Max Normalization (CMMN)

The maximum value of whole coefficients in each dimension of feature vectors is obtained by

$$M_j = \max_i(\tilde{a}_{ij}) \quad (4)$$

The normalization of Eq.1 by Eq.4 can be represented by

$$\tilde{\mathbf{A}} = \tilde{\boldsymbol{a}}(0)\tilde{\boldsymbol{a}}(1)\text{L}\ \tilde{\boldsymbol{a}}(i)\ \text{L}\ \tilde{\boldsymbol{a}}(I-1) \quad (5)$$

where $\tilde{\boldsymbol{a}}(i) = (\tilde{a}_{i1}, \tilde{a}_{i2}, \text{L}\ , \tilde{a}_{ip}, \text{L}\ , \tilde{a}_{iP})^T$

and $\tilde{a}_{ij} = \dfrac{a_{ij} - \mu_j}{M_j}$.

3.3.3 Cepstral Standard-Score Normalization (CZN)

The standard-score value of coefficient in each dimension of feature vectors is obtained by

$$SD_j = \frac{1}{I}\sum_{i=0}^{I-1} (\tilde{a}_{ij})^2 \quad (6)$$

The normalization of Eq.1 by Eq.6 can be represented by

$$\tilde{\mathbf{A}} = \tilde{\boldsymbol{a}}(0)\tilde{\boldsymbol{a}}(1)\text{L}\ \tilde{\boldsymbol{a}}(i)\ \text{L}\ \tilde{\boldsymbol{a}}(I-1) \quad (7)$$

where $\tilde{\boldsymbol{a}}(i) = (\tilde{a}_{i1}, \tilde{a}_{i2}, \text{L}\ , \tilde{a}_{ip}, \text{L}\ , \tilde{a}_{iP})^T$

and $\tilde{a}_{ij} = \dfrac{a_{ij} - \mu_j}{SD_j}$.

3.4 Feature Extraction

The military vehicles sound feature extraction is a difficult take witch has attracted a great deal of interest. It is very important take because EHMM recognition processes depend on the quality of the features extracted.

The parameter values used in the simulations for 10kHz sampling frequency are as follows. The number of bits per sample of the military vehicles sound waveform was 16 bits. The coefficient (a) of pre-emphasis filter ($H(z) = 1 - az^{-1}$) is 0.97. The analysis window is Hamming window. The analysis frame length and frame overlap are 256 points and 128 points, respectively. The baseline feature vectors are 8 dimensions of FFT cepstral analysis. The Real Cepstral is the inverse Fourier transforms of the military vehicles sound spectrum in each sequence show in Fig. 5. The normalization of cepstral coefficient as feature vectors and used wavelet transform as front-end applied to the FFT cepstral feature vector show in Fig. 6-7.

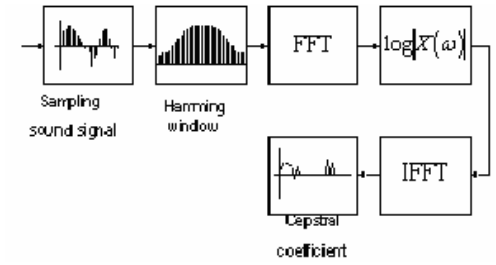

Fig. 5 *Real Cepstral Coefficient Feature Extraction.*

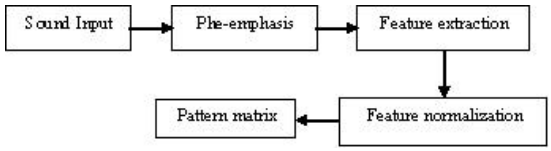

Fig. 6 *Cepstral Coefficient Normalization.*

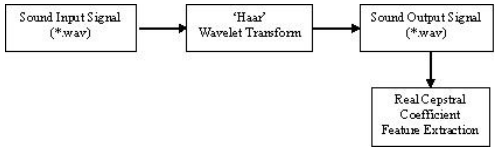

Fig. 7 *Wavelet Transform Process.*

3.4 Recognizers and Templates

For compared the overall of performance, The Errgodic Hidden Markov model (EHMM) recognition was investigated. It used to make statistical templates form as a model. The EHMM setting is given by 8 states of diagonal transition matrix and single Gaussian Mixture parameter. The likelihood between test and references pattern is obtained by Viterbi's algorithm.

3.5 Results

The result of this simulation, baseline feature vector, CMN, CMMN and CZN, shown in Table 1, respectively. The evaluated recognition rate of the baseline feature vectors, when tested with a large sample size the recognition rate were decreased. For CMN,CMMN and CZN, the recognition rate will be decreased when compared with the real ceptral coefficients.

TABLE 1: *Recognition rate on normalization of cepstrum as feature vectors feature vector simulation with EHMM engine.*

Normalized technique	The front of vehicle sample train data	The front of vehicle sample test data	The end of vehicle sample test data
Baseline	100	100	50

CMMN	56.66	33.33	10.00
CZN	53.33	33.33	13.33

Furthermore, using wavelet transform Coiflets, Haar family before extraction feature vectors processed, it can increase recognition rate. Because of wavelet transform consists of a lowpass (LP) and highpass (HP). After decomposed, Approximation (A) of military vehicles sound original signal is result of Lowpass filter, as well as and result of Highpass filter is detail (D). The process selected detail subband essential of filter banks from wavelet transform before extraction feature vectors processed. The result of this simulation shown in Table 2

4. DISCUSSION AND CONCLUSIONS

The purposes of the paper are to study the effects of the feature vector normalization techniques, such as CMN, CMMN, CZN and analysis filter banks of wavelet transform are separate feature frequency of signal out off original signal before extraction feature vector with Real Cepstral processed, that affect to the recognizer in the military vehicles recognition system and to increase the recognition rate compared with the Real Cepstral front-end. [6] The simulation results show that the recognition rate is increase by using function Haar3. Because of waveform function look like the military vehicles sound signal which sharp of Wavelet family are effectively of decompose and synthesis signal. The result at table 3 show the recognition rate average on real cepstrum and normalization of cepstrum as feature vectors and used wavelet transform as front-end process simulation with EHMM engine. The simulation results show that the recognition rate is increase by using Haar3 function wavelet transform accuracy was average is approximately 97.77%.

In the future work, we will implement the system in to aiming at a high degree of noise robustness, it is still obligatory to perform noise compensation in the recognition unit using either model adaptation techniques and/or implement the system in to DSP chip.

Table 3. *Recognition rate average on real cepstrum and normalization of cepstrum as feature vectors and used wavelet transform as front-end process simulation with EHMM engine.*

Signal Condition	Recognition rate (%)
Real cepstrum	83.33
CMN	42.22
CMMN	33.33
CZN	33.33

***Abstract*- This paper proposes an automatic method for locating phone boundaries in speech utterances based on HMM-based forced alignment together with some context-dependent refinements. HMM-based forced alignment has been a preferred method for speech segmentation in many applications. However, the resulting boundaries are usually not consistent with real boundaries, defined based on abrupt changes in acoustic properties, which are often required in a number of applications such as landmark- and segment-based speech recognizers. In this work, the boundary refinement process fine-tunes boundary locations by utilizing acoustic features selected according to boundary types, categorized by their manners of articulation. Several acoustic measurements are combined with spectral features to form the set of acoustic features to be selected from. Performances of the refinements on different boundary types are investigated on a development set. Refinements working well are identified and these refinements are applied to an unseen test set. The maximum accuracy of 87.13% is achieved from speaker-independent speech segmentation experiments on 490 continuous speech utterances. This introduces a 14.7% error reduction when compared to the baseline HMM-based forced alignment.**

I. INTRODUCTION

Precise phone boundary labeling in speech waveform plays an important role in speech recognition and speech synthesis systems. Information on the timing of phone boundaries is usually needed in many applications. Relying on manual labeling, speech segment boundaries in a speech utterance could be located by having labelers listen to the computer playback of that utterance, visually observe its associated waveform and spectrogram, and mark down their timing. Although manual labeling by human is reliable and accurate, it is not at all feasible for large speech corpus since generating the associated labels for all boundaries is laborious and very time-consuming. Another disadvantage of manual labeling is possible inconsistency. Automatic segmentations, in which automatic methods are used for finding the location (or, more specifically, timing), of boundaries between all adjacent speech units when the sequence of speech units, or phonetic transcription, associated with the utterance of interest is a required prerequisite, are usually desirable.

Currently, techniques based on Hidden Markov models (HMMs) have been widely used in automatic speech recognition systems, as well as in performing forced alignments, where HMM-based recognizer is employed to find the most probable sound unit boundaries for speech utterances with known transcriptions, i.e. phonetic sequences without associated time labeling. Phone boundaries proposed by HMM forced alignment are not always, and are rarely, placed precisely at acoustic abruptness. Although it is not crucial for typical HMM-based speech recognizer, such precision is necessary for many other applications such as landmark- and segment-based speech recognizer, as well as other applications in need of acoustic-phonetic analysis. Some post refining methods were employed to improve the precision of sound unit boundaries from HMM forced alignment. Various refining techniques, such as HMM itself [1], Artificial Neural Networks (ANN) [2], Multi-Layer Perceptrons (MLP) [3, 4], Dynamic Time Warping (DTW) [5] and Gaussian Mixture Models (GMM) [6], have been proposed as post-processing techniques. Attempts to explicitly capture abrupt acoustic changes were also made. Andre-Obrecht [7] detected the sequential abrupt changes of some model parameters for speech segmentation. Dusan and Rabiner [8] relied on Spectral Transition Measures (STM) as their feature vectors.

The sound units in this work are phones, each of which possesses homogeneous acoustic characteristics, i.e. there are no significant changes during its interval. This paper proposes a method for locating phone boundaries. In such an approach, the system attempts to mimic manual labeling by incorporating information from spectrogram and temporal acoustic features in speech waveform. Several acoustic features [9] and temporal cues are combined in order to refine phone boundaries proposed by the forced alignment process.

II. BACKGROUND

A. Acoustic Characteristics of Phone Boundaries

Human's speech production is described as a two-staged process. Firstly, a source signal is produced either at the vocal folds or constrictions in the speaker's vocal tract. Then, the source signal is acoustically shaped according to the transfer function of the vocal tract at the moment the sound is produced. When vocal folds vibrate as a part of speech production, the corresponding sound is said to be 'voiced'. Otherwise, it is 'unvoiced'. Acoustic shaping of the source signal depends on the resonance properties of the vocal tract which change over the course of uttering phonemes due to the changing configuration of related articulators. Therefore, phonemes can be distinguished by their spectral shapes of the

resulting speech signals. There are marked changes in vocal tract configuration when the articulation translates from one phone to another. Consequently, abrupt discontinuities [10] manifest in the speech signal during phone transitions in both time and frequency domains. Examples of abrupt acoustic changes, marked by vertical solid lines, can be clearly observed in the spectrogram of the speech utterance /*n-aa-j^-s-a-ng-aa-s-a-p^-sp-ph-a-s-ii*/ shown in the upper panel of Figure 1.

B. HMM-Based Forced Alignment

HMM-based forced alignment is basically a speech recognition process that relies on HMM. However, with a known phonetic sequence, the decoding process in a typical recognition reduces from finding the best possible path in the network, whose topology is defined with an associated grammar, of HMM acoustic models to just finding the most likely state sequence, emitting the observed acoustic feature vectors, in a network that has only one path, constrained by the known phonetic sequence. Therefore, there are no substitution, insertion, and deletion errors. Still, the most likely state sequence might not always yield phone boundaries that precisely locate at abrupt acoustic changes as required in some applications. Figure 1 also illustrates an example of a set of phone boundaries resulted from an HMM forced alignment (lower panel) compared to ones precisely conform with abrupt acoustic changes (upper panel).

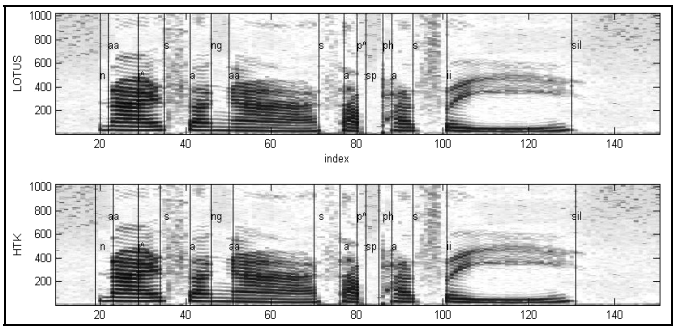

FIGURE 1. SPECTROGRAM OF A SPEECH UTTERANCE DESCRIBED IN THE CONTEXT WITH PHONE BOUNDARIES (UPPER PANEL) AND WITH AN HMM FORCED ALIGNMENT RESULT (LOWER PANEL)

III. PROPOSED METHOD

A. Overview

Figure 2 describes our overall boundary detection system. It is divided into two steps: 1) HMM forced alignment is used to propose rough phone boundaries. 2) The boundaries proposed in the first step are refined using context-dependent acoustic measurements. In this work, the aspect of contexts that concerns with which acoustic measurements will be used is a broad categorization of speech sounds based on their manners of articulation. Specifically, the boundary types of interest in this work include *stop-vowel*, *stop-sp*, *sp-stop*, *sp-nasal*, *vowel-sp*, *nasal-sp*, *vowel-nasal*, *vowel-stop*, *vowel-semivowel*, *nasal-vowel*, *fricative-vowel*, *affricate-vowel*, and *semivowel-sp*, where *sp* represents silence or a short pause. These boundaries make up to more than 90% of all boundaries and they are the only ones refined in this work. Speech frames in the vicinity of the initially proposed boundaries, including the frame where the boundaries are originally in, are considered candidates for locations of refined boundaries. Selected acoustic measurements are extracted from these speech frames and used as features for deciding where boundaries should be refined to.

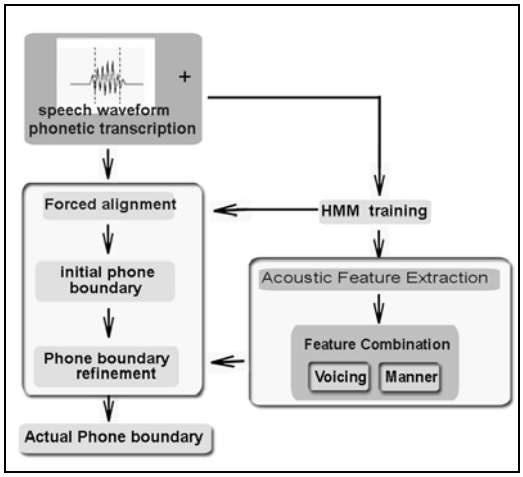

FIGURE 2. BLOCK DIAGRAM OF THE PROPOSED METHOD

B. Acoustic measurements

The set of acoustic measurements for the refining task is selected so that each of them reflects some aspects of acoustic difference. These measurements are:

1) Difference in the total signal energy in the speech frame of interest and the one in the preceding frame.
2) Correlation coefficient between the speech signal in the frame of interest and the speech signal in the preceding frame.
3) Difference in the Zero-Crossing Rate (ZCR) obtained from the speech signal in the frame of interest and the one from the preceding frame.
4) Energy ratios in different frequency bands between the speech signal in the frame of interest to the one in the preceding frame. Five frequency bands are used. Their ranges are: 1) below 400 Hz., 2) from the first formant frequency to the second formant frequency, 3) from the second formant frequency to the third formant frequency, 4) from the third formant frequency to 5,000 Hz., and 5) from 5,000 Hz. to 8,000 Hz.
5) Difference in the first formant frequency, as well as the second formant frequency, of the speech signal in the frame of interest and the ones from the preceding frame.

Only the last two measurements are applied to boundary types where there is no change in voicing property across the boundaries. Energy ratios in specific frequency bands are used with different boundary types according to a heuristic derived

from their acoustic-phonetic characteristics. For boundary types where the voicing property of the phones changes, the first three measurements are applied together with the last two since the first three since the first three measurements are closely related to voicing detection [11].

C. *Boundary Refining*

The location of each initial boundary proposed by HMM forced alignment is refined in order to obtain a location that is precisely at its corresponding acoustic discontinuity, if it is not there already. A refining region is defined around the frame, indexed n_o, containing each initial boundary. The region spans from the frame at n_o- γ to the frame at n_o- γ. The size of each refining region is an important factor to the resulting accuracy. An optimal size depends also upon the characteristic of results from the initial force alignment. A large refining region allows recovery of largely deviated boundaries, yet it may detect false alarms. A small refining region might not uncover real boundaries if the HMM force alignment propose heavily deviated boundaries.

Speech frames falling into the refining region are candidates for the real boundaries. The decision rules adopt in this work for selecting the best candidate in a refining region are based on the assumption that the most likely boundary, in a short-time speech interval, must demonstrate the maximum acoustic change. Therefore, candidates with the maximum difference (lowest correlation coefficient), demonstrated across all acoustic measurements, are picked as the resulting boundaries.

IV. Experiment Details

A. *Speech Corpus*

Large vOcabulary Thai continUous Speech recognition (LOTUS) corpus [12] is used. In this task, the phonetically distributed (PD) set containing 5,000 lexical items and manual transcriptions with phone boundaries information for every speech utterance is used to evaluate the performance of the proposed method. Developing and test sets contain the total of 28,828 and 22,145 boundaries, respectively. Utterances were recorded in a quiet environment at 16 kHz. sampling rate.

B. *Baseline System*

HMM forced-alignment is used as our baseline. A 39-dimensional feature vector (MFCCs together with their deltas and accelerations) is extracted every 10 ms. The observation frame size is 25 ms. A Hamming window is applied to each frame before the feature extraction. Five-state left-to-right HMMs are used as acoustic models for triphones representing 76 phonemes in Thai language. Gaussian mixtures with five components are used as probability density functions governing how each state in the HMMs emits its output.

C. *Evaluation*

To evaluate the performance of the proposed refining method, the detection accuracy percentage, which is the percentage of a ratio between the number of boundaries correctly located to the total number of boundaries tested, is measured. To determine whether a boundary is located correctly tolerance thresholds are set in terms of the numbers of frames allowed to be deviated from the frame marked in the associated manually prepared labels. The frame size used for extracting acoustic measurements for refining is either 7.5 ms. or 15 ms. for this work. The accuracies of the refined boundaries are compared with the ones obtained from the forced alignment alone.

Refinements are first performed on all of the thirteen boundaries types in the test set, and the result is compared with the performance obtained without the refinements in order to evaluate the performance of the method. The benefit obtained from the refinement of each boundary type is observed in terms of its contribution to the overall improvement on the development set. We then opt to apply the refinement on only the boundary types showing significant benefits as observed on the development set to the refinement on the test set. Note that since the test set is treated as if it was an unseen data set and the selective refinement is judged based on observations made on the development set, which is a different set than the test set, the accuracy obtained in this case should be an unbiased reflection of the performance of the proposed method even though the refinement is not applied to all boundaries.

V. Results and Discussions

Table I shows the boundary detection accuracy of the proposed method on the test set compared to the one obtained from the baseline system when refinement is performed on every boundary types. Note that the detection was test on 22,145 boundaries in the test set and the frame size used in this case is 15 ms. The performance is evaluated at a 1-frame tolerance level. The proposed method yields a 3.5% error reduction.

TABLE I.
BOUNDARY DETECTION PERFORMANCE WHEN UNSELECTIVE REFINEMENT IS APPLIED

Tolerance (frames)	%Accuracy (out of 22,145 boundaries)	
	frame size = 15 ms.	
	Baseline	Proposed
1	84.91	85.44

Figure 3 listed figures of merit of the proposed refinement on the thirteen boundary types. The figures of merit are evaluated based on the performance of the refinement of 28,828 boundaries in the development set. The larger the figure of merit, the more benefit its corresponding boundary type receives from the refining. Even though the overall boundary detection result improves over the baseline method, not all boundary types are fully benefited from the refinement. A few of them worsen the result.

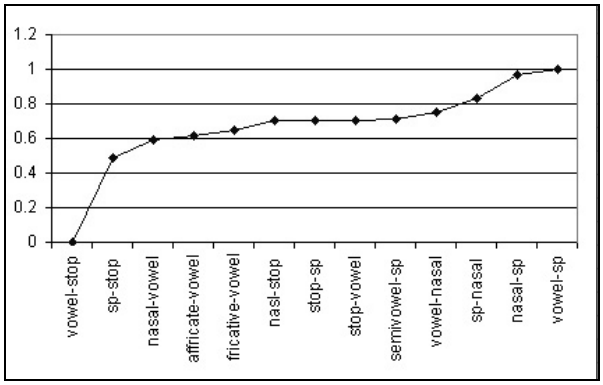

FIGURE 3. FIGURE OF MERIT OF THE REFINEMENT ON ALL BOUNDARY TYPES

Table II shows the boundary detection accuracies when the refinement is selectively applied to only the boundary types receiving significant benefits from the refinement performed on the development set. These boundary types include the top five of boundary types shown in Figure 3. The refining regions used in these cases are 2 frames.

TABLE II
BOUNDARY DETECTION PERFORMANCE WHEN SELECTIVE REFINEMENT IS APPLIED

Tolerance (frames)	%Accuracy (out of 22,145 boundaries)			
	frame size = 7.5 ms.		frame size = 15 ms.	
	Baseline	Proposed	Baseline	Proposed
1	54.54	60.53	84.91	87.13
2	78.26	80.51	94.98	95.11

From the table, we can see that when the frame size used is 7.5 ms., the proposed method yield the detection accuracy of 60.53% and 80.51% with 1-frame and 2-frame tolerance levels respectively. These introduce error reductions of 13.2% and 10.4% over the baseline method. When the frame size used is 15 ms., the proposed method yield the detection accuracy of 87.13% and 95.11% with 1-frame and 2-frame tolerance levels respectively. These introduce error reductions of 14.7% and 2.6% over the baseline method.

Typically, phone boundaries are considered as accurate when they are located within 10-20 ms. from their correct locations. Therefore, according to this criterion, the best boundary detection accuracy from our method is the accuracy obtained when the tolerance level is one 15-ms frame which is 87.13% with 14.7% error reduction over the baseline.

Results from another experiment suggest that the top five beneficiaries observed from the development set are located correctly with the overall accuracies of 93.36% when tested on the test set. These boundary types are located with 82.32% accuracy via the HMM forced alignment.

Table III shows another measure of the performance of the proposed method compared to the one of the baseline method. The table lists average deviation in frames when the frame sizes are 7.5 ms. and 15 ms. These average deviations are calculated by dividing the total number of frames for which all of the detected boundaries deviated from their corresponding true locations with the total number of boundaries. The less the average deviation, the better its corresponding method performs. From the table, the proposed method also shows a better performance than the baseline in this aspect.

TABLE III.
AVERAGE DEVIATION (FRAMES)

Detection Method	Frame size	
	7.5 ms.	15 ms.
Baseline	2.00	0.87
Proposed	1.86	0.78

VI. CONCLUSION AND FUTURE WORKS

This paper proposes a method for locating phone boundaries using context-dependent refinement on HMM forced alignment. The proposed algorithm achieves 87.13% detection accuracy when the refining is applied on some specific boundaries. Further investigation is needed on the adjustment of refining area, the frame size for the feature extraction procedure, as well as additional acoustic features.

***Abstract*- This article introduces a novel version for implementing current-mode precision full-wave rectifier and class B push-pull current amplifier. The features of the proposed circuits are that: it can rectify and amplify current signal with controllable output magnitude via an input bias current: the output current save ideally free from temperature variation. In addition, direction of the output current signals can be arbitrarily controlled by current in the circuits to be either positive or negative without changing circuit topology, which differs from the previous literatures. Circuit descriptions merely consist of 3 BiCMOS CCCIIs. The performances of the proposed circuits are investigated through PSPICE. They show that the proposed circuits can function as a current-mode precision full-wave rectifier and push-pull current amplifier where input current range from -80μA to 80μA can be achieved at ±2.5V power supplies. The maximum power consumption is 1.43mW. In addition, the highest frequency is restricted at up to megahertz range.**

I. INTRODUCTION

A precision rectifier is extensively used in signal processing circuits, for instance, in an AC to DC converter, in a signal polarity detector, in a peak signal detector, in an amplitude demodulation circuit, and in an automatic gain control system [1-2]. Basically, a voltage-mode precision rectifier employs an operational amplifier and a diode [3]. The output signal confronts a zero-crossing distortion due to characteristic of the diode [4]. This problem has been subsequently solved by proposing the novel circuit without a diode [5]. In addition, the precision rectifiers are modified to use other active elements to achieve wider frequency response, for example, current conveyor [6] and current feedback operational amplifier [7].

Since a low-voltage operating circuit becomes necessary as in portable and battery-powered equipment, the current-mode technique is ideally suited for this purpose more than the voltage-mode one. Presently, there is a growing interest in synthesizing the current-mode circuits because of more their potential advantages such as larger dynamic range, higher signal bandwidth, greater linearity, simpler circuitry and lower power consumption [8-9]. From our investigations, there are seen that the previous literatures have proposed the current-mode precision rectifiers [10-12]. Unfortunately, the output magnitude of those proposed circuits can not be adjusted. Consequently, they require a proper amplifier to achieve appropriate level of output signal. Furthermore, in case of opposite polarity of output signal is required, it must be unavoidably changed the circuit topology or added a current inverter. This makes the circuit more complicated. Some of them employ a number of passive elements, which is not suitable for realizing into an integrated circuit [13]. The operations of all mentioned circuits, moreover, are dependent on temperature.

On the other hand, the current amplifiers find wide applications, particularly in a system that requires a low power supply voltage, such as in communication system, instrumentation system, biomedical system, etc. [14]. Recently several current amplifiers have been proposed, however, their current gain cannot electrically and linearly be tuned [15]-[17]. Basically, class-A current amplifiers have linear characteristics. However, they require DC bias currents that restrict the allowable signal swing range and lead a high-power consumption. The DC power consumptions of class-A amplifiers do not depend on the signal amplitude but it is determined by the DC bias current and voltage of the power source. On the other hand, class-B amplifiers require no DC bias current, thus there is no power consumption when no signal is processed in the amplifiers. In addition, the DC power of the class-B amplifiers vary with the magnitude of the processing signal, thus quite good power efficiencies are expected.

The purpose of this paper is to introduce novel current-mode precision rectifier and class B push-pull current amplifier, whose output magnitude and polarity are electronically controllable without changing a circuit topology or adding any more circuit. They can be applied in an automatic control via a microprocessor. Each circuit construction consists of 3 CCCIIs. The PSPICE simulation results are also shown. They confirm that the proposed circuits provide a wide range of input current, temperature-insensitive, wide range of frequencies. In addition, controllability of the output magnitude and polarity can be achieved via an input bias current and control current, respectively.

II. CIRCUIT PRINCIPLE

A. BiCMOS Current Controlled Current Conveyor (BiCMOS CCCII)

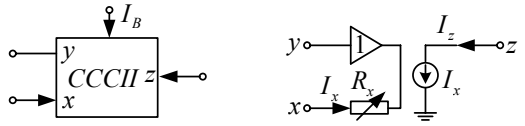
CCCII is a versatile analog building block which is similar to the conventional Current Conveyor (CCII) except that the CCCII has a finite input resistance (R_X) at the X terminal. CCCII has the advantage of electronic adjustability over the CCII, because it allows the adjustment of intrinsic resistance R_X via the bias current I_B as shown in the following equation.

$$R_X = \frac{V_T}{2I_B}. \tag{1}$$

Where V_T is the thermal voltage. The matrix-relationship between the voltage and current variables among port X, Y and Z of an ideal CCCII can be described by the following matrix equation

$$\begin{bmatrix} i_y \\ v_x \\ i_z \end{bmatrix} = \begin{bmatrix} 0 & 0 & 0 \\ 1 & R_x & 0 \\ 0 & \pm 1 & 0 \end{bmatrix} \begin{bmatrix} v_y \\ i_x \\ v_z \end{bmatrix}. \tag{2}$$

Where the positive and negative signs of the current i_z denote the positive (CCCII+) and negative type (CCCII-), respectively. The symbol and the equivalent circuit of the CCCII+ are illustrated in Fig.1.



(a) (b)

Figure 1. CCCII (a) symbol (b) equivalent circuit

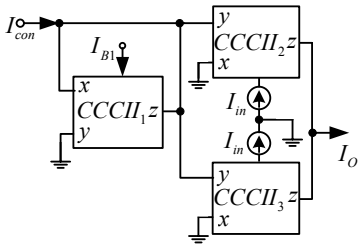


Figure 2. Proposed current-mode full-wave circuit

B. The proposed current-mode rectifier circuit

Fig. 2 displays the proposed current-mode rectifier circuit. Considering the circuit in Fig. 2 and using the CCCII properties described in section A, we will receive

$$i_{z2} = \begin{cases} \frac{I_{con}}{2I_{B1}} I_{in} & \text{if} \quad I_{in} > 0 \\ 0 & \text{if} \quad I_{in} < 0 \end{cases}, \tag{3}$$

$$i_{z3} = \begin{cases} 0 & \text{if} \quad I_{in} > 0 \\ \frac{I_{con}}{2I_{B1}} I_{in} & \text{if} \quad I_{in} < 0 \end{cases}, \tag{4}$$

and

$$I_o = i_{z2} + i_{z3} = \frac{I_{con}}{2I_{B1}} |I_{in}|. \tag{5}$$

It can be seen form Eq. (5) that the circuit in Fig. 2 can perform as a precision current-mode full-wave rectifier whose output magnitude can be controlled via controlled current I_{con} or I_{B1} and is theoretically temperature independent.

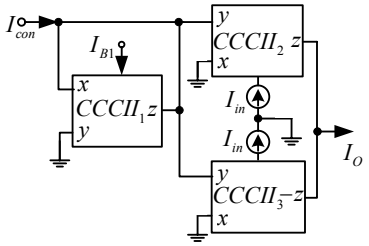

Figure 3. Proposed class B push-pull current amplifier circuit

C. The proposed class B push-pull current amplifier circuit

Fig. 3 shows the proposed class B push-pull current amplifier. Considering the circuit in Fig. 3 and using the CCCII properties described in section A, we will receive

$$i_{z2} = \begin{cases} \frac{I_{con}}{2I_{B1}} I_{in} & \text{if} \quad I_{in} > 0 \\ 0 & \text{if} \quad I_{in} < 0 \end{cases}, \tag{6}$$

$$i_{z3} = \begin{cases} 0 & \text{if} \quad I_{in} > 0 \\ -\frac{I_{con}}{2I_{B1}} I_{in} & \text{if} \quad I_{in} < 0 \end{cases}, \tag{7}$$

and

$$I_o = i_{z2} + i_{z3} = \frac{I_{con}}{2I_{B1}} I_{in}. \tag{8}$$

It can be seen from Eq. (8) that the circuit in Fig.3 can perform as class B push-pull current amplifier whose current gain can be controlled via control current I_{con} or I_{B1} and which is temperature independent.

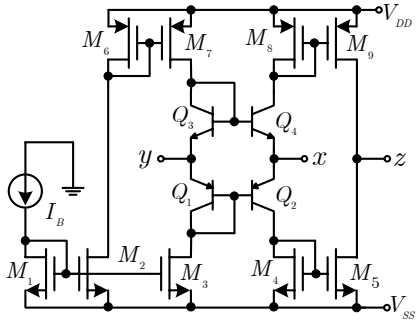

Figure 4. Internal construction of BiCMOS CCCII

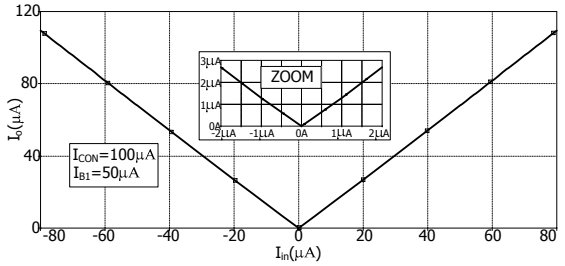
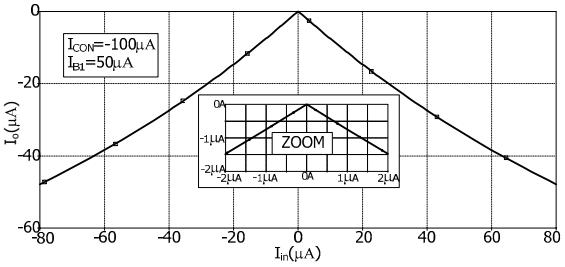
III. SIMULATION RESULTS

To prove the performances of the proposed circuits, the PSPICE simulation program was used for the examinations. The PNP and NPN transistors employed in the proposed circuit were simulated by using the parameters of the PR200N and NR200N bipolar transistors of ALA400 transistor array from

AT&T [18]. The PMOS and NMOS transistors were simulated by using the parameters of a 0.35µm TSMC CMOS technology [19]. The aspect transistor ratios (W/L) of PMOS and NMOS are 55/2.4µm and 12/2.4µm, respectively. The circuit was biased with ±1.5V supply voltages. Fig. 4 displays the internal construction of the CCCII used in the proposed circuit. Fig.5 shows DC transfer characteristics of proposed rectifier, where $I_{B1}=50\mu A$ and $I_{con}=100\mu A$. It can be seen that the proposed circuit can provide a wide range of input currents and that the polarity of the output current can easily be changed by the change of polarity of the control current I_{con}. Fig. 6 shows the output current versus temperature variations at $27^{\circ}C$, $50^{\circ}C$ and $100^{\circ}C$. It is clearly observed that the output current is almost not dependent on the temperature variations due to internal temperature compensation in the CCCIIs used in the circuit, as explained earlier.



(a) *with* $I_{con} = 100\mu A$



(b) with $I_{con} = -100\mu A$

Figure 5. DC transfer characteristics of proposed rectifier

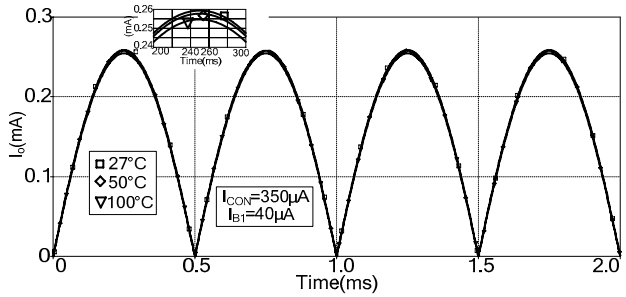


Figure 6. Output current with temperature variations

The output current responses with various input frequencies are also shown in Fig. 7. They confirm that the proposed circuit can rectify when frequency is up to megahertz range without disturbing magnitude of the output current. Fig. 8 displays the output currents as a function of the control current I_{con} while $I_{in}= 50\mu A$. These figures prove that the magnitude of the output current can easily be controlled electronically in accordance with the theoretical anticipations.

(b) 1MHz

Figure 7. The results of output current with various input frequencies

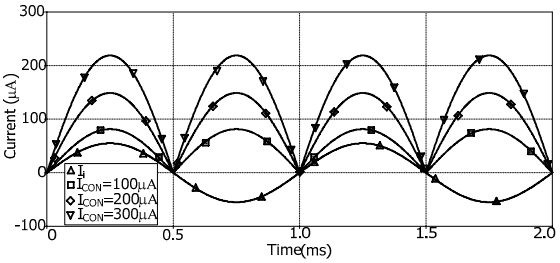

Figure 8: Output currents relative to input current

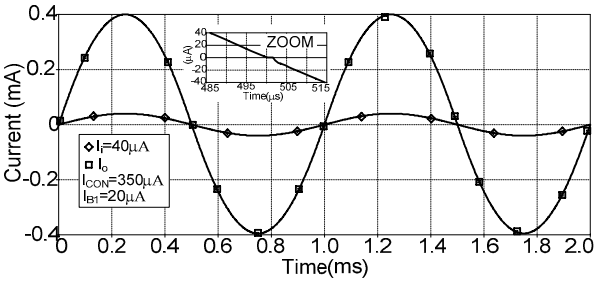

Figure 9. Output current due to input current of proposed current amplifier

The proposed controllable gain class B push-pull current amplifier in Fig. 3 was tested by setting $I_{in}=40\mu A$ and $f=1kHz$, the results obtained are shown in Fig. 9. Fig. 10 shows the current transfer characteristic of the proposed current amplifier circuit. Fig. 11 represents plots of the current gain $Ai = I_{out}/I_{in}$ versus the control current. Fig. 12 shows the output current relative to temperature variations at $27^{o}C$, $50^{o}C$ and $100^{o}C$. Fig. 13 insists that the proposed circuit can also amplify current signal when frequency is up to megahertz range. Slight cross over distortion at high frequency stems from the parasitic elements in the CCCIIs.

IV. CONCLUSIONS

The novel current-mode precision rectifier and push-pull current amplifier, based on BiCMOS CCCIIs, which can rectify and amplify an input current with electronic controllability of output magnitude, have been reported in this paper. In addition, direction of the output current signal can be arbitrarily controlled by current in the circuit to be either positive or negative without changing circuit topology, which differs from the previous literatures. Each circuit description merely consists of 3 CCCIIs. The performances of the proposed circuits have been also investigated through PSPICE. They show that the proposed circuits can function as a current-mode precision full-wave rectifier and class B push-pull current amplifier where input current range from *-80μA* to *80μA* can be achieved at *±2.5V* power supplies. The maximum power consumption is 1.43mW. Furthermore, the highest frequency is restricted at up to megahertz range. With claimed outstanding features, it is very appropriate to further develop the proposed circuits to be a part of a monolithic chip for working in a current-mode signal processing.

***Abstract* - This paper proposes to simultaneously analyze far-field diffraction patterns in both reflection and transmission modes in order to investigate the dimensions of a micron-size object. Our experimental demonstration shows a promising result obtained from both modes of operation. However, the quality of all edges of the object induces a variation in optical intensity, causing a small fluctuation in our measurement. This result also implies that if both modes of operation provide different results, a surface perpendicularity problem might occur on the object and our proposed non-invasive diffraction-based dimensions analyzer structure can be used to investigate this issue.**

I. INTRODUCTION

There are several optically noninvasive techniques for measuring shape and size of an object [1]. These include vibration insensitive approaches such as a time of flight method, an optical triangulation approach, a moiré technique, and a laser speckle pattern sectioning method, where a high resolution electronic controller is required and a minimum object size is limited to submillimeters. A smaller object size can also be accurately investigated by using an interferometric method but it needs a very good vibration control system. In addition, because these techniques typically operate in the reflection mode in which only one surface (e.g., front surface) of the object is analyzed, it is not appropriate to use in applications where the effect of front and back surfaces of the object (e.g., a harddisk slider) need to be taken into consideration. Hence, it would be highly desirable to have a measurement system that can determine the object dimensions in both reflection and transmission modes and it is also insensitive to the vibration.

One promising optical metrology approach is Fourier Optics [2] that can be used to analyze the object size and dimensions through its near-field or far-field diffraction pattern. Previously, it was used in a transmission mode for classifying biological cells [3], studying small cracks [4], and determining size and shape of the objects [5-6]. With this in mind, this paper proposes to simultaneously investigate the far-field diffraction patterns of the micron-size object in both reflection and transmission modes.

II. OUR PROPOSED ARCHITECTURE

Fig.1 shows our proposed non-contact diffraction-based dimensions analyzer architecture. In our scheme, an incident collimated optical beam having an operating wavelength of λ passes through an optical beam splitter (BS) where the amplitude of the optical beam is equally split into two optical beams. One optical beam is reflected by 90° to the right hand side and it is blocked by an absorber. Another optical beam travels through the BS and it partially falls on a micron-size object. In this way, part of the optical beam that hits the front surface of the object will be reflected back to the BS. It is then directed by the BS to a spherical lens (S1) where it is Fourier transformed onto a camera 1 (Cam1) located at a distant of F from the lens S1. Similarly, the remaining part of the incident optical beam will pass through all edges of the object and then a mirror (M) sends it to the Cam2 via another Fourier transform lens S2. Two recording diffraction patterns will be analyzed by an electronic control unit (ECU). By assuming that our tested object is a rectangle like a harddisk drive slider, a normalized optical intensity of the diffraction pattern in a reflection mode can be mathematically written as follows [2].

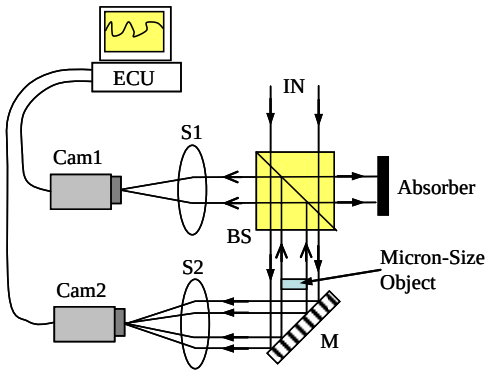

Fig.1 Our non-contact vibration-insensitive diffraction-based dimensions measurement architecture.

$$I(x,y) = K\left|\left[\frac{\sin\left(\frac{\pi d_x x}{\lambda F}\right)}{\frac{\pi d_x x}{\lambda F}}\right]\left[\frac{\sin\left(\frac{\pi d_y y}{\lambda F}\right)}{\frac{\pi d_y y}{\lambda F}}\right]\right|^2, \quad (1)$$

where K is a constant. d_x and d_y are the dimensions of the object in the x and y axes, respectively. Similarly, a normalized optical intensity of the diffraction pattern in a transmission mode can also be expressed as.

$$I(x,y) = K\left|\delta(x,y) - \left[\frac{\sin\left(\frac{\pi d_x x}{\lambda F}\right)}{\frac{\pi d_x x}{\lambda F}}\right]\left[\frac{\sin\left(\frac{\pi d_y y}{\lambda F}\right)}{\frac{\pi d_y y}{\lambda F}}\right]\right|^2. \quad (2)$$

From eqns(1) and (2), it is obvious that the object sizes along the x and y axes can be verified from the far-field diffraction pattern. The spacing between adjacent diffracted order beams also depends on λ and F.

III. Our Experimental Demonstration

We follow our proposed structure shown in Fig.1 by using a measured 638-nm wavelength laser diode with a fiber-connectorized collimator that provides a measured 3-mm 1/exp(2) output optical beam diameter with a < 0.3 mrad optical beam divergence. A camera available in our laboratory is used in our experiment having 640×480 active pixels with a pixel pitch of 8.4 μm and it is interfaced through our computer via a 10-bit frame grabber. A spherical lens has a focal length of 30 cm and our test object is a very fine and well fabricated harddisk drive slider. Its measured dimensions is 691μm × 835 μm by using a scanning electron microscope (SEM) as shown in Fig.2.

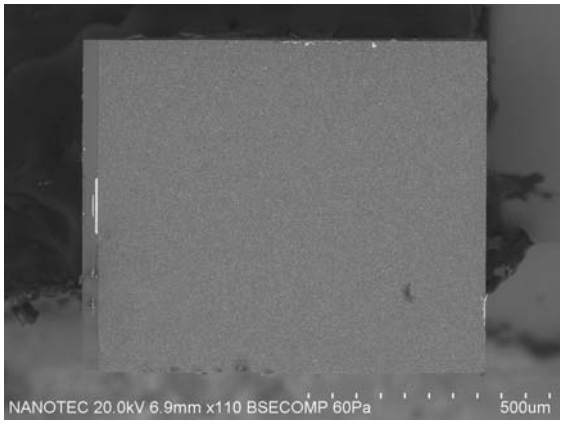

Fig. 2 SEM Image of our test object

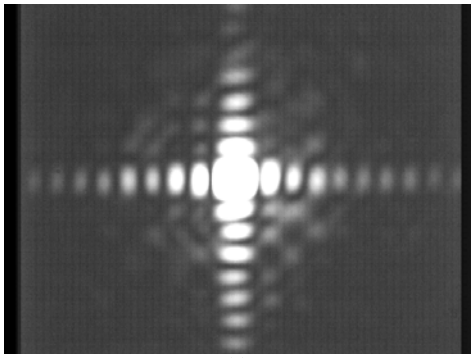
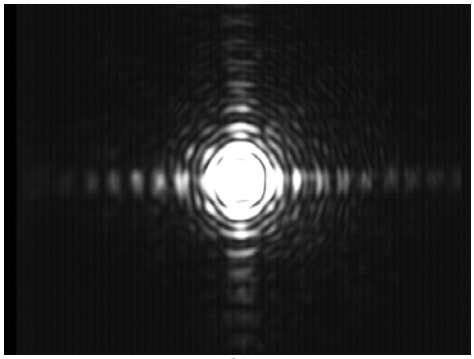
Fig.3 shows snap shots of two far-field diffraction patterns obtained from the reflection and transmission modes. These two far-field diffraction patterns agree very well with our mathematical expressions in eqns(1) and (2). By determining the spacing between adjacent diffracted order beams and using eqn(1) or eqn(2), the length and the width of the object can be determined.



(a)



(b)

Fig.3 Far-field diffraction patterns from our rectangular object observed in (a) reflection and (b) transmission modes.

Table 1 Our Experimental Result

Modes of Operation	**Dimensions of Object from Diffracted Order Beams**			
	Left	**Right**	**Top**	**Bottom**
Reflection	690 μm	696 μm	800 μm	794 μm
Transmission	691 μm	696 μm	815 μm	800 μm

From Fig.3, as there are four wings on each diffraction pattern, the diffracted order beams on the left and right hand sides are used to determine the width of the object while the diffracted order beams on the top and bottom sides are used for calculating the length of the object. Another good thing about using this well-fabricated rectangular object as well as its Fourier transform for our analysis is the symmetry of the far-field diffraction pattern that provides an orientation invariant property. As a result, when the object is rotated, its far-field

diffraction pattern is also changed accordingly without affecting the spacing between adjacent diffracted order beams. Table 1 summarizes our calculated data, indicating that both modes of operation give similar results. This result also implies that if both modes of operation provide different results, a surface perpendicularity problem might occur on the object which more or less can affect the performance of the harddisk drive slider. Note that the surface perpendicularity of the object cannot be investigated directly from the SEM. In addition, if we compare our experimental result in Table 1 with our SEM result, there are errors of < 5 μm and < 40 μm along the width and the length of the object, respectively. These errors come from a variation in optical diffraction intensity that can affect the spacing between adjacent diffracted order beams. Hence, based on our experimental result, our proposed non-contact diffraction-based dimensions analyzer architecture is a low cost and vibration insensitive optical system that can be used to analyze the dimensions of a small object and has the possibility to examine the surface perpendicularity of the object.

IV. CONCLUSION

This paper proposes a far-field diffraction analyzer for simultaneously determining the object dimensions in both reflection and transmission modes of operation. Our experiment shows that both modes of operation give similar measuring results. In addition, if both modes of operation are employed, our far-field diffraction analyzer structure is a low cost and vibration insensitive optical system that has the possibility to indicate the surface perpendicularity problem of the object. However, a change in optical diffraction intensity has to be taken into consideration in order to reduce measuring errors. In the future, we plan to increase the number of test samples and statistically analyze our experimental result in order to clearly see the possibility of deploying it in the field.

***Abstract*- In this article, a novel circuit, which can function both as quadrature oscillator and universal biquad filter (lowpass, highpass and bandpass functions) is introduced. The features of the circuit are that, working as quadrature oscillator, the oscillation condition and oscillation frequency can be adjusted independently with the input bias currents: functioning as universal biquad filter, the quality factor and natural frequency can be tuned orthogonally via the input bias currents: the circuit can work as either the quadrature oscillator or the universal biquad filter without changing circuit topology: it provides output signals both in current-mode and voltage-mode simultaneously. The circuit description is very simple, consisting of merely 2 Current Controlled Current Differencing Transconducatance Amplifiers (CCCDTAs), 1 voltage buffer and 2 grounded capacitors. Without any external resistors and using only grounded elements, this circuit is then suitable for IC architecture. The PSPICE simulation results are depicted. The given results agree well with the theoretical anticipation. The circuit was biased with ±1.5V supply voltages.**

***Index Terms*- Biquad filter, Current-mode, CCCDTA**

I. INTRODUCTION

An oscillator and a filter are 2 basic important building blocks which are frequently employed in electrical engineering works. A quadrature oscillator is widely used because the circuit provides two sinusoids with 90° phase difference, as for example in telecommunications for quadrature mixers and single-sideband [1]. In similar, nowadays, the applications and advantages in the realization of various active transfer functions, called as universal biquad filters, have received considerable attention. A universal filter may be used in phase locked loop FM stereo demodulators, and crossover networks used in three-way high fidelity loudspeakers [2]. However, a current-mode universal filter has being been more popular than voltage-mode one. This is due to operating in low-voltage environment as in portable and battery-powered equipment. Since a low-voltage operating circuit becomes necessary, the current–mode technique is ideally suited for this purpose more than the voltage-mode one. Presently, there is a growing interest in synthesizing the current-mode circuits because of more their potential advantages such as larger dynamic range, higher signal bandwidth, greater linearity, simpler circuitry and lower power consumption [3]. However, from our investigations, there are seen that the previous literatures have proposed the universal filters and the quadrature oscillators require too many components and component matching conditions [4]. Some universal filters require floating capacitors, which is not ideal for IC implementation [5]. In addition, each circuit can work only one function, either quadrature oscillator or universal filter. Recently, the versatile quadrature oscillator and biquad filter using current controlled current differencing buffered amplifier (CCCDBA) was proposed [6]. Unfortunately, it is rather complicated topology, due to consisting of 3 CCCDBAs and 2 grounded capacitors, which results in low frequency of operation and high power consumption.

The purpose of this paper is to introduce a current-mode universal biquad filter, based on CCCDTA as the active building block recently proposed in [7], providing three standard transfer functions (lowpass, highpass and bandpass). The natural frequency can be adjusted independently from the quality factor. Moreover, in case of no input current and appropriated condition, the proposed circuit can provide quadrature sinusoidal signals in both voltage-mode and current-mode simultaneously. The circuit construction consists of 2 CCCCTAs, 1 voltage buffer and 2 grounded capacitors. The PSPICE simulation results are also shown, which are in correspondence with the theoretical analysis.

II. CIRCUIT PRINCIPLE

A. The Current Controlled Current Differencing Transconductance Amplifier (CCCDTA)

Since the proposed circuit is based on CCCDTAs, a brief review of CCCDTA is given in this section. Basically, the CCCDTA is composed of translinear elements, mixed loops and complementary current mirrors. Generally, CCCDTA properties are similar to the conventional CDTA, except that input voltages of CCCDTA are not zero and the CCCDTA has finite input resistances R_p and R_n at the p and n input terminals, respectively. These parasitic resistances are equal and can be controlled by the bias current I_{B1} as shown in Eq. (1)

$$\begin{bmatrix} V_p \\ V_n \\ I_z \\ I_x \end{bmatrix} = \begin{bmatrix} R_p & 0 & 0 & 0 \\ 0 & R_n & 0 & 0 \\ 1 & -1 & 0 & 0 \\ 0 & 0 & 0 & \pm g_m \end{bmatrix} \begin{bmatrix} I_p \\ I_n \\ V_x \\ V_z \end{bmatrix}. \quad (1)$$

When $$R_p = R_n = \frac{V_T}{2I_{B1}} \quad (2)$$

and $$g_m = \frac{I_{B2}}{2V_T}. \quad (3)$$

Where g_m is the transconductance of the CCCDTA and V_T is the thermal voltage. The symbol and the equivalent circuit of the CCCDTA are illustrated in Figs. 1(a) and (b), respectively.

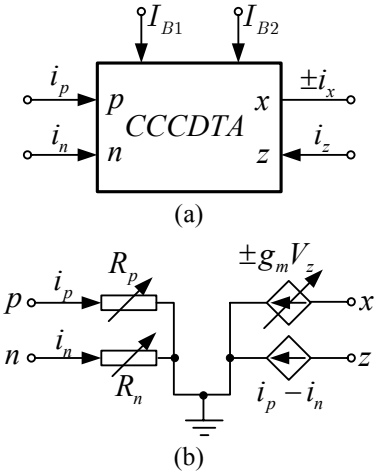

Figure 1. CCCDTA (a) Symbol (b) Equivalent circuit.

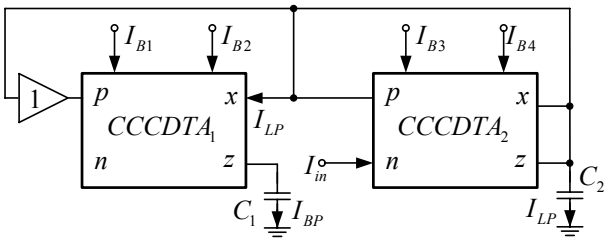

Figure 2. Proposed circuit working as universal filter

B. The operation of proposed circuit working as a universal biquad filter

Fig. 2 demonstrates the circuit scheme of the proposed circuit working as the universal filter. The depicted bias currents; I_{B1}, I_{B2}, I_{B3} and I_{B4} are respectively the input bias currents of CCCDTA1 and CCCDTA2. From the circuit and the CCCDTA properties in section A including routine analysis, the following current transfer functions are obtained

$$\frac{I_{HP}}{I_{in}} = \frac{s^2}{s^2 + \left(\frac{2}{R_{p2}} - g_{m2}\right)\frac{s}{C_2} + \frac{g_{m1}}{R_{p1}C_1C_2}}, \quad (4)$$

$$\frac{I_{LP}}{I_{in}} = \frac{g_{m1}/C_1C_2R_{P1}}{s^2 + \left(\frac{2}{R_{p2}} - g_{m2}\right)\frac{s}{C_2} + \frac{g_{m1}}{R_{p1}C_1C_2}}, \quad (5)$$

$$\frac{I_{BP}}{I_{in}} = \frac{s/C_2R_{P1}}{s^2 + \left(\frac{2}{R_{p2}} - g_{m2}\right)\frac{s}{C_2} + \frac{g_{m1}}{R_{p1}C_1C_2}}. \quad (6)$$

From Eqs. (4)-(6), the parameters ω_0 and Q_0 can be expressed as

$$\omega_0 = \sqrt{\frac{g_{m1}}{R_{P1}C_1C_2}}, \quad (7)$$

$$Q_0 = \omega_0 \frac{C_2}{(2/R_{P2}) - g_{m2}}. \quad (8)$$

For easy consideration, if $I_{B1}=I_{B2}=I_B$ and $C_1=C_2=C$, Eqs. (7) and (8) can be reduced to

$$\omega_0 = \frac{I_B}{V_TC}, \quad (9)$$

$$Q_0 = \frac{I_B}{4I_{B3} - (I_{B4}/2)}. \quad (10)$$

It is obviously found that, from Eqs. (9) and (10), the quality factor can be adjusted by I_{B3} or I_{B4} without affecting the pole frequency. Reversely, the pole frequency can be controlled via I_B. In addition, bandwidth (BW) of the system can be expressed by

$$BW = \frac{\omega_0}{Q_0} = \frac{4I_{B3} - (I_{B4}/2)}{V_TC}. \quad (11)$$

In the same view, the bandwidth can be linearly tuned by I_{B3}. Another advantage of the proposed circuit is that the high Q_0 circuit can be obtained by setting $I_{B4}/2$ close to $4I_{B3}$, which differs from conventional universal filters in such that the maximum Q_0 is limited by component values.

C. Circuit Sensitivities

The sensitivities of the proposed circuit are low and can be found as

$$S_{I_B}^{\omega_0} = 1;\ S_C^{\omega_0} = -1, \quad (12)$$

and

$$S_{I_B}^{Q_0} = 1;\ S_{I_{B3}}^{Q_0} = \frac{-4I_{B3}}{4I_{B3} - (I_{B4}/2)},\ S_{I_{B4}}^{Q_0} = \frac{I_{B4}}{8I_{B3} - I_{B4}}. \quad (13)$$

D. The operation of proposed circuit working as a quadrature oscillator

If no input current applied to the circuit as shown in Fig. 3, system characteristic equation can be expressed as

$$s^2 + \left(\frac{2}{R_{p2}} - g_{m2}\right)\frac{s}{C_2} + \frac{g_{m1}}{R_{p1}C_1C_2}. \quad (14)$$

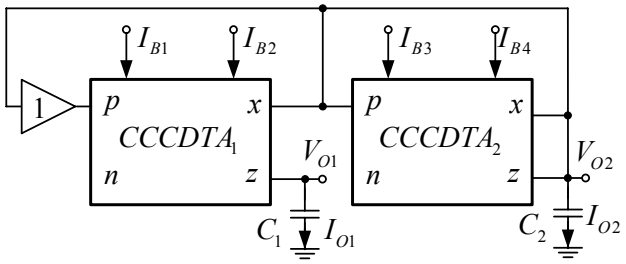

Figure 3. Proposed circuit working as quadrature oscillator

From Eq. (14), it can obviously be seen that the proposed circuit can be set to be an oscillator if

$$\frac{2}{R_{p2}} = g_{m2}. \quad (15)$$

Eq. (15) is called as condition of oscillation, this is achieved by $I_{B3}= I_{B4}/8$, then the oscillation frequency of this system can be obtained as

$$\omega_0 = \sqrt{\frac{g_{m1}}{R_{P1}C_1C_2}}. \quad (16)$$

If letting $I_{B1}=I_{B2}=I_B$ and $C_1=C_2=C$, Eq. (16) can be reduced to

$$\omega_0 = \frac{I_B}{V_T C}. \quad (17)$$

It can be seen that the oscillation frequency (ω_0) can be linearly controlled by bias current.

Furthermore, the quadrature sinusoidal signals can be simultaneously obtained at I_{O1} and I_{O2} or V_{O1} and V_{O2} as seen in Fig. (3), in current-mode and voltage-mode, respectively. The free terminals of I_{O1} and I_{O2} can be achieved by using multiple Z-terminal output CCCDTAs.

E. Non-ideal case

For non-ideal case, the I_z and I_x of CCCDTA can be respectively characterized by

$$I_z = \alpha_p I_p - \alpha_n I_n, \quad (18)$$

and

$$I_x = \beta V_z. \quad (19)$$

Where α_p, α_n and β are transferred error values deviated from one. In the case of non-ideal and brief consideration, the ω_0 and Q_0 are changed to

$$\omega_0 = \sqrt{\frac{\alpha_p\beta_1\beta_b g_{m1}}{R_{p1}C_1C_2}}, \quad (20)$$

$$Q_0 = \omega_0 \frac{C_2}{\left(1+\alpha_{p2}\right)/R_{P2} - \beta_2 g_{m2}}. \quad (21)$$

III. Simulation Results

To prove the performances of the proposed circuit, the PSPICE simulation program was used for the examination. The PNP and NPN transistors employed in the proposed circuit were simulated by respectively using the parameters of the PR200N and NR200N bipolar transistors of ALA400 transistor array from AT&T [6]. Fig. 4 depicts schematic description of the CCCDTA used in the simulations, the ideal voltage buffer was used in the simulations. The CCCDTAs were biased with ±1.5V power supplies, the capacitor values of C_1 and C_2 are 1nF. Firstly, the operation as the universal biquad filter is verified. The gain responses of the proposed universal filter are shown in Fig. 5. It shows that the proposed filter obtains LP, HP and BP responses at the same time. By varying I_{B4} to 100μA, 200μA and 3000μA, only the quality factor is changed as shown in Fig. 6. Therefore, it is confirmed that the quality factor can be adjusted by I_{B3} or I_{B4} which is linearly independent of the pole frequency, as mentioned.

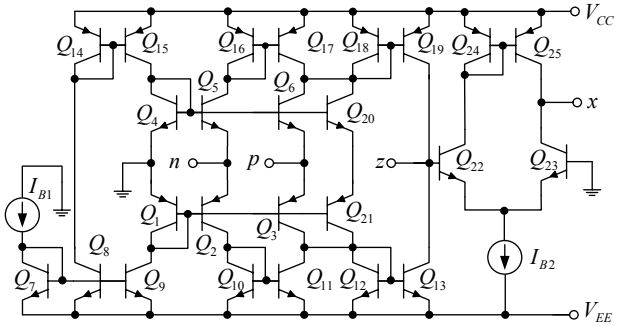

Figure 4. Internal construction of CCCDTA

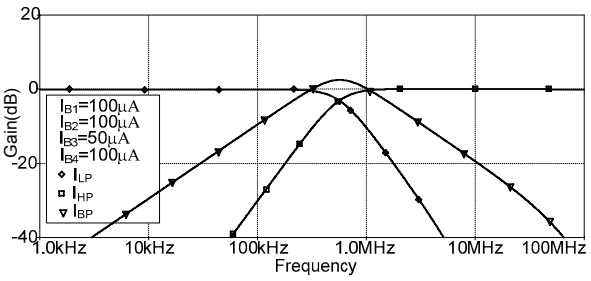

Figure 5. Gain response of the proposed circuit working as universal biquad filter

Fig. 7, 8 and 9 show the responses when operating as quadrature oscillator, where the total harmonic distortion (THD) is about 1.12% and the maximum operating frequency is approximately 1.58MHz.

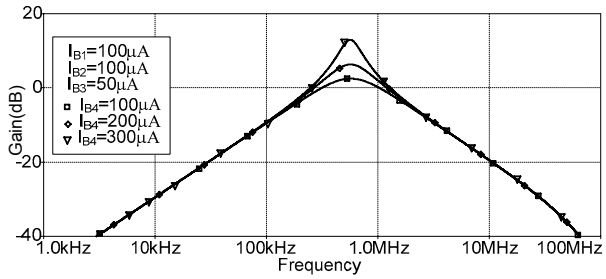

Figure 6. BP response when I_{B3} is varied

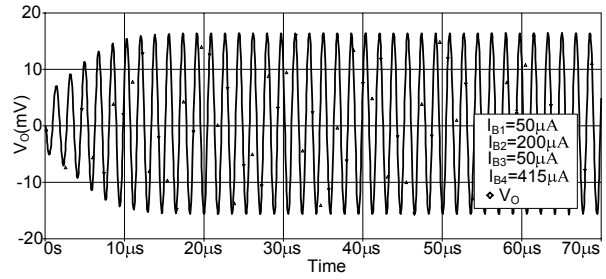

Figure 7. The simulation results of waveforms when working as quadrature oscillator

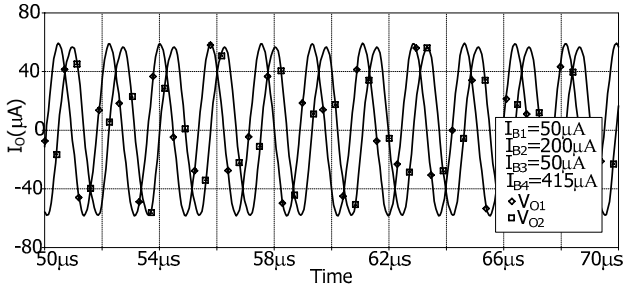

Figure 8. The simulation results of current waveforms of quadrature oscillator

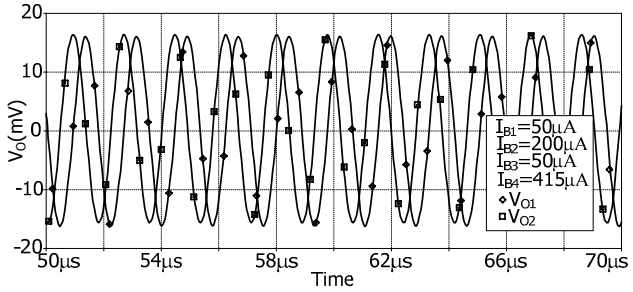

Figure 9. The simulation results of voltage waveforms of quadrature oscillator

IV. CONCLUSION

The novel circuit, which can function both as quadrature oscillator and current-mode universal biquad filter has been presented. The proposed circuit can work as either the quadrature oscillator or the universal biquad filter without changing a circuit topology. Working as current-mode universal biquad filter, the quality factor and pole frequency can be tuned orthogonally via the input bias currents. When no input current and suitable condition, the proposed circuit can function as a quadrature oscillator. Its oscillation condition and oscillation frequency can be adjusted independently with the input bias currents. It can provide quadrature sinusoidal signals in both voltage-mode and current-mode simultaneously. The PSPICE simulation results are well agreed with the theoretical anticipation with maximum power dissipation of 1.03mW at ±1.5V supply voltages. Since it consists of merely 2 CCCCTAs, 1 voltage buffer and 2 grounded capacitors, this circuit is then suitable for an IC architecture.

***Abstract* – This paper proposes and experimentally demonstrates a fiber-connectorized optical system that can be used to study both the optical transmittivity and phase retardation of the material. Our key idea comes from the inherent advantage of the fiber loop mirror (FLM) in which all optical components are easily connected to each other without the need of a precise free-space optical alignment. In addition, its two output optical powers can be controlled via adjusting the phase retardation inside the FLM. Our experimental proof of concept using three known waveplates shows promising results which agree very well with our theoretical analysis.**

I. INTRODUCTION

A variety of optical sensing structures has been proposed and demonstrated for measuring some optical properties of materials. For example, an optical absorption coefficient (α) can be determined by using a typical optical spectrometer [1] where the optical power emerging from the test material is compared to the incident optical beam power, also called the optical transmittivity. Apart from the α of the material, another interesting parameter of the material is its birefringence (Δn) which tells us how different states of polarized lights refract into the material and suffer different phase delay. It is sometimes mentioned as a phase retardation ($\Delta\phi$) as well. In this case, another instrument such as a polarimeter is needed. With this in mind, it is obvious that only one equipment can handle in measuring only one interesting parameter. In addition, these instruments are designed and implemented in a free-space architecture and therefore a precise free-space optical alignment is a very important issue. Hence, it would be desirable to have a fiber-based optical instrument in which more than one parameters (e.g., both optical transmittivity and $\Delta\phi$) can be investigated.

One of the promising fiber-based optical structures is the fiber loop mirror (FLM) [2]. Since its invention in 1988, it has been proposed and experimentally demonstrated for optical fiber current sensors [3], liquid-level sensors [4], microwave filters [5], and multiwavelength 2x2 add-drop switches [6]. Based on the operating principle of the FLM, this paper proposes and experimentally demonstrates how the FLM structure can be explored in investigating both the optical transmittivity and the $\Delta\phi$ of the material [7].

II. OUR PROPOSED ARCHITECTURE

Fig.1 shows our proposed FLM-based absorption and phase retardation measurement structure. In our proposed FLM-based structure, an optical beam is fed in at the IN port and it passes through a fiber-optic circulator where the optical beam is allowed to go from the left to the right hand sides. Once the optical beam comes out of the fiber-optic circulator, it then travels to a 2x2 fiber-optic coupler in which its amplitude is split into two equal amplitude optical beams. In this case, one optical beam travels clockwise passing through a polarization controller (PC) and two fiber-optic collimators. Another optical beam also travels anticlockwise passing two fiber-optic collimators and then the PC.

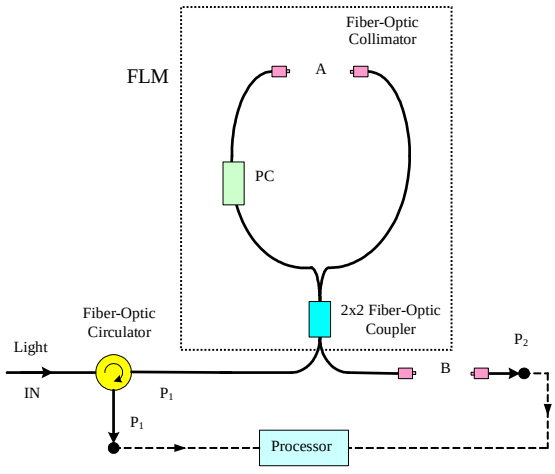

Fig. 1 Our proposed FLM-based optical absorption and phase retardation measurement architecture.

From the basic operation of the FLM, the relationship between output optical powers at the port1 and port2 can be written as follows [2].

$$\frac{P_1}{P_1+P_2} = 4K(1-K)|J|^2, \quad (1)$$

and

$$\frac{P_2}{P_1+P_2} = 1-4K(1-K)|J|^2, \quad (2)$$

where

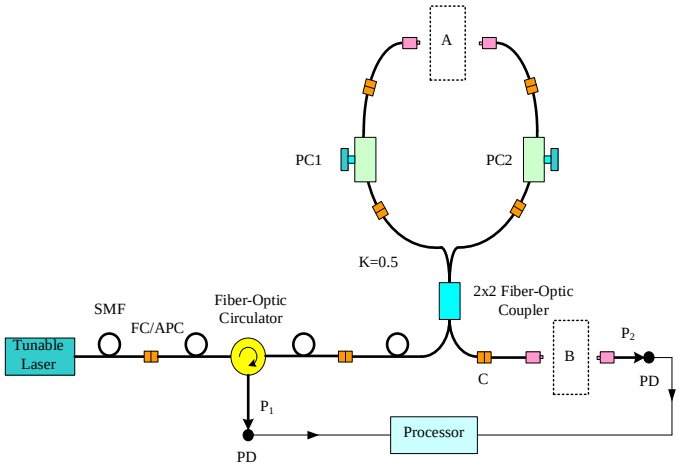
$$J = e^{j\Delta\phi}\sin^2\theta + \cos^2\theta. \quad (3)$$

Here, θ is the orientation angle of the phase retardation plate and K is the coupling ratio of the 2x2 fiber-optic coupler. Δϕ is equal to 2πLΔn/λ and it is the phase retardation between the ordinary and extraordinary rays. Δn is the birefringence of the material (e.g., an optical fiber), L is the length of the optical fiber, and λ is the operating wavelength.

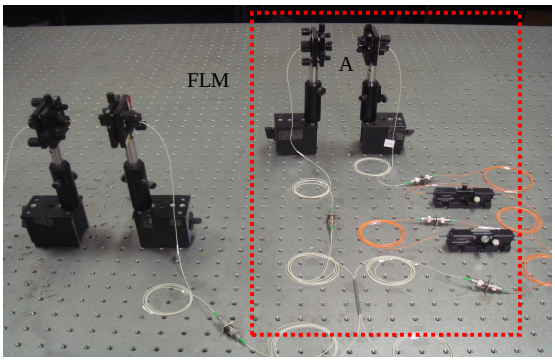
This basic FLM operation implies that if we have a test sample inside the FLM (i.e., at A), the Δϕ of the sample can inherently determined by just rotating the test sample on the plane normal to the propagation direction of the optical beam and then measuring the optical power ratio expressed in eqn(1) or eqn(2). Apart from the Δϕ of the test sample, the optical transmittivity of the test sample can also be investigated by just inserting the test sample at the position B outside the FLM and initially adjusting the FLM in such a way that we obtain the maximum P_2. These two operations indicate that both the optical transmittivity and the Δϕ of the test sample can be studied in our proposed FLM-based architecture.

III. Our Experimental Demonstration

To verify our proposed FLM-based absorption and phase retardation measurement concept, our experimental setup is shown in Fig.2. In this case, a tunable laser diode in the C-band telecomm region is connected to the fiber-optic circulator via a fiber-connectorized/angle polished contact (FC/APC) adapter. A 2x2 fiber-optic coupler having K of 50% splitting ratio is also employed. Two mechanically controlled PCs (e.g., PC1 and PC2) are inserted inside the FLM in order to easily and initially adjust the appropriate Δϕ of the FLM. In addition, a photodetector (PD) is used to measure both the output optical powers P_1 and P_2. In our experiment, we also use three known zero-order waveplates as our test samples and they are situated on a rotational stage having 2.5 deg per step. The first two known zero-order waveplates are the quarter waveplate (QWP1) (i.e., a 90-deg waveplate) and the half waveplate (HWP1) (i.e., a 180-deg waveplate) designed to operate at a 1550-nm wavelength [8]. The last one is the HWP designed to operate at a 632.8-nm (HWP2). For our optical absorption analysis, we initially adjust the two PCs inside the FLM such that we have a maximum optical output power at the port2.



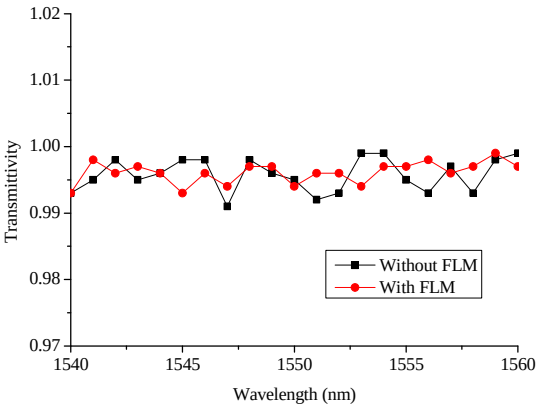
(a)



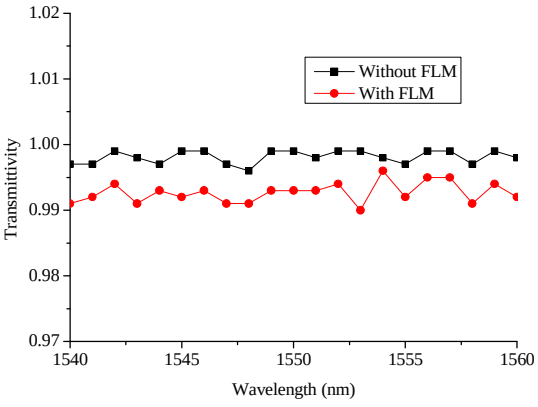
(b)

Fig. 2 (a) Schematic illustration of our experimental setup and (b) photograph of our experimental setup taken at the FLM section. SMF: Single mode optical fiber.

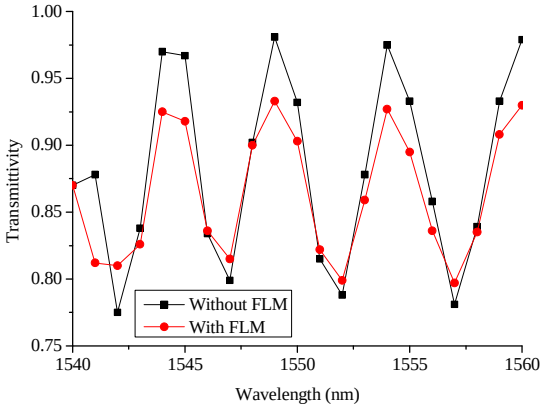
Before testing the sample, we have to make sure that there is less amount of the optical beam reflected back from the FLM to the port1. This can be analyzed by looking at the optical isolation of the system and it is defined as the ratio between the output optical power at the port2 and the output optical power at the port1. In this case, the measured optical isolation is 33.1±1.2 dB over a 20 nm wavelength band. In other words, the ratio of P2 and P1 in our proposed FLM-based absorption and phase retardation measurement architecture is about 2089 which is high enough for investigating the test samples. The optical less of our proposed FLM-based absorption and phase retardation measurement architecture is also an important system issue. A measured optical loss of 2.47 dB is determined and it is limited by eight FC/APC adapters (0.2 dB), a one-way trip through the fiber-optic circulator (0.5 dB), two PCs (0.13 dB), and free-space coupling efficiency at the locations A and B (1.64 dB). Another important system issue is the polarization dependent loss (PDL). In this case, by scrambling the state of polarization of the input light in front of the fiber-optic circulator, a measured PDL of 0.38 dB is obtained.



(a)



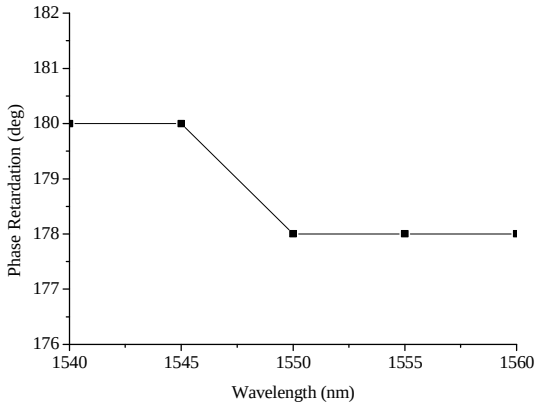
(b)



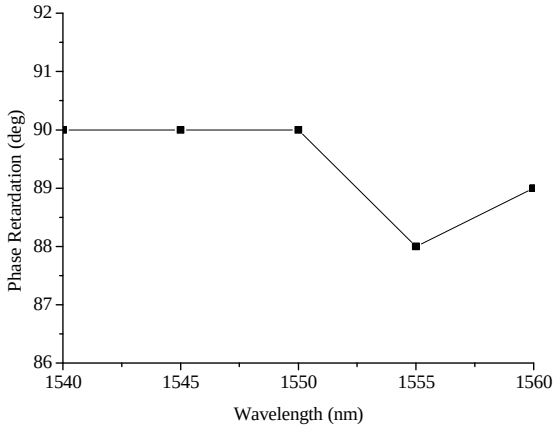
(c)

Fig. 3 Measured optical transmittivity versus operating wavelength for (a) QWP1, (b) HWP1, and (c) HWP2.

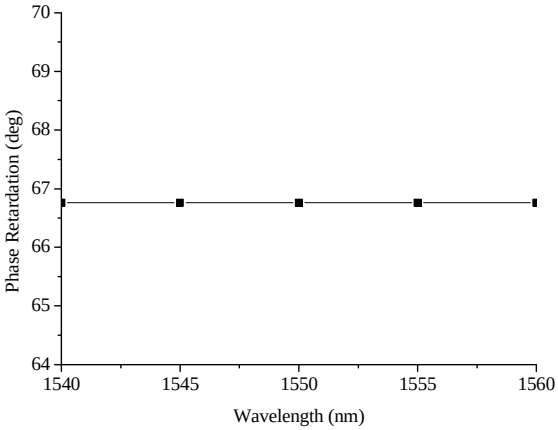
Later on, we place the test sample at the position B and our measured optical transmittivities are shown in Fig.3. We also compare our experimental results obtained from our proposed



(a)



(b)



(c)

Fig. 4 Measured optical phase retardation versus operation wavelength for (a) QWP1, (b) HWP1, and (c) HWP2.

FLM-based absorption and phase retardation measurement architecture with a typical spectrometer architecture. This can be done by just connecting the tunable laser directly at the position C. It can be observed that our experimental results for the HWP1 and QWP1 obtained from both architectures have less than 0.84% difference in measured optical transmittivity. For the HWP2, a variation of the measured optical transmittivities versus operating wavelength is much higher compared to the previous two samples. This is because at the 1540-1560 nm operating wavelength, the HWP2 which is optimally designed to operate at the 632.8 nm with a low optical loss value induces the Fabry-Perot interference effect. The FLM also pays an important role in inducing the optical loss in the structure and therefore a higher 6.6% difference in measurement between the two architectures is obtained. In addition, there is a very small < 0.9% fluctuation in our measured optical transmittivity values, limited by a < 3% accuracy of our PD used in our experiment [9].

For our $\Delta\phi$ analysis of the test sample, we initially adjust the two PCs inside the FLM so that we have a maximum reflected optical power at the port1. Then we insert our test sample at the position A and rotate it from 0 to 45 deg. Fig. 4 shows our $\Delta\phi$ measurement which agrees quite well with our theoretical analysis. There is also a 2 deg difference between our experimental results and the expected values and it is limited by our rotational stage. Note that for the HWP2, its phase retardation is reduced to 0.191x360 = 68.7 deg at the 1550 nm wavelength [10]. By varying the operating wavelength, $\Delta\phi$ values with a small error of < 2 deg are achieved, pointing out that our waveplate samples are indeed zero-order waveplates.

IV. CONCLUSIONS

We have proposed and experimentally demonstrated an FLM-based optical absorption and phase retardation measurement structure. Our key idea comes from the use of the inherent FLM operation, allowing the flexibility to control the optical output powers via varying phase retardation inside the FLM. Without the test sample, our proposed FLM-based absorption and phase retardation measurement system offers a very high measured optical isolation of 33.1 dB, a 2.47 optical loss, and a PDL of 0.38 dB. Our experimental demonstration using three known zero-order waveplates shows promising results associated with the expected values. Our experiment also confirms that these three waveplates are designed as zero-order waveplates. For our optical transmittivity study, our experimental result from the FLM-based structure corresponds to the result obtained from a non FLM system. In the future, we plan to test the performance of our FLM-based absorption and phase retardation measurement structure with other samples.

***Abstract*- The application of parametric spectral analysis for attenuation estimation on the reflected ultrasound signal of soft biological tissue. The attenuation coefficient used to estimate the projection data which used to reconstruct the image model. Tomogram of the soft tissue can be reconstructed by using its projections resolved from the ultrasonic broadband pulsed waves which pass through the tissue. While a data from ultrasonic transmission mode tomography cannot be used to image the character of soft tissue where shadowed by a bone, an ultrasonic reflection mode tomography is realized to be a solution for this. There are many ways to extract the projections, in most case the attenuation coefficient, of the tissue from the pulsed wave. Almost all of these methods were proved to implement with the transmission mode signal, but however, some adaptation may takes benefit from those method to implement with the reflection mode. We choose the spectral centre-frequency or centroid shift method to be analyzed because its advantage in a computational viewpoint. The simple filtered back-projection algorithm was implemented to reconstruct the tomographic images of the soft tissue suffered by bone. The results show the successful of this method over the transmission mode tomography.**

I. INTRODUCTION

The measurement of acoustic attenuation in biological tissue has received much interest in the field of ultrasound tissue characterization. Over the past decade, several clinical applications have shown a correlation between attenuation values and pathological states. For most biological tissues, the attenuation appears to be almost linearly dependent on frequency in the range of medical frequencies. Therefore, spectral analysis may lead to an estimation of attenuation. Generally, the attenuation estimation uses spectral methods. Many methods based on pulse echo techniques have been proposed for the estimation of the attenuation coefficient. They are based on either a time domain or a frequency domain processing of the reflected pulses. Then the ultrasonic computed tomography has an advantages over the X-ray computed tomography in some viewpoint; not only it is considered to be safer for a patient, but also we can record its waveform in the function of time and convert into function of frequency for spectrum analysis. However, the major problems of the ultrasound are expanded into two cases. Firstly, the diffraction and refraction of the ray while it get through the interfaces of the tissue where having difference reflective indexes make it travels not in the straight line, so we cannot use the line integral geometry as in the X-ray case. The approaches to this problem are somewhat more complicate, known as the Fourier diffraction theorem [6] and the filtered back-propagation algorithm [7]. But anyway, we still can use the straight line integration if we assume the soft biological tissue having a little change in the refractive index. But, the reflected pulse also contains the character of the tissue; brings us a possibility to utilize this waveform.

The conventional pulse-echo B-scan imaging [5] is one method that use the reflected pulse for reconstruct the tomogram, but the image only shows the interfaces of tissue, not the local properties of it. In the other hand, the ultrasonic transmission mode can image the local properties such as the refractive index or the attenuation coefficient of the tissue from the received pulse, many methods was reviewed in [3]. Recently, we used the reflected pulse to find the integrated attenuation coefficient using the linear least-square fitting method [1]. The simulated results show how the reflection mode superior over the transmission mode tomography where the tissue is shadowed by a bone.

II. REFLECTION-MODE ULTRASONIC TOMOGRAPHY

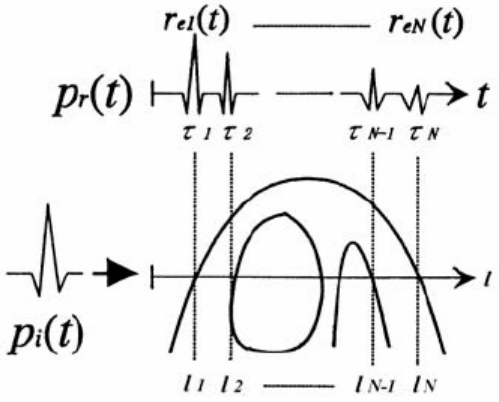

Figure 1. The waveform of incident and reflected pulse. Where the reflections occur at the tissue interfaces.

When the specimen is issued by the broadband ultrasonic pulse $p_i(t)$, the reflection of the pulse will occur every time it passes each interface where the refractive indexes are difference, subsequently return us the attenuated waveform pr(t) as illustrated in figure 1. Only the latest pulse in the waveform or $r_{en}(t)$ that we need, because it passes the entire tissue's length from l_1 to l_N and reflected at the N^{th} interface. The equations for the reflected waveform and concern parameters are written below. Keep in mind that we never know about the character of the reflectance and transmittance between each layer.

$$P_r(t) = \sum_{n=1}^{N} r_{en}(t) \tag{1}$$

$$r_{en}(t) = \sqrt{R_n}\left(\prod_{k=1}^{n-1} T_K\right) \times P_i(t-\tau_n) \times e^{-2\int_{l_1}^{l_N} \alpha(x,y,f_0)dl} \tag{2}$$

Where R_n and T_K are the reflectance and transmittance of the power at the n^{th} interface, τ_n is the delay time corresponding to the distance from the transducer to the n^{th} interface, and $\alpha(x, y, f)$ is the frequency-dependent attenuation coefficient of the tissue at coordinate (x, y). The latest reflected pulse must be converted to be in the frequency domain as shown in equation 3

$$R_{eN}(f) = \sqrt{R_N}\left(\prod_{K=1}^{N-1} T_K\right) \times P_i(f) \times e^{-2\int_{l_1}^{l_N} \alpha(x,y,f)dl} \times e^{-2j\int_{l_1}^{l_N} \beta(f)dl} \tag{3}$$

Where $\beta(f)$ is the phase shift of the reflected pulse $R_{eN}(f)$ and $P_i(f)$ is the incident pulse insonified along the object; T_K and R_N are transmittance and reflectance respectively which are never known for the case.

III. Evaluation of Attenuation Coefficient and Projection Data.

The latest ultrasound signal $r_{en}(t)$ reflected by a biological tissue is digitized with a sampling interval $\Delta t = 1/F_S$ in N samples (F_S is the sampling frequency, T is the signal duration). On this signal $r_{en}(t)$, a window of T_W seconds (N_W samples) is shifted with a constant step T_r (N_r samples). In each window centered at position τ_i, the spectrum is evaluated with a spectrum estimator and we estimate the center frequency or spectral centroid defined by

$$f_C(\tau_i) = \frac{m_1(\tau_i)}{m_0(\tau_i)} \tag{4}$$

Where

$$m_j(\tau_i) = \int_{-\infty}^{+\infty} f^i . R_{en}(\tau_i, f) df \tag{5}$$

Due to the random position of scatters in the medium, the output of the estimator fluctuates. The variance of the estimate is reduced by averaging the spectra of incident pulse independent (uncorrelated) the lasted pulse and/or echo signals.

With the classical assumption of a linear-with-frequency attenuation:

$$\alpha(x, y, f) = \beta(x, y).f \tag{6}$$

Where α is varied along to x and y axis with which attenuates by frequency f which equals to β then multiplied by frequency f; the system of this equation shows that they are the relation of linear-with-frequency attenuation which can be reviewed the detail in [2]. While the centroid-shift obtained as :

$$\beta = \frac{-8.68}{c\sigma^2(\tau)} \times \frac{df_C}{d\tau} \tag{7}$$

Where df_c is the spectral center-frequency which differ by the time $d\tau$ both of relation are expressed in *(MHz/s)*, then c is denoted for the speed of ultrasound in the tissue which is expressed in *(m/s)*; and finally, $\sigma^2(\tau)$ is Spectral variance of ultrasonic pulse in function of time, is expressed in *(MHz^2)*. Furthermore, the process of deriving the projection data shown as figure 2,

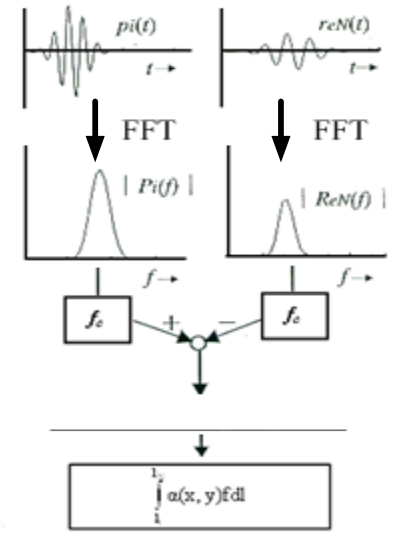

Figure 2. The process of derive the projection data

Figure 2 shows the process of deriving the projections where $p_i(t)$ and $r_{eN}(t)$ are the incident and the reflected pulse. Both Signals are converted into frequency domain by taking Fast Fourier Transform. The power spectrum is then computed. The spectrum centroid for each spectrum, equation (5), is derived. Then the centroid shift (df_c) between both spectrum can be computed Finally, the integration of attenuation coefficient β along the ultrasonic path is derived from equation (7) which is the a projection to be used in the reconstruction process.

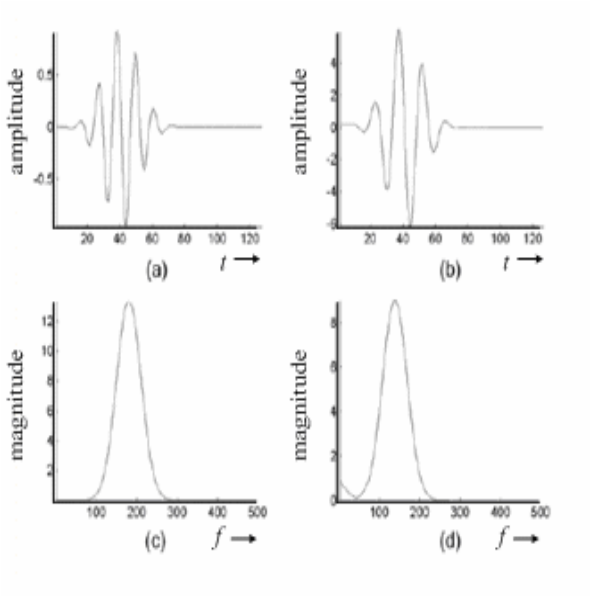

Figure 3. (a) and (b) are the incident pulse and reflected pulses. (c) and (d) are the power spectrum of incident pulse and reflected pulses respectively.

Figure 3 is the noise-free incident and reflected pulse respectively, which are converted into frequency domain then find the power spectrum of them, after that determine the spectral center-frequency f_c from those power spectrum and finally used the obtained values in attenuation estimation procedure.

IV. SIMULATION

A. Methods

This part starts from define parameters which are used inside Phantom or image model that used in this research; the detail of each size of the small phantom are filled as of the parameter. While the filled parameters are conformed to the characters of Human's abdomen, the detail of those parameter are shown as Table 1.

TABLE I
PARAMETERS IN CREATED PHANTOM

Center Coordinate(x,y)	Radius r	Gray Level	Alpha α
(00.00,00.00)	55.95	1.00	Bone
(00.00,-1.27)	53.39	0.50	Muscle
(15.29,00.00)	14.60	0.19	Tissue 1
(-15.29,00.00)	19.81	0.19	Tissue 2
(00.00,24.32)	15.95	0.09	Fat
(00.00,6.95)	3.20	0.15	Tissue 3
(00.00,-6.95)	3.20	0.15	Tissue 3
(-5.56,-42.05)	3.20	0.15	Tissue 3
(00.00,-42.05)	1.60	0.15	Tissues 4
(4.17,-42.05)	2.40	0.15	Tissue 4

Tomographic model created by using the parameters in Table 1, while it is summary of center coordinate of image *(x,y)*, radius in unit *(mm)*, gray level *(ρ)*is expressed begin from *0* to 1, respectively. In the simulation process, the model was issued by the *3.5 MHz* broadband ultrasonic pulse (figure3a), sampled at *40 MHz*, along the vertical axis, its latest reflected pulse were then calculated and resolved by the spectral center-frequency method to get the value of the integrated attenuation coefficient. Do this repeatedly on the horizontal axis from left to right; we got the array of attenuation coefficients, or called as the projection at the zero angle. Next, the model was rotated by the degrees of two to simulate and obtain the second projection. The process keeps going until we got 90 projections from the half-plane stepping rotation. Subsequently, the model was reconstructed from all of the projections using the simple filtered back-projection algorithm.

B. Results

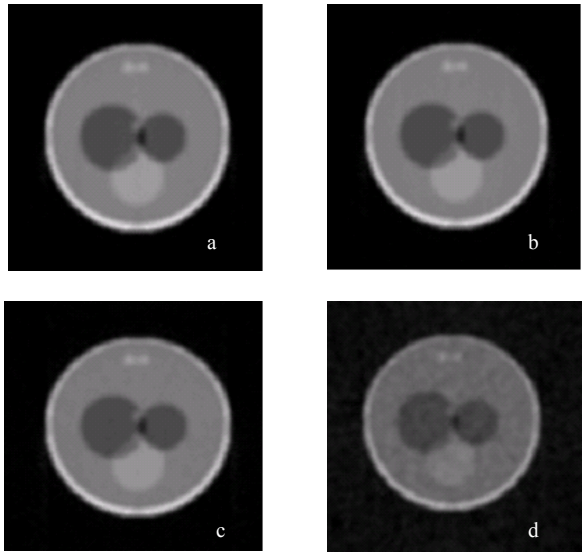

Figure 4. Reconstructed models:
(a) from noise-free object
(b) to (d) are 40dB, 30.45dB, 15dB signal to noise ratio objects.

The reconstructed results are shown in the figure 4 for different cases of image models. The profiles of the reconstruction are plotted against the original profiles in figure 5. To provide numerical evidence, we opt to use the Mean Square Error (MSE) for deriving the error between the reconstructed image and the original image. The formula of MSE is given by

$$MSE = \frac{\iint \left[o(x,y) - o'(x,y)\right]^2 dxdy}{\iint \left[o(x,y)\right]^2 dxdy} \times 100 \qquad (8)$$

The Error obtained the formula above are shown as table 2.

As we can see, the reconstructed result from the noisiest image (figure 4. a) still maintains its pattern, **this caused by the low-pass filters in filtered back-projection algorithm** that suppress most of the noise out with the trade of some blurring. The 17.73% of error in the noise-free image case mainly dues to the back-projection process.

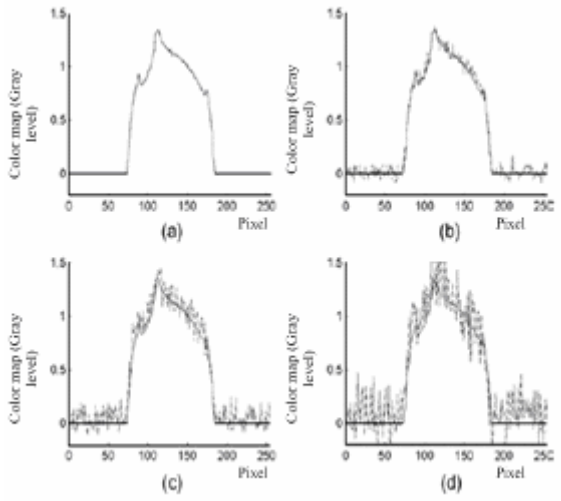

Figure 5. Profiles at 128th line of the reconstructed model, which against to those reconstructed models in figure 4, (real profiles are remarked as solid line, reconstructed profiles as blue dash line)

TABLE II
ERROR OF RECONSTRUCTED MODELS

Signal Per Noise (dB)	Mean Square Error (%)
Noise-Free	17.73
40	29.45
30.45	48.05
15	68.73

V. DISCUSSION AND CONCLUSION

The ultrasonic reflection mode tomography using the frequency centroid-shift method to resolve the integrated attenuation coefficient from the reflected waveform was purposed in this paper. The simulated demonstrated the promising results in the case of the wave path obstructed by the bone. Also the noise sensitivity of the reconstruction process is in the acceptable level. This method might be appropriately utilized in the medical diagnostic to gain the benefits of the ultrasound over the conventional X-ray tomography. Further work may be done in the following manners: Firstly, this method should be implemented in the real-world experiment for realizing more problems that never seen from the simulation. Secondly, we may reduce the noise level in the waveform by using the interpolation algorithm. And the last suggestion is – doing the tomograms of the organ followed by the volume rendering to view the tissue in 3-dimensional style is also possible.

***Abstract*- Color-based image retrieval usually uses color histogram as image feature. Regular color histogram is uniformly quantized. However, color variation is non-uniformly distributed. Consequently, uniform quantization may lead to inappropriate separation of colors. Similar colors can be treated as dissimilar because of the uniform quantization of each color axis. This causes inefficiency of the retrieval performance. Therefore, this paper proposes non-uniform color quantization used for color histogram generation. The proposed non-uniform color histogram incorporated with color correlogram is stored in the database as image indices. Retrieval results using the proposed color features have been compared with uniform color features to show the improvement of the proposed retrieval system..**

I. INTRODUCTION

With the growth of development in image technology and the increase in the number of pictorial archives, this creates a need for efficient and effective methods and techniques to store and retrieve images from large databases. Color is known as powerful information for image content analysis, recognition, and visualization. Among several color features, a color histogram is the most commonly used since it is efficient to compute and insensitive to image rotation and translation. Several color histograms have been proposed in the literature [1,2]. Most of color histogram generations are based on uniform quantization of color space. Uniformly quantized histogram is simple and easy to calculate. However, color deviation is non-uniformly distributed. Consequently, uniform quantization may lead to inappropriate separation of colors. Similar colors can be treated as dissimilar or vise versa. This causes inefficiency of the retrieval performance. Therefore, this paper presents non-uniform color quantization for color histogram generation. The proposed non-uniform color histogram incorporated with color correlogram is used as image indices and stored in the database. To retrieve similar images to the query, these color features of the query image are compared to those of the images in the database. The most similar images are retrieved and order according to their distances to the query.

II. COLOR QUANTIZATION

A. *Uniform color quantization*

Most of color features are uniformly quantized [1,2,3]. Even though uniform quantization is fast and simple, it may lead to inappropriate separation of colors. Bountha et. al. [1] uniformly quantizes R, G, and B into 4 groups as shown in fig. 1. Also, uniform quantized HSI color proposed in [2] separates Hue into 51 equal ranges for colors and 17 equal ranges for gray scale as shown in fig. 2. We can see from fig. 1 and fig. 2 that some similar colors are considered as dissimilar.

B. *The proposed non-uniform color quantization*

We have researched the visual properties of the HSI color space and its usefulness in content based image retrieval applications. The proposed non-uniform color quantization is based on HSI color model as shown in fig. 3 and 4. The HSI color space is divided into achromatic, low chromatic, and high chromatic sub-regions. Each sub-region is separated based on the value of saturation. In achromatic sub-region, the lightness component is clearly more important and is used to separate color into 4 groups (saturate: 0-0.2, 4 levels of intensity). In the low chromatic sub-region, the chromatic component can be perceived but the perceived color differs according to the hue and lightness. Therefore, hue and lightness are used to separate color into 54 groups (saturate: 0.21-0.6, 3 levels of intensity and 18 subgroups for each level). In the high chromatic sub-region, nearly the same color is perceived regardless of saturation. Therefore, hue is used for the high chromatic quantization, which separate color into 36 groups (saturate: 0.61-1.0, 2 levels of intensity and 18 subgroups for each level).

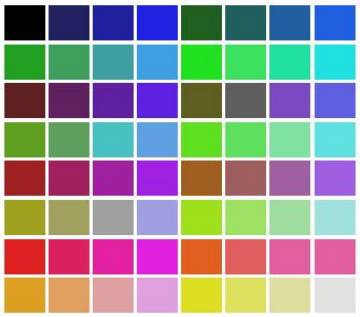

Figure 1. Representation of uniform RGB color quantization [1]

C. *The Propose Indexing Algorithm*

In the proposed indexing algorithm, each image in the database is quantized and segmented using JSEG algorithm [4]. Then, color histogram and correlogram are extracted from each region in the segmented image. These features are stored in the database and used as image indices to retrieve relevant

images from the database. Color histogram is generated based on the proposed non-uniform color quantization as described in section 2. Color correlogram [5] is a spatial extension of the histogram. Given any pixel of color in the image, color correlogram gives the probability that a pixel at distance away from the given pixel is of color can be calculated as followed.

$$\gamma^{(k)}_{C_iC_j}(I) \cong \Pr_{P_1 \in I_{c_i}, P_2 \in I_{c_j}} [p_1 \in I_{c_i}, p_2 \in I_{c_j}, |p_1 - p_2 = k|] \quad (1)$$

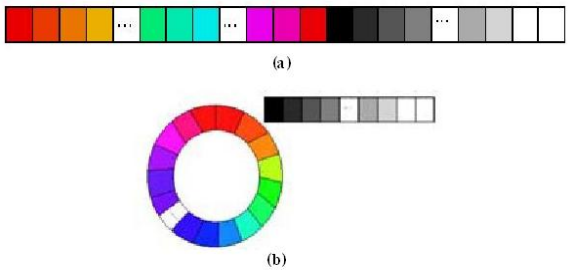

Figure 2. Representation of uniform HSI color quantization [2]

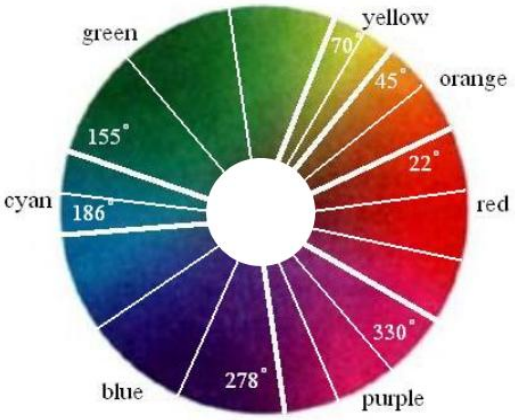

Figure 3. The proposed non-uniform hue quantization

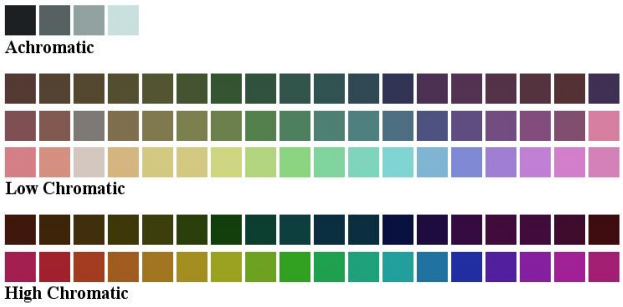

Figure 4. Representation of the proposed non-uniform HSI quantization

D. The Proposed Retrieval System

In the proposed system, users are allowed to impose their desired requirements on the query image using rectangular box. The Region of Interest (ROI) selection area is then segmented into N regions using JSEG algorithm as in the indexing process. Each region in the ROI is exacted color feature, color histogram and color correlogram as same as previous section. In matching process between selected ROI and indexing form database is performed using similarity comparision between the exacted features. The similarity measured by modified L1 distance [6] of color histogram and color correlogram as in equation 2 and 3, respectively.

$$|I - I'|_{h_1 d_1} \triangleq \sum_{i \in [m]} \frac{|h_{c_i}(I) - h_{c_i}(I')|}{1 + h_{c_i}(I) + h_{c_i}(I')} \quad (2)$$

$$|I - I'|_{\gamma_1 d_1} \triangleq \sum_{i \in [m]} \frac{|\gamma^{(k)}_{c_i,c_j}(I) - \gamma^{(k)}_{c_i,c_j}(I')|}{1 + \gamma^{(k)}_{c_i,c_j}(I) + \gamma^{(k)}_{c_i,c_j}(I')} \quad (3)$$

where I and I' are the query and the indexing image. $h_{c_j}(I)$ and $h_{c_i}(I')$ are the color histograms and $\gamma^{(k)}_{Ci,Cj}(I)$ and $\gamma^{(k)}_{Ci,Cj}(I')$ are color correlogram of I and I' images, respectively.

To retrieve relevant images, hierarchical query is performed instead of static query, which searches for N query regions to retrieve N query results and uses all the retrieved results to produce a single query result. Static query requires a large amount of search time due to a large number of regions containing in each indexing image. Even though hierarchical query requires less amount of search time, it is possible that a mistake from one level can propagate to next levels and cause retrieval errors at the end of query. Therefore, in this paper, two-level search is proposed, which not only can reduce the search time compared to the static search algorithm but also can reduce the effects of the mistakes propagating from one level to the next.

The hierarchical search [1] is a combination of the static search and the traditional hierarchical search. In the first-level query, the most important regions from user's query, usually the largest regions at the center of user's query, are matched with the regions in the indexing images using the static search technique. To select the important region for first-level search, we consider the window positioned at the center of selected ROIs. The region covering more than 20% at the window is chosen and used to search for the first-level. The indexing images, which contain all the most important regions and have matching errors less than predefined thresholds, are retrieved from the database. The refinement search is performed in the second-level query to look for the remaining regions in user's query from first-level retrieved images.

During matching task, the distance between the ROIs and feature of the indexing images in the database is calculated as shown in equation 4. Let the color histogram weight be 0.8 and the correlogram weight be 0.2.

$$\text{Distance } (I\text{-}I') = \begin{pmatrix} |I - I'|_{h_1 d_1} * weigth\,(\text{Histogram}) + \\ |I - I'|_{\gamma_1 d_1} * weigth\,(\text{Correlogram}) \end{pmatrix} \quad (4)$$

III. The Experimental Results

We have conducted the experiments using the proposed indexing approach. Color features of regional non-uniform color histogram and a its corresponding correlogram are used as image indices. These features are extracted from regions in the indexing images and the selected ROI of user's query. The database consists of 2,000 images from internet and Corel stock photo gallery, and video clips. The images in the database can be categorized into 7 categories; building creature, foodstuff, human, material, natural, and plant. These images are indexed based on the proposed indexing algorithm as described in section III. The indices of each image will later be used for retrieval process. We have performed the retrieval experiments using a query set consisting of 70 queries, each chosen to represent various situations such as different objects and colors, different views of the ROI, spatial translations and backgrounds. The retrieval performance of all the queries is shown in fig. 5 and fig. 7.

The retrieval performance [7] is evaluated using average precision at each recall level (x) as follow:

$$\overline{P}(r) = \sum_{i=1}^{N_q} \frac{P_i(r)}{N_q} \qquad (5)$$

where $\overline{P}(r)$ is the average the precision at the recall level r, N_q is the number of queries used, and $P_i(r)$ is the precision at recall r for the $i-th$ query.

An example of retrieval results using the proposed non-uniform color quantization compared to uniform color quantization are presented in fig. 5 and fig.8 while corresponding recalls and precisions for each technique are shown in fig. 6 and fig. 7, respectively. In addition, a comparison of the average retrieval performance of recall and precision is shown in fig. 9. From experimental results, the retrieval performance of using the proposed color features is better than those of using uniformly quantized color features.

IV. Conclusion

In this paper, non-uniform color quantization used for color histogram generation is developed based on visual properties of the HSI color space and its usefulness in content based image retrieval applications. The objective is to construct a suitable representation for color histogram, which helps to prevent colors that are perceptually similar from being treated as dissimilar. The non-uniform color histogram incorporated with color correlogram is used to search for similar images to the query from the database. Retrieval results using the proposed color features have been compared with uniform color features to show the improvement of the proposed retrieval system. From the results, it can be seen that the proposed non-uniform color quantization outperforms the uniform quantization in most cases of recall and precision.

***Abstract*-Image coding requires a small bit rate for high-speed data transmission and a small space for data storage. Simultaneously, the peak signal to noise ratio (PSNR) has to be maintained. This paper proposes a method of image coding design using wavelet transform (WT). By applying the WT for defining groups of pixels with the same intensity in spatial domain, the groups of pixels are allocated in a low frequency range. Hence, locations of pixels are the key factor to determine the size of each block. In this method, image blocks with appropriate size in the image set are initiated, and then used wavelet transform to decompose each block into sub-band components. The low-frequency components (LL) of each block is selected as representative of the block, and their vertical (HL), horizontal (LH) and diagonal (HH) are used to define 3D vectors. The 3D vectors are then classified into 8 groups corresponding to quadrants of spatial coordinates. Magnitudes of vectors in each group are coded as representatives of each block. By applying the proposed method, performance has been improved which indicated by lower bit rate (75%) and better PSNR (4.23%) (Airplane from table 2) compared to the A Genetic Grey-Based Neural Network with Wavelet Transform for Search of Optimal codebook (WT+GGCLN) methods.**

I. INTRODUCTION

Data compression is the mapping of data set into a bit stream to decrease the number of bits required to represent the data set. The data storage space is saved, and memory access time is fastened in case of applying an efficient image coding. In order to enhance the efficiency of communication system for real-time image transmission, we need to decrease the bit rate, and simultaneously maintain PSNR for image quality. To satisfy the mentioned conditions, many developments and researches are undertaken, and results have been published. M. Antonini, M. Barlaud, P. Mathieu, and I. Daubechies in [1] propose wavelet transform as a tool to reduce memory sizes, and increase the quality of image by using multi-resolution codebook. They design codebook by using a well known splitting technique. The initial codebook is generated by splitting the centroid (center of gravity) of this training set. This splitting technique classifies data image into code vectors and determines mean squared error (MSE). In the splitting technique, median of group data is analyzed without the consideration of the interpixel information. Hence, the adjacent block with high frequency data is not considered in the process. Furthermore, the process with 1 bpp compensates PSNR by using two different sizes of blocks, 2x2 (N = 256) and 4x4 (N = 128), which results in higher PSNR. Chaur-Heh Hsieh group in [2] applies several fast search algorithms based on TIE with multiple control points and the Haar wavelet transform. TIE is constructed with multiple control vectors. A systematic way for determining the control vector is developed. A codebook with 256 code vectors is generated by the fast fuzzy C-mean algorithm with block size of 4x4. L. Chin-Yuan and C. Chin-Hsing in [3], apply wavelet transform to reduce bit rate using in data transmission and data storage. The image quality is improved by using multi resolution codebook designed by the genetic algorithm and the grey-base designed competitive learning network. Both of these techniques provide a better quality of image. However, designing the codebook with this technique considers only the center of each group which calculated from individual pixel in the same group. The codebook composes of two different block sizes (e.g., 2x2 with 512 code vectors and 4x4 with 64 code vectors). The results shown that the bit rate is 0.84 bpp.

In this paper, the authors aim to find VQ-based coding method as discussed in [4]-[9] with low bit rate and high PSNR. We propose a novel technique which utilizing frequency components to determine size of blocks. One of the main advantages of the proposed method is that the size of each block is adjustable to minimizing coding errors. Section 2 describes problem analysis in an image coding. Sections 3 to 4 an image coding system and codebook design. Finally, experimental results and a conclusion are in sections 5 and 6, respectively.

II. PROBLEM ANALYSIS IN IMAGE CODING

One issue of researches in image coding is to find coding methods with low bit rate and high PSNR. As conventional method, L. Chin -Yuan etc. [3] proposed A Genetic Grey-Based Neural Networks with Wavelet Transform for Search of Optimal codebook in order to enhance PSNR as quality. However, bit rate is still high, because of multi-resolution.

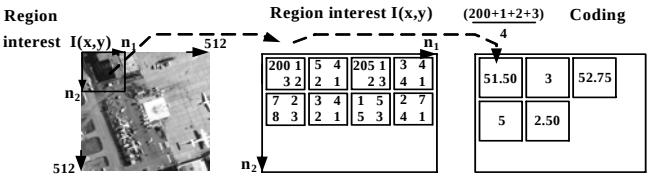

Figure 1. A simple of coding conventional method.

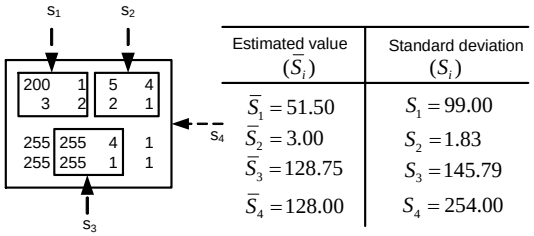

Figure 2. A case of image sample in block for coding.

As shown in figure 1, the conventional method employs average of intensity in the 2x2 blocks for coding. Normally, if we enlarge a block for coding, bit rate is decreased. On the other hand, since coded data is generated from intensity average in the block, PSNR becomes worse. In this paper, we raise "To decrease bit rate while maintaining PSNR" as theme, and declare it as problem statement.

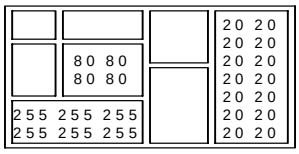

Figure 3. The similar intensity pixel.

In figure 2, small block will absorb distortions between intensity values and their averages. That means PSNR is decreased according to block size. However, block size should be enlarged to cover area consisting of similar intensity values in order to decrease bit rate maintaining PSNR as shown in figure 3. Therefore, we should determine block location and size depending on adjacent pixels that have similar intensity values. In frequency domain as shown in figure 4, spectrum representing block that contains similar-intensity pixels is located in low frequency range. On the other hand, a block with different-intensity pixels will be located in high frequency range.

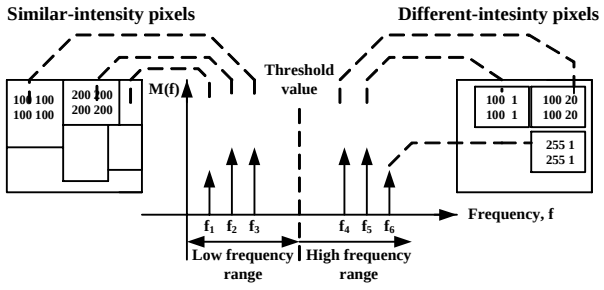

Figure 4. An analysis of the signal in frequency domain.

Obviously, we can use frequency components to determine block location and size in spatial domain. Separating the low frequency components and high frequency components can be done in many ways. One way is the decomposition of the image using a Discrete Wavelet Transform (DWT) [10]-[12], which is being used in a number of different applications.

III. AN IMAGE CODING SYSTEM

The system of image compression mentioned in this paper can be described as follows. Image data coding proposed in this paper consists of encoding stage and decoding stage.

3.1 Encoding System

Encoding process, due to the aim for high PSNR, (encoding processing step) consists of three important processes. First process, the 512x512 input-image (X_i) is divided into 256 of 32x32 square blocks (Bn) which is called input vector. Second process consists of two important steps: Interpixel codebook and Nearest Neighbor Rule. The Nearest Neighbor Rule is an error retrieved from the calculation of mean square error (MSE) between input vector and code vector in the following formula:

$$d(X_i, X_i'') = \frac{1}{K}\sum_{m}^{K}[X_i(m) - X_i''(m)]^2, \qquad (1)$$

where

$d(X_i, X_i'')$ is mean square error,

$X_i(m)$ is input vector,

$X''(m)$ is code vector, and

K is dimension of code vector

The third process is finding the index. The index is the result of the comparison between input vector and code vector with the least error. The index is then used to indicate position of code vector which is kept in the Interpixel codebook.

3.2 DECODING SYSTEM

Decoding process, in order to have the image reconstructed, the decoding process needs to have the reverse process of the encoding. Result is that the image data or reconstruction (X_o).

IV. CODEBOOK DESIGN

In the present, wavelet transform is a popular research topic applying for signal processing such as image and sound signals. It is an effective display technique for analyzing time and frequency [13]. Moreover, this technique is widely accepted. In the paper, wavelet transform is applied to determine a block location and size which depend on adjacent pixels that have similar intensity values as shown in figure 3. A group of vector code from a wavelet's theory is also implemented to experiment assumptions. And the mother function of wavelets, $\Psi(x)$, can be any function if it satisfies the following condition

$$\int_{-\infty}^{\infty} |\Psi(x)|^2 \, dx < \infty \tag{2}$$

Basically, a mother wavelet function is derived from its corresponding mother scaling function $\Phi(x)$ which satisfies the scaling equation

$$\Phi(x) = \sum_{i \in Z} c_i \Phi(2x - i) \tag{3}$$

For any integer j, the vector space V^j is define as

$$V^j = span\{\Phi_i^j(x), \forall i \in z\} \tag{4}$$

$$\Phi_i^j(x) = \Phi(2^j x - i), i, j \in z \tag{5}$$

If V^j satisfies the following four multi resolution analysis conditions

Condition 1: $f(x) \in V^j \Leftrightarrow f(2^{-j}x) \in V^0, \forall j \in z$
Condition 2: $\bigcap_{i \in z} V^i = \{0\}$
Condition 3: $\bigcup_{i \in z} V^i = L^2(R)$
Condition 4: $... \subset V^{-2} \subset V^{-1} \subset V^0 \subset V^1 \subset V^2 \subset ...$

That the mother wavelet is given by

$$\Psi(x) = \sum_{i \in z} (-1)^i c_{1-i} \Phi(2x - i) \tag{6}$$

One of the most important characteristics of the wavelet transform is multi resolution. The wavelet transform converts the pixel values of an image to its wavelet representation, without losing any information, in the spatial domain. In this paper, the Interpixel codebook is designed by applying the wavelet transform theory. The Interpixel codebook design consists of the following steps:

Step 1: The input image size 512x512 pixels are separated into 256 square sub-blocks. Each sub-block has 32x32 pixels and nominated as E_1 to E_{256}.

Step 2: Analyze the characteristics of each sub-block to define address of sub-block associated with frequency of input image.

- Each sub-block is decomposed into 5 levels. The five level wavelet transform is performed on image to generate the corresponding transformed coefficients.
- 3D vector ($\vec{B}_1, \vec{B}_2, \vec{B}_3, .., \vec{B}_{256}$) is constructed by using the coefficient values of LH_5, HL_5, and HH_5 sub-bands to determine of the unit vector i, j, k.
- Find magnitudes (B_1, B_2, B_3,…B_{256}) of 3D vectors which can be described are:

Step 3: Divide sub-blocks into eight groups (*Total_group*) according to 3D vector signs and *Small_group* less than 256 blocks, as shown in (7)-(8).

$$Total_group = \begin{Bmatrix} Big_group(m)(-\hat{i}, -\hat{j}, -\hat{k}); m = 1, \\ Big_group(m)(-\hat{i}, -\hat{j}, \hat{k}); m = 2, \\ .., Big_group(m)(\hat{i}, \hat{j}, \hat{k}); m = 8 \end{Bmatrix} \tag{7}$$

$$Big_group(m) = \begin{Bmatrix} Small_group(1), Small_group(2), \\ .., Small_group(n) \end{Bmatrix} \tag{8}$$

Step 4: Find amount code vector (block size in figure 3 corresponding to resolution of step value) by applying the following equation.

$$Bit(bit_for_calculator) = Log_2(small_grouproup) \tag{9}$$

- If *Bit* for calculator more than real bit, step = Max/2
- If *Bit* for calculator less than real bit, step = step/2

Step 5: Find Interpixel codebook from sub-blocks size 32x32 pixels, as shown in figure 5 (Address of sub-blocks is defined as address of E_1 to E_{256}).

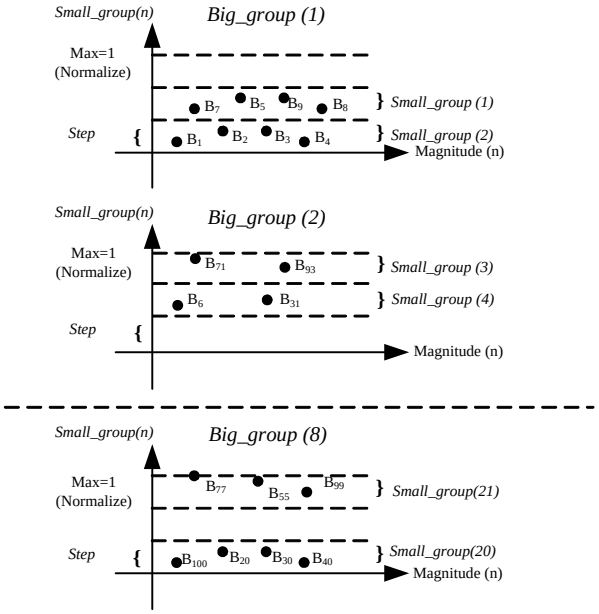

Figure 5. A grouping sample of magnitude value

where *small_ group* is on integer value (1, 2,..,256).

And find Interpixel codebook by applying the following equation.

$$C_{Small_group(n)}(1, j) = \frac{1}{m} \sum_{i=1}^{m} (X_{i,j}); j = 1, 2, .., 1024 \tag{10}$$

V. EXPERIMENTS AND RESULTS

For evaluating the performance of proposed image coding method, the image coding has been produced by specification

Pentium(R) 4 CPU 3.01 GHz, Block size 32x32, codebook size 210, and Image size 512x512.

Table 1 shown PSNR and MSE of the "Airplane", "Girl", "Lena" and "Pepper" image reconstructed from three bit rates of size 0.38, 0.44 and 0.50. Table 2 shown bit rate, compression ratio of the "Airplane", "Girl" and "Lena" image reconstructed from bit rate size 0.48 and the test of PM system using the three standard images, block size 4x4 are demonstrated in figure 6, and Set Partitioning in Hierarchical Trees (SPIHT) [14]-[15] is a wavelet-based image compression coder. It first converts the image into its wavelet transform and then transmits information about the wavelet coefficients. The decoder uses the received signal to reconstruct the wavelet and perform an inverse transform to recover the image.

VI CONCLUSIONS

This paper proposes a method for image coding design using vector quantization based on low-frequency component to determine block location and size in spatial domain. The experiments on the propose method have been performed with four standard images. The experimental results reveal proposed method is evaluated as 0.48bpp, and 28.83dB for bit rate and PSNR respectively, that is improved by 75% and 4.23% for bit rate and PSNR comparing with the conventional method (WT+GGCLN).

***Abstract*-Vector Quantization (VQ) is Lossy image compression system (irreversible compression). The information loss then causes reconstruction containing loss information. Moreover, system error non-compensation will cause low peak signal to noise ratio (PSNR). Therefore, this paper proposes a method of system error compensation on VQ. At encoding system, system error compensation (e2) is calculated difference image between input image (X_i) and the reconstruction image (X_i'). It is decomposed by 2-dimentional 3-level Discrete Wavelet Transform (DWT). System error is known by looking at the sub-band LL3. At decoding system, system error is composed by 2-dimentional 3-level Inverse Wavelet Transform (IDWT). However, before the composition, LH3 HL3 and HH3 must be set to zero. The reconstructed image and system error compensate will be combined in order to construct an output image (X_o). By applying the proposed method, performance has been improved which indicated by better PSNR (11.63%) compared to the A Genetic Grey-Based Neural Network with Wavelet Transform for Search of Optimal Codebook (WT+GGCLN) methods.**

I. INTRODUCTION

Vector quantization, which has been widely applied in speech and image coding [1]-[2], provides an efficient technique for signal compression due to it excellent rate-distortion performance. Image storage and transmission pose an important problem to the development of intelligent communication systems due to memory and bandwidth requirements. In image data transmission, the 3rd generation communication (3G) [3], is currently installed in mobile phones is used, and expected to be popular for the near future [4]. We need to decrease the bit-rate, and simultaneously maintain PSNR for image quality. To overcome this problem, several PSNR and bit-rate improved algorithms [5]-[6] have been proposed. The algorithms can be roughly categorized as lossy and lossless approaches [7]. M. Antonini, M. Barlaud, P. Mathieu, and I. Daubechies in [8] propose wavelet transform as a tool to reduce memory sizes, and increase the quality of image by using multi-resolution codebook. They design codebook by using a well known splitting technique. The initial codebook is generated by splitting the centroid (center of gravity) of this training set. This splitting technique classifies data image into code vectors and determines mean squared error (MSE). In this system, and the process is analyzed system error compensation on VQ is not taken into consideration**.** Furthermore, the process with 1 bpp compensates PSNR by using two different sizes of blocks, 2x2 (N = 256) and 4x4 (N = 128), which results in higher PSNR. L. Chin-Yuan and C. Chin-Hsing in [9], apply wavelet transform to reduce bit-rate using in data transmission and data storage. The image quality is improved by using multi resolution codebook designed by the genetic algorithm and the grey-base designed competitive learning network. Both of these techniques provide a better quality of image. The codebook composes of two different block sizes (e.g., 2x2 with 512 code vectors and 4x4 with 64 code vectors). The results shown that the bit-rate is 0.84 bpp. However, this system, the process is analyzed and also same as [8].

The focus of this paper is a system error compensated approach utilizing wavelet transform and vector quantization techniques, hoping to achieve the best result in term of compression ratio with acceptable recovery quality. This new approach will be called error compressed vector quantization. The paper is organized in the following way. Section 2 describes problem analysis in an image coding. Sections 3 and 4 a coding system and image quality enhancement techniques mixed scheme technique. Finally, experimental results and a conclusion are in sections 5 and 6, respectively.

II. PROBLEM ANALYSIS IN AN IMAGE CODING

One of research issues in image coding is to find coding methods with low bit-rate and high PSNR. In [9] L. Chin-Yuan and C. Chin-Hsing propose A Genetic Grey-Based Neural Networks with Wavelet Transform for Search of Optimal codebook. In this paper, a new image compression technique combining the genetic algorithm (GA) and the grey-based competitive learning network (GGCLN) in the wavelet transform domain. This method can enhance PSNR as quality. However, bit-rate is still high because of multi-resolution.

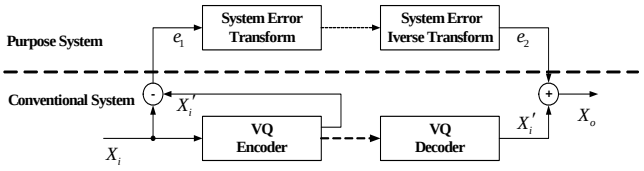

Figure 1. A simple of VQ coding system.

As shown in Fig. 1, the conventional system employs average of intensity in the 2x2 blocks for coding. Normally, if we enlarge a block for coding, bit-rate is decreased. On the other hand, since coded data is generated from intensity average in the block, in addition to, is system error non-compensation, PSNR becomes worse. In this paper, we raise "To decrease bit-rate while maintaining PSNR" as theme, and declare it as problem statement. The system error compensate can be calculated, is defined as

$$e_1 = X_i - X_i' \quad (1)$$

$$e_2 = \mathrm{T}^{-1}(e_1) \quad (2)$$

$$X_o = X_i' + e_2 \quad (3)$$

$$X_o = (X_i - e_1) + e_2 \quad (4)$$

$$X_o = X_i - e_1 + \mathrm{T}(e_1) \quad (5)$$

Where e_1 is system error, e_2 is system error compensate, T^{-1} is inverse transform, X_i is input image, X_i' is reconstructed image and X_o is output image. Therefore, if system error compensates approaches system error as close as possible the output image will approach input image, and the image has low bit-rate and high PSNR, is define as (5).

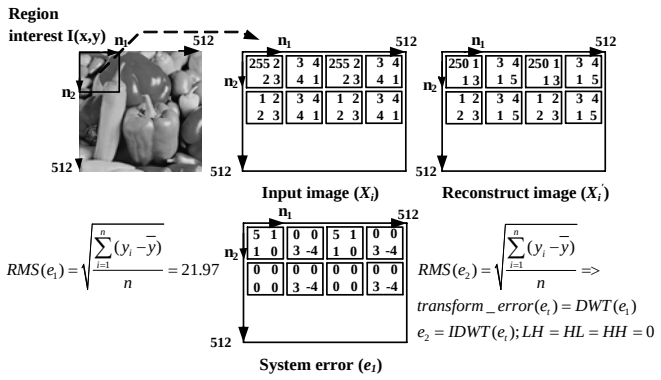

Figure 2. A case of image sample in block for coding.

In system error as shown in Fig. 2, the system error compensate is transform system error. Obviously, we can use transform system error components ($e_t = DWT(e_1), e_2 = IDWT(e_t); LH = HL = HH = 0$) to determine the system error compensate.

III. CODING SYSTEM

The system of image compression can be described as follows.

3.1 Encoding / Decoding System

In this paper image data coding consists of encoding stage and decoding stage that are demonstrated in Fig. 3. The aim of encoding process is to produce the image with high PSNR. Therefore, the development of encoding process is necessary. The process consists of two steps. The first step is the closed loop control. In this step, the image is reconstructed from the relationship between the codebook and the nearest neighbor rule. The codebook designed by Quadrant technique [10]. In the second step, to reduce the system error, the 3-level DWT is applied to transform to the system error in frequency domain then, only the low frequency component is transmitted to the decoding process.

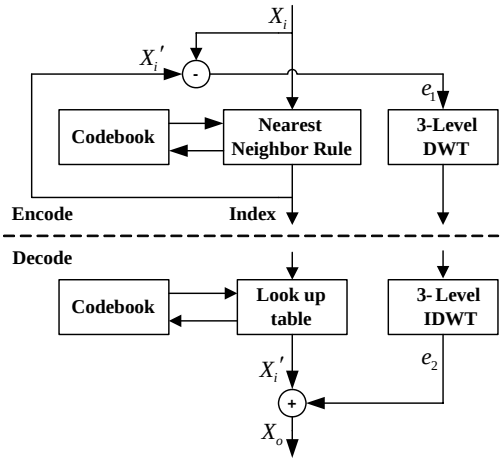

Figure 3. Diagram of implementation error added VQ.

The image is compressed in a lossy style. The system error and system error compensate can be calculated, is defined as (1) and (2). In order to cover all frequency, the Haar wavelet is applied as wavelet transform. The system error will be decomposed by 3-level wavelet transform. Only the sub-band LL will be transmitted and sub-bands LH, HL, and HH are discarded.

Decoding process, in order to have the image reconstructed, the decoding process needs to have the reverse process of the encoding. Furthermore, the system error will be inverse transformed in the three levels which will yield the system error compensate. Then the construction of output image is generated from the merging of reconstruction image and system error compensate.

IV. IMAGE QUALITY ENHANCEMENT TECHNIQUES

Image coding using vector quantization based on system error compensated in this paper can be accomplished by 3 different techniques:

- **Techniques 1** Closed Loop Control (CLC)
- **Techniques 2** System Error Compensation (SEC)
- **Techniques 3** Combination of CLC and SEC (CLC+SEC)

Details of each technique are mentioned in the following subsections.

4.1 Closed Loop Control

The closed system that demonstrated in Section 3.1 (encoding processing step) consists of three important processes. First process, the 512x512 input images is divided into 4,096 of 8x8 square blocks which is called input vector. Second process consists of two important steps: codebook and Nearest Neighbor Rule. The Nearest Neighbor Rule is an error retrieved from the calculation of mean square error (MSE) between input vector and code vector as follows

$$d(X_i, X_i'') = \frac{1}{K}\sum_{m}^{K}[X_i(m) - X_i''(m)]^2, \qquad (6)$$

where $d(X_i, X_i'')$ is mean square error,

$X_i(m)$ is input vector,

$X_i''(m)$ is code vector, and

K is dimension of vector.

(a) 26.70 dB, 0.13 bpp (b) Closing up

Figure 4. A sample of basic VQ on image.

The third process is to find the index and image data or reconstruction image. The index is the result of the comparison between input vector and code vector with the least error. The index is then used to indicate position of code vector which is kept in the codebook.

(a) Original image (b) System error

Figure 5. Quantization error of basic VQ on an image.

The result is the image data of the reconstruction as shown in Fig. 4. The figure shows the serious blocky effect of implement basic VQ. The blocky effect and loss of information is more pronounced when the error image in Fig. 5 is inspected as, it is associated with quantization error.

4.2 System Error Compensation

Compression in the VQ pattern basically causes information loss. The information loss then causes reconstruction containing loss information. Moreover, system error non-compensation will cause blocky effect to occur. Therefore, the VQ compression needs improvement to contain system error compensation. The system error compensation consists of two main processes. In the first process, system error is calculated from input image of size 512x512 pixels, and the reconstruction image. In the second part, system error is decomposed into 4 sub-bands (LL_1, LH_1, HL_1, HH_1). Then LL_1 will be decomposed further into 4 sub-bands (LL_2, LH_2, HL_2, HH_2). However, only sub-band LL_2 is used for further decomposition until the pixel of data exist in the block is reduced to 64x64 (LL_3, LH_3, HL_3, and HH_3). Result of the decomposition allows us to know system error by looking at the sub-band LL_3. The other three sub-bands (LH_3, HL_3, and HH_3) will be discarded.

4.3 Combination of CLC and SEC

Due to the blocky effect and loss information that occur during the image reconstruction, the combination of CLC and SEC is used to solve the problems. The combination of CLC and SEC consists of three parts. In part I, input of decoding processing step consists of index and system error. Part II consists of a look up table, codebook and inverse wavelet transform (IDWT). In this second part, system error, 64x64 pixels, in sub-band LL_3 LH_3 HL_3 HH_3 is composed to sub-bands LL_2 LH_2 HL_2 and HH_2. However, before the composition, LH_3 HL_3 and HH_3 must be set to zero. After that, LL_2 LH_2 HL_2 and HH_2 will be composed further into sub-band LL_1 LH_1 HL_1 and HH_1 respectively. Finally, the all four sub-bands will be composed by IDWT in order to construct system error compensate. In part III, the reconstructed image and system error compensate will be combined in order to construct an output image, the value of output image is defined as (3) to (5). The quality of the output image is demonstrated in Fig. 7.

(a) 27.57 dB, 0.13 bpp (b) Closing up

Figure 7. A sample of image system error compensate.

V. EXPERIMENTS AND RESULTS

For evaluating the performance of proposed image coding method, the image coding has been produced by specification Pentium(R) 4 CPU 3.01 GHz, Block size 32x32, Codebook size 210, and Image size 512x512.The value of *PSNR* is also calculated for evaluating the system performance.

5.1 VQ Based on CLC

The tests of CLC system using the four standard images are “Airplane”, “Girl”, “Lena”, “Pepper” and block size 4x4. The results reveal the PSNR and bit-rate as in Table 1. The result of PSNR comparison between low frequency image and high frequency image are shown in Table 1. They reveal the

advantage of CLC system in low frequency image, rather than in high frequency image.

5.2 VQ Based on CLC and SEC

The tests of CLC+SEC system using the four standard images, block size 4x4 and block size 32x32 show in Table 1. The results reveal the PSNR and bit-rate as shown in Table 1. According to Table 2, the CLC+SEC system are better than the CLC system.

TABLE I
The image reconstructed from proposed CLC + SEC system

Images	CLC+SEC		CLC	
	PSNR (dB)	Bit rate (bpp)	PSNR (dB)	Bit rate (bpp)
Airplane	26.07	0.13	25.53	0.13
Girl	29.31	0.13	27.90	0.13
Lena	27.96	0.13	27.66	0.13
Pepper	26.81	0.13	26.70	0.13

5.3 Varied bit-rates

Table II and III show the PSNR and MSE of the "Airplane" "Girl", "Lena" and "Pepper" image reconstructed from four bit-rate 0.38 bpp, 0.44 bpp, 0.48 bpp and 0.84 bpp blocks size 4x4 designed by the LBG and CLC systems. The LBG design algorithm is an iterative algorithm which alternatively solves two optimality criteria (Nearest Neighbor and Centroid Condition). The algorithm requires an initial codebook by the *splitting* method. According to Table II and III the average PSNR produced by CLC is 1.96 dB higher than that by the typical VQ (LBG). Further, the average PSNR produced by the proposed CLC+SEC system is 6.69 dB higher than that by VQ(LBG) conventional algorithm. The comparison between WT+GGCLN and CLC, CLC+SEC systems is shown in Table IV which shows the compression ratio (CR) of [512*512*8 / (512*512*7.71/(4*4))] = 16.59 for CLC, and [((512*512) + (64*64))*8 / (((512*512*7.71) /(4*4))+(8*64*64))] = 13.38 for CLC+SEC respectively. From the experimental simulation, the reconstructed images obtained from the CLC+SEC is significantly better than those from the CLC system.

TABLE II
PSNR and MSE of the images reconstructed from designed by the LBG and CLC system.

Algorithms	Images	0.38 bpp PSNR MSE	0.44 bpp PSNR MSE	0.48 bpp PSNR MSE
CLC	Airplane	27.02 129.30	28.03 102.33	28.83 85.13
LBG		24.11 252.39	25.29 192.30	26.34 132.94

VI. CONCLUSIONS

This paper proposes a method for image coding design using vector quantization based on system error compensate. The experiments on the propose method have been performed with four standard images. The experimental results reveal proposed method is evaluated as 0.84 bpp, and 33.15 db for bit-rate and PSNR respectively, that is improved by 11.63 % for the average PSNR comparing with the conventional method.

Abstract - **The task of 3D-object modeling is made difficult due to at least two reasons. First, 3D modeling software generally has a high learning curve due to its complicated commands. Secondly, object manipulation is generally unnatural. A 3D direct manipulation with physically based simulation is one such solution. However, use of physically based simulation for this purpose is inappropriate due to its high computational complexity, and reduction in design flexibility. This paper presents a gesture-based 3D-manipulation technique where a 3D object responses to manipulation according to certain parameters. By adopting a pseudo-physical simulation approach, complexity requirement is lower than a physically based approach. In addition, a user still gains flexibility and efficiency in manipulation an object. The pseudo-physical simulation model is described for a Bezier curve object type. Extension to other object types is achieved by requiring that an object skeleton is modeled by a curve segment(s). The simulation model imposes two types of pseudo-physical constraints onto a curve, namely the length and bending angle constraints. A prototype of a 3D-curve-modeling tool has been developed. By adjusting a combination of model parameters, curves can reflect differences in the associated physical properties by being shaped differently to the same gesture-based manipulation.**

I. INTRODUCTION

Currently, 3D modeling has been widely used for various applications. Depending on an interaction technique adopted, as well as the underlying virtual object mathematical model, ease of use of a 3D modeling tool may vary. Direct manipulation based on a 2-D mouse is universally used in current 3D modeling tools as a principal interaction technique. However, in using a 2D-pointing device for 3D virtual object manipulation, a mouse-keyboard compound command is generally required. This can affect ease of learning and usage retention. In addition, 3D virtual objects are based on either a mathematical model of parametric curve, or a polygon model. With such models, virtual objects generally response to manipulation in a way that is quite different from real objects. Thus, time is required to develop a skill needed to efficiently model an object so that it has an intended shape.

A technique of 3D direct manipulation has been proposed for various virtual reality and simulation applications, to provide a more natural human computer interaction. This can result in reduced learning time. Currently, many VR devices have been developed for 3D direct manipulation techniques. An electronic glove is perhaps the most widely used VR device for such purpose because it allows gesture-based interaction to be performed. It is this type of VR device that is applied for our study.

In addition to an interaction technique used, a mathematical model of a virtual object also affects how natural the interaction experience is. To allow virtual objects to react more naturally to user manipulation action, physically based rules may be applied in performing shape manipulation [1-2]. In [1], a virtual spring model is used to make object manipulation more realistic. In [2], a different physically based model is applied so those virtual 3D objects behave more like a real object. In [3], direct manipulation using physically based sculpting with B-spline surface is developed to simplify object manipulation. However, such physically based simulations generally require high computation, and may be inappropriate for interaction applications. In addition, such physical rules impose a rigid constraint on how virtual objects are manipulated, and thus reducing design flexibility.

In this paper, use of a gesture-based 3D direct manipulation technique in combination with a pseudo-physical simulation model is proposed for 3D-curve modeling. Gesture-based interaction has been proposed for 3D-curve manipulation [4-5]. For example, in [4], a specialized input device called ShapeTape is used to obtain a shape of a tangible stripe object in controlling a computer-generated curve. Such approach is, however, inflexible for its degree of freedom is limited by the input device physical characteristics. Instead, an electronic glove is adopted in this paper to achieve more flexibility in performing object manipulation. The pseudo-physical simulation method is applied in defining the shape of a manipulated curve. The model used is composed of two pseudo-physical constraints imposed on a curve object With this simulation model, by varying the model parameters, 3D curves can behave differently to the same manipulation to

mimic different types of string material (such as robe or wire). The technique can also be extended to model 3D surface object shapes by using the skeleton technique [6].

The rest of the paper is organized as follows. In section 2, a 2D direct manipulation technique for Bezier curve modeling is described. In section 3, a 3D direct manipulation technique for Bezier curve is given. In section 4, detail of the pseudo-physical simulation method is provided. The modeling tools developed under the proposed method with results are explained in section 5. The paper ends with some concluding remarks.

II. 2D DIRECT MANIPULATION OF A BEZIER CURVE

A. Bezier curve

Bezier curve is defined by control points, which in turn define shape and characteristic of a curve. Four control points are used here for a Bezier curve. Such cubic Bezier curve will refer to simply as a Bezier curve. Points on the curve can be obtained according to the following equation.

$$\boldsymbol{R}(t) = (1-t)^3\boldsymbol{P}_0 + 3t(1-t)^2\boldsymbol{P}_1 + 3t^2(1-t)\boldsymbol{P}_2 + t^3\boldsymbol{P}_3 \quad (1)$$

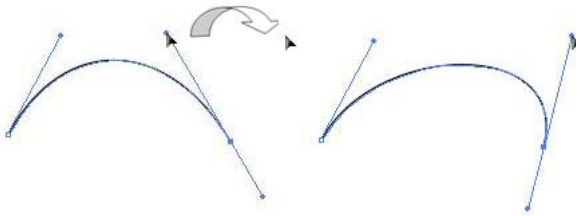

Figure 1. 2D direct manipulation of a Bezier curve as typically performed by a drawing tool

From the equation, $\boldsymbol{P}_0$, $\boldsymbol{P}_1$, $\boldsymbol{P}_2$, $\boldsymbol{P}_3$ are four control points (which are represented here as vectors from the origin).

B. Direct manipulation of a Bezier curve

Usually direct manipulation of a Bezier curve is performed at its control points. In 2D direct manipulation, a pointing device (e.g., a mouse) is used to manipulate the control points. Figure 1 illustrates how a Bezier curve is typically manipulated in a 2D graphic drawing tool.

C. Multiple-segment Bezier curve

Bezier curve can be used to represent many shapes. However, many of them cannot be well represented by a single curve segment. In that case, multiple segments of Bezier curve are used to represent complex shapes. If two or more segments are directly combined, however, it will result in discontinuity at the intersection.

Let s_1 and s_2 be the first and second consecutive segments, respectively. Bezier curve is continuous if the following condition is met.

$$\boldsymbol{P}_{3s1-1} - \boldsymbol{P}_{3s1} = -(\boldsymbol{P}_{3s2-2} - \boldsymbol{P}_{3s1}) \quad (2)$$

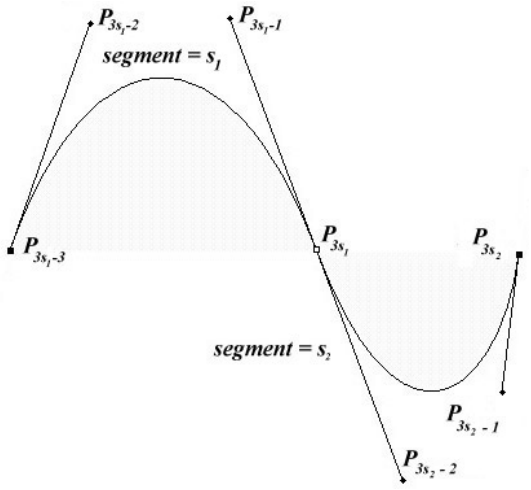

Figure 2. Preserving continuity at the intersection of two Bezier segments.

D. Bezier curve fragmentation

Fragmentation is an algorithm for splitting one segment into two segments, to realize a more complex curve. From definition of De Casteljau's algorithm [7], a polynomial $B(t)$ in Bernstein form of degree n can be expressed as

$$B(t) = \sum_{i=0}^{n} \beta_i^{(0)} b_{i,n}(t), \in [0,1] \quad (3)$$

where $b_{i,n}$ is a Bernstein basis polynomial. The polynomial at point t can be evaluated with the following recurrence relation.

$$\beta_i^{(0)} = \beta_i, i = 0,..,n \quad (4)$$

$$\beta_i^{(j)} = \beta_i^{j-1}(1-t) + \beta_{i+1}^{j-1}t, i = 0,..,n-j, j = 1,..,n \quad (5)$$

where

$$\boldsymbol{B}(t) = \beta_0^n \quad (6)$$

When choosing a point t_0 to evaluate a Bernstein polynomial, we can use the two diagonals of the triangle scheme to construct a division of the polynomial in (3) into

$$\boldsymbol{B}_1(t) = \sum_{i=0}^{n} \beta_0^i b_{i,n}\left(\frac{t}{t_0}\right), \in [0, t_0] \quad (7)$$

and

$$\boldsymbol{B}_2(t) = \sum_{i=0}^{n} \beta_{n-i}^i b_{i,n}\left(\frac{t-t_0}{1-t_0}\right), \in [t_0, 1] \quad (8)$$

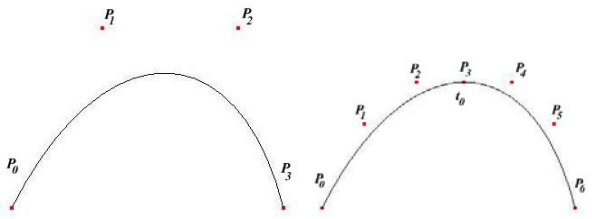

Figure 3. Bezier curve fragmentation at t_0

III. 3D DIRECT MANIPULATION OF A BEZIER CURVE

Here, 3D direct manipulation technique for curve shaping is performed through an electronic glove device using gesture-based human-computer interaction technique.

A. Gesture-based direct manipulation of a Bezier curve

A gesture-based direct manipulation technique was developed to model a Bezier curve. By using a (one or two-handed) electronic glove device, hand position and orientation are used to control the curve parameters. In particular, the hand position is used to control the position of $\boldsymbol{P_1}$ ($\boldsymbol{P_2}$), while its orientation (denoted by unit vectors $\boldsymbol{V_1}$ $\boldsymbol{V_2}$) is used to control the control point direction. See Figure 4 for illustration.

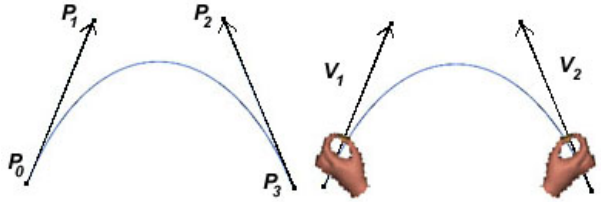

Figure 4. Manipulation of control parameters of a Bezier curve using hand position and orientation

This control can be expressed mathematically by the following equations.

$$\boldsymbol{P_1} - \boldsymbol{P_0} = \alpha \boldsymbol{V_1} \tag{9}$$

$$\boldsymbol{P_2} - \boldsymbol{P_3} = \beta \boldsymbol{V_2} \tag{10}$$

Only the direction part of the above equations is controlled by a hand orientation. The length parameters (α and β) are controlled by the two pseudo-physical constraints to be explained later.

By substituting (9)-(10) into (1), we arrive at

$$\begin{aligned}\boldsymbol{R}(t) = {} & (t-1)^2(2t-1)\boldsymbol{P_0} + 3t(1-t)^2\alpha\boldsymbol{V_1} \\ & + 3t^2(1-t)\beta\boldsymbol{V_2} + t^2(3-2t)\boldsymbol{P_3}\end{aligned} \tag{11}$$

where α and β are control parameters, whose values are obtained under the pseudo-physical constraints to be described shortly.

B. Collision detection

To perform 3D direct manipulation, collision between an electronic glove device and the object under manipulation must be detected. Here, a simple spherical shape with its center at a user palm is used as a collision proxy. In addition, line segments are used in rendering of a Bezier curve. Thus, collision point is calculated by using the method of line segment-sphere intersection [8].

From method of line segment-sphere intersection, $\boldsymbol{R}$ (t_1) and $\boldsymbol{R}$ (t_2) is start and end point of line segment that collides with sphere.

C. Curve control parameter mapping

As previously stated, a Bezier curve is manipulated by changing its control-point parameters. However, it is the hand orientation and position that are measured when gesture-based direct manipulation is applied. Therefore, there is a need to map the measured hand position and orientation to Bezier curve parameters. To do this, consider first Figure 4. From the figure and (9) - (10), the control points' positions and orientations are defined by $\boldsymbol{P_0}$, $\boldsymbol{P_3}$, $\boldsymbol{V_1}$, $\boldsymbol{V_2}$, α, and β. The left and right hand positions can be directly mapped to $\boldsymbol{P_0}$ and $\boldsymbol{P_3}$, respectively. In addition, hand orientations can be directly mapped to $\boldsymbol{V_1}$, and $\boldsymbol{V_2}$.

$$\begin{aligned} a_1 &= (1-t_1)^2(1+2t_1) & a_2 &= (1-t_2)^2(1+2t_2) \\ b_1 &= 3t_1(1-t_1)^2 & b_2 &= 3t_2(1-t_2)^2 \\ c_1 &= 3t_1^2(1-t_1) & c_2 &= 3t_2^2(1-t_2) \\ d_1 &= t_1^2(3-2t_1) & d_2 &= t_2^2(3-2t_2) \end{aligned} \tag{12}$$

$\boldsymbol{R}$ (t_1) and $\boldsymbol{R}$ (t_2) are points on Bezier curve that collide with user hand(s) using a collision detection method as described in Section III-*B*. From this, the vector $\boldsymbol{V}_1$ and $\boldsymbol{V_2}$ can be calculated from

$$\boldsymbol{V_1} = \frac{1}{\alpha}\frac{c_2\boldsymbol{R}(t_1) - c_1\boldsymbol{R}(t_2) + (a_2c_1 - a_1c_2)\boldsymbol{P_0} + (c_1d_2 - c_2d_1)\boldsymbol{P_3}}{b_1c_2 - b_2c_1} \tag{13}$$

$$\boldsymbol{V_2} = \frac{1}{\beta}\frac{b_2\boldsymbol{R}(t_1) - b_1\boldsymbol{R}(t_2) + (a_2b_1 - a_1b_2)\boldsymbol{P_0} + (b_1d_2 - b_2d_1)\boldsymbol{P_3}}{b_2c_1 - b_1c_2} \tag{14}$$

With the above equations, all curve parameters except α and β are mapped from user hand positions and orientations. These two parameters are obtained by imposing pseudo physical constraints as described next.

D. Pseudo physical constraints

As noted, α and β are two curve parameters left not matched to any hand parameters. Here, these remaining curve parameters are defined by two pseudo-physical constraints. The constraints are imposed on a curve object to mimic physical properties of different string-type objects (such as elastic rope and wire etc.). These constraints are described below.

1) Length constraint: this constraint imposes a limit on how a curve length can vary from its original value. For example, a wire has a strong length constraint so that it tends to being bended sharply in response to a shape manipulation, to retain its original length.

2) Bending angle constraint: this constraint imposes a limit on how much a bending angle is allowed for a curve. For example, an elastic rope has a strong bending constraint. Therefore, it tends to stretch in response to a shape manipulation, to avoid sharp bend.

E. Multiple-segment Manipulation Modes

In direct manipulation of multiple-segment Bezier curve, we can choose from different manipulation modes to affect the

object's shape differently. First, let $\boldsymbol{V}_{12}$ and $\boldsymbol{V}_{21}$ represents control vectors as described in Figure 5(a). If both sizes and directions of $\boldsymbol{V}_{12}$ and $\boldsymbol{V}_{21}$ are equal, the Bezier curve is continuous over multiple (two) segments. If the two have opposite direction with arbitrary sizes, the two segments form G^1 continuity. If the two have arbitrary size and direction, the two curves can be manipulated independently. In summary, manipulation modes of multiple-segment Bezier curve supported by the system are G^2 *connected*, G^1 *connected* and G^0 *connected* (Split) mode.

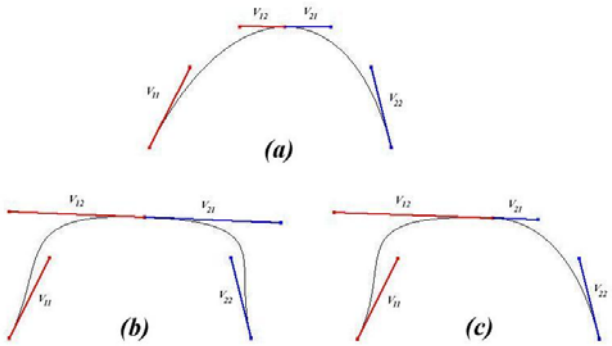

Figure 5. (a) Multiple-segment Bezier curve; (b) Bezier curve in G^2 *connected* mode; (c) Bezier curve in G^1 *connected* mode

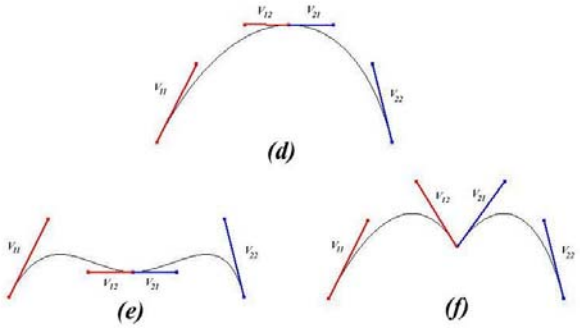

Figure 6. (d) Multiple-segment Bezier curve; (e) Bezier curve in G^2 *connected* mode; (f) Bezier curve in G^0 *connected* mode

IV. PSEUDO-PHYSICAL SIMULATION

A pseudo-physical simulation technique is applied here to provide a physical-like property to a 3D virtual object. The technique is much simpler than a common physically based method. The two types of constraints as explained in Section III-*D* are combined into the following cost function

$$C = w_1 \Delta L + w_2 (1 - \cos\theta_{\max}) \qquad (15)$$

where C is a cost value to minimize, w_1 and w_2 are user definable parameters. From the same equation, ΔL is a normalized length difference as defined by

$$\Delta L = \frac{L - L_0}{L_0} \qquad (16)$$

From (15) and (16), L is the current curvature length, and L_0 is the original length. In addition, $\theta_{\max}$ is the largest bending angle along the curve. From Figure 7 the angle is obtained by finding the angle $\theta(t)$ between the vectors $\boldsymbol{R}_t\boldsymbol{R}_{t-1}$ and $\boldsymbol{R}_{t+1}\boldsymbol{R}_t$. Then, $\cos\theta_{\max}$ is obtained from

$$\cos\theta_{max} = \max_{t=0\to 1} \cos\left(\frac{\mathbf{R}_t\mathbf{R}_{t-1} \bullet \mathbf{R}_{t+1}\mathbf{R}_t}{\left|\mathbf{R}_t\mathbf{R}_{t-1}\right|\left|\mathbf{R}_{t+1}\mathbf{R}_t\right|}\right) \qquad (17)$$

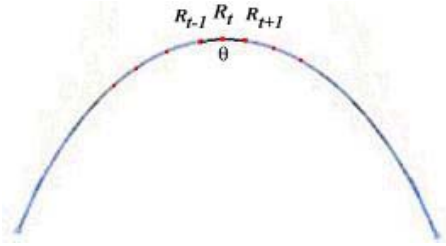

Figure 7. Calculation of a bending angle along a Bezier curves.

From (15) and (16), L is implicitly a function of α and β. Also, from (11) R_t is implicitly a function of α and β. Therefore, $\theta_{\max}$ and C are all the functions of α and β.

From (15) - (17), we can calculate C (α, β) from w_1, w_2, ΔL and M. and C must be minimized with respect to α and β. As a result, α and β are obtained from.

$$(\alpha_{\min}, \beta_{\min}) = \arg \min_{\alpha,\beta} C(\alpha, \beta) \qquad (18)$$

V. SOFTWARE PROTOTYPE AND RESULTS

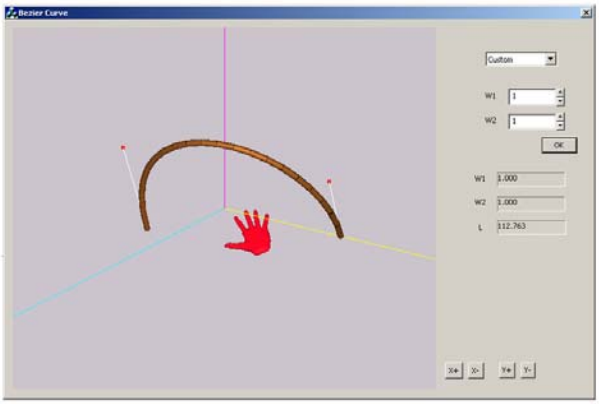

Figure 8. Software prototype

A software prototype was developed using Visual C++ and OpenGL library for graphic display. Experiments were performed with one-handed and two-handed electronic glove (CyberGlove®) configurations. Different values of w_1 and w_2 were tested. Figure 9 shows the result of the manipulation. Figure 10 compares the shapes obtained using different sets of w_1 and w_2.

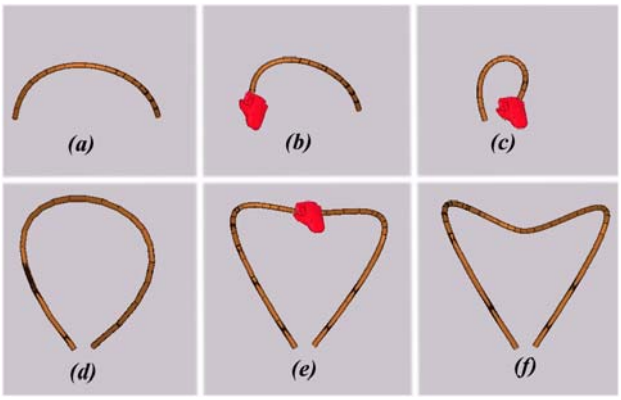

Figure 9. (a) normal Bezier curve; (b) and (c) curve end-points translation by hand gesture; (d) gesture-based manipulation with pseudo-physical constraints; (e) gesture-based manipulation with auto-fragmentation operated in the non-continuous mode; (f) the final shape

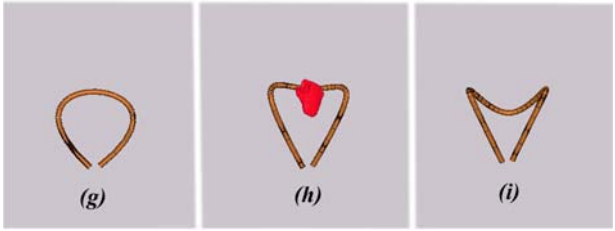

Figure 10. (g) Pseudo-physical constraints using different parameter; (h) manipulation with auto-fragmentation; (i) final shape

Figure 9a shows a normal Bezier curve before manipulation. The manipulated curve shown in Figure 9b and 9c was obtained by translating the curve end-point with gesture-based manipulation. Using gesture-based manipulation with pseudo-physical constraint with w_1 = 1.0 and w_2 = 1.0, the manipulation result is shown in Figure 9d. By using auto-fragmentation operated in the non-continuous mode, a more complex shape was obtained as shown in Figure 9e. Figure 10 shows the same curve undergone similar manipulation, but with different set of constraint parameters (w_1 = 0.3 and w_2 = 14.0).

VI. Conclusion

In this paper, a pseudo-physical simulation method for 3D direct manipulation of a 3D curve has been described. The method features the ease of use of a 3D direct manipulation metaphor, and a simulated real-object behavior of a virtual object. Unlike a physically based simulation approach, with its simple equation the proposed pseudo-physical method can reduce processing time and offers more flexibility in designing 3D curves. Software tool has been developed based on the proposed method and was applied to manipulate simple and complex curve shapes.

Sequence Mirroring Properties of Orthogonal Transforms Having Even and Odd Symmetric Vectors

Do Nyeon Kim and K. R. Rao, *Fellow, IEEE*
E.E. Dept., 416 Yates Street
UTA, Box 19016
Arlington, TX 76019 USA

***Abstract*-This paper presents sequence mirroring properties for discrete orthogonal transforms consisting of the even and odd symmetric row vectors. As an application, mirroring an image (horizontally or vertically) and rotation by 90°, 180° and 270° in the spatial domain is implemented by changing the signs of the 2D orthogonal transform coefficients of the original image appropriately.**

I. INTRODUCTION

As the discrete transforms, in general, have been utilized in a number of image/video compression/coding schemes, it is helpful to implement the mirroring/resizing operations in the transform domain. This paper presents sequence mirroring properties for discrete orthogonal transforms consisting of the even and odd symmetric row vectors. These properties are valid for DCT [1], DST (also all their integer revisions – integer DCT (IntDCT) [5], IntDST [8], integer cosine transform (ICT) [2], IST [8] etc.), slant [9], and Hadamard transforms. Variants of ICT are developed for H.264 [3], WMV9 [4] and AVS China [6], and they also hold these inherent properties. Orthogonal transforms that are not symmetric include MDCT, Haar transform and Hartley transform. This property for the DCT has been presented by Shen and Sethi [7], but it is generalized for other transforms in this paper. We show specific applications using some of these transforms.

II. PROPOSED ALGORITHM

We can prove sequence mirroring properties for discrete orthogonal transforms consisting of even and odd symmetric row vectors as follows. Let $[S_4]$ be one of these orthogonal matrices of size (4×4) and be defined as

$$[S_4]=\begin{bmatrix} a & b & b & a \\ c & d & -d & -c \\ e & -f & -f & e \\ g & -h & h & -g \end{bmatrix} \begin{matrix} even \\ odd \\ even \\ odd \end{matrix} . \quad (1)$$

Since $[S_4]$ is orthogonal, it follows that $[S_4]^T[S_4]=[I]$, where the superscript T represents transpose, and I is the identity matrix. For later use, let column vectors of $[S_4]^T$ be

$$[S_4]^T=(\underline{s}_{R,0}, \underline{s}_{R,1}, \underline{s}_{R,2}, \underline{s}_{R,3}) \quad (2)$$

$$=(\underline{e}_R, \underline{o}_R, \underline{e}_R, \underline{o}_R) \quad (3)$$

where $\underline{e}_R$ and $\underline{o}_R$ represent even and odd symmetric column vectors of $[S_4]^T$. Also, let column vectors of $[S_4]$ be

$$[S_4]=(\underline{s}_{C,0}, \underline{s}_{C,1}, \underline{s}_{C,2}, \underline{s}_{C,3}) \quad (4)$$

where $\underline{s}_{C,n}$ for n = 0, …, 3 are column vectors of $[S_4]$.

Let an input sequence or column vector be $\underline{x}$. We can get the mirrored transform coefficients $\underline{X}_M$ if we set input sequence in reverse order and then transform it.

$$\underline{X}_M=[S_4][J_4]\underline{x} \quad (5)$$

where the permutation matrix

$$[J_4]=\begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix} \quad (6)$$

is the opposite diagonal unit matrix. The matrix multiplication $[S_4][J_4]$ arranges the column vectors of $[S_4]$ in reverse order. Thus the signs of elements of odd symmetric row vectors of $[S_4]$ are changed whereas the signs of elements of even symmetric row vectors are not changed while absolute values of elements of $[S_4]$ are not changed, since $[S_4]$ is a matrix having either even or odd symmetric rows. Thus

$$\underline{s}_{C,0}=[K_4^I]\ \underline{s}_{C,3} \quad \text{and} \quad \underline{s}_{C,1}=[K_4^I]\ \underline{s}_{C,2} \quad (7)$$

where

$$[K_4^I]=diag(1, -1, 1, -1). \quad (8)$$

It is noted a diagonal element of $[K_4^I]$ is the positive number one if the corresponding column vector of $[S_4]$ is of even symmetry, and an element is the negative number one if the corresponding column vector is of odd symmetry. From (8), $[S_4][J_4]=(\underline{s}_{C,3}, \underline{s}_{C,2}, \underline{s}_{C,1}, \underline{s}_{C,0})$

$$= \left(\left[K_4^I\right] \underline{s}_{C,0}, \left[K_4^I\right] \underline{s}_{C,1}, \left[K_4^I\right] \underline{s}_{C,2}, \left[K_4^I\right] \underline{s}_{C,3} \right)$$
$$= \left[K_4^I\right] \left(\underline{s}_{C,0}, \underline{s}_{C,1}, \underline{s}_{C,2}, \underline{s}_{C,3} \right)$$
$$= \left[K_4^I\right] \left[S_4\right]. \quad (9)$$

Let the mirrored sequence of an input sequence $\underline{x}$ be $\underline{x}_M$. From (10), we can compute $\underline{X}_M$ transform coefficients of $\underline{x}_M$ as

$$\underline{X}_M = \left[S_4\right] \underline{x}_M = \left[S_4\right]\left[J_4\right] \underline{x}$$
$$= \left[K_4^I\right] \left[S_4\right] \underline{x} = \left[K_4^I\right] \underline{X} \quad (10)$$

or

$$\underline{x}_M = \left[S_4\right]^T \underline{X}_M = \left[S_4\right]^T \left[K_4^I\right] \underline{X}. \quad (11)$$

We can generalize transforms represented by (1) for size *N*.

$$\left[S_N\right]^T = \left(\underline{s}_{R,0}, \underline{s}_{R,1}, \ldots, \underline{s}_{R,N-2}, \underline{s}_{R,N-1} \right)$$
$$= \left(\underline{e}_R, \underline{o}_R, \ldots, \underline{e}_R, \underline{o}_R \right) \quad \text{for } N \text{ even}$$
$$= \left(\underline{e}_R, \underline{o}_R, \ldots, \underline{o}_R, \underline{e}_R \right) \quad \text{for } N \text{ odd.} \quad (12)$$

We refer to orthogonal transforms represented by (1) as type 1 orthogonal transform, and the type 1 includes DCT, DST and slant transform.

The Hadamard transform has a similar property. Let $\left[S^{WH}\right]$ be a matrix of size (8×8) representing the Hadamard transform. Then,

$$\left[S^{WH}\right]^T = \left(\underline{e}_R, \underline{o}_R, \underline{o}_R, \underline{e}_R, \underline{o}_R, \underline{e}_R, \underline{e}_R, \underline{o}_R \right). \quad (13)$$

To change an input vector into reverse order, the signs of elements of even symmetric row vectors of $\left[S^{WH}\right]$ are not changed however the signs of elements of odd symmetric row vectors are changed.

Similarly with (9), we can compute $\underline{X}_M^{WH}$ transform coefficients of the mirrored sequence of an input sequence $\underline{x}$ as

$$\underline{X}_M^{WH} = \left[S^{WH}\right]\left[J_8\right]\left[x\right] = \left[K_8^{II}\right] \underline{X}^{WH} \quad (14)$$

where $\left[J_8\right]$ is a permutation matrix and the opposite diagonal unit matrix of size (8×8), and

$$\left[K_8^{II}\right] = diag\left(1, -1, -1, 1, -1, 1, 1, -1\right). \quad (15)$$

We can get the signs of (15) in the same manner explained in (8). We refer to orthogonal transforms represented by (13) as type 2 orthogonal transform, and the type 2 includes the Hadamard transform.

Thus we can mirror a sequence in the transformed domain just by changing signs of transform coefficients. Applications of these very useful properties for compressed-domain image editing by using the DCT have been presented in [7]. Two-dimensional extension is presented in the next section.

III. Two-Dimensional Extension

Mirroring or rotation of an image is illustrated using an (8×8) block. Given

$$\left[x\right] = \begin{pmatrix} x_{00} & x_{01} & \cdots & x_{07} \\ x_{10} & x_{11} & \cdots & x_{17} \\ \vdots & \vdots & \ddots & \vdots \\ x_{70} & x_{71} & \cdots & x_{77} \end{pmatrix}, \quad (16)$$

horizontally mirrored sequence of $\left[x\right]$ is

$$\left[x_h\right] = \begin{pmatrix} x_{07} & x_{06} & \cdots & x_{00} \\ x_{17} & x_{16} & \cdots & x_{10} \\ \vdots & \vdots & \ddots & \vdots \\ x_{77} & x_{76} & \cdots & x_{70} \end{pmatrix}. \quad (17)$$

Similarly, we can get the vertically mirrored sequence of $\left[x\right]$, $\left[x_v\right]$. $\left[x\right]$ rotated by 90° is

$$\left[x_{90^o}\right] = \begin{pmatrix} x_{70} & x_{60} & \cdots & x_{00} \\ x_{71} & x_{61} & \cdots & x_{01} \\ \vdots & \vdots & \ddots & \vdots \\ x_{77} & x_{67} & \cdots & x_{07} \end{pmatrix}. \quad (18)$$

Let $\left[x\right]$ rotated by 180° be $\left[x_{180^o}\right]$, and $\left[x\right]$ rotated by 270° be $\left[x_{270^o}\right]$.

Image can be represented as nonoverlapping blocks of size $N \times N$ (for example $N = 8$). Each block can be represented as a matrix $\left[x\right] = \{x(n_1, n_2)\}_{n_1,n_2=0}^{7}$ shown in (16). Let $\left[S_8\right]$ be an orthogonal transform of size (8×8). Then we can compute the two-dimensional transform coefficients matrix $\left[X\right]$ of an input image block or matrix, $\left[x\right]$ as follows:

$$\left[X\right] = \left[S_8\right]\left[x\right]\left[S_8\right]^T. \quad (19)$$

Let the 2D-transform of horizontally mirrored sequence $\left[x_h\right]$ be $\left[X_H\right]$ and the 2D-transform of vertically mirrored sequence $\left[x_v\right]$ be $\left[X_V\right]$. Then we can compute $\left[X_H\right]$ and $\left[X_V\right]$ as follows:

$$\left[X_H\right] = \left[X\right]\left[K_8\right] \quad (20)$$

$$\left[X_V\right] = \left[K_8\right]\left[X\right] \quad (21)$$

where the matrix $\left[K_8\right]$ can be $\left[K_8^I\right]$ or $\left[K_8^{II}\right]$ depending on the associated orthogonal transform. Here $\left[K_8^I\right]$ is defined as

$$\left[K_8^I\right] = diag\left(1, -1, 1, -1, 1, -1, 1, -1\right) \quad (22)$$

and $\left[K_8^{II}\right]$ is defined in (15).

Thus we can select a group of consecutive 2D-transform blocks of an image and flip horizontally according to the following steps:

1. Apply the (8×8) 2D-transform to the nonoverlapping blocks of size (8×8) of the image.
2. Set the size of a rectangular block to be horizontally flipped. Horizontal and vertical sizes should be integer multiples of eight according to the transform size.
3. Compute transform-domain image flipping for each 2D-transform block by using (20).
4. Rotate horizontally transform blocks within the rectangular block. The most left transform block goes to the most right, and vice versa.

In general this is applicable to $(N \times N)$ 2D-transforms having even and odd symmetric vectors by choosing $[K_8^I]$ appropriately. We can also rotate an image block by 90° in the 2D-transform domain by using the proposed scheme. Let us denote the 2D-transform of the 90°, 180° and 270° rotated blocks in the spatial domain $[x_{90^o}]$, $[x_{180^o}]$ and $[x_{270^o}]$ as $[X_{90^o}]$, $[X_{180^o}]$ and $[X_{270^o}]$ respectively. Then we can compute 2D-transform of rotated blocks in the spatial domain using (9) as follows:

$$[X_{90^o}] = [S][x]^T[J_8][S]^T = [S][x]^T[S]^T[K_8^I] = [X]^T[K_8^I] = [X_V]^T. \quad (23)$$

Let the symbol $\otimes$ represent element-by-element multiplication.

$$[X_{180^o}] = [K_8][X][K_8] = [W] \otimes [X] \quad (24)$$

where the matrix $[W]$ can be $[W^I]$ or $[W^{II}]$ depending on the associated orthogonal transform. Here the matrices $[W^I]$ and $[W^{II}]$ are defined as

$$[W^I] = \begin{bmatrix} 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \\ -1 & 1 & -1 & 1 & -1 & 1 & -1 & 1 \\ 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \\ -1 & 1 & -1 & 1 & -1 & 1 & -1 & 1 \\ 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \\ -1 & 1 & -1 & 1 & -1 & 1 & -1 & 1 \\ 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \\ -1 & 1 & -1 & 1 & -1 & 1 & -1 & 1 \end{bmatrix} \quad (25)$$

$$[W^{II}] = \begin{bmatrix} 1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 \\ -1 & 1 & 1 & -1 & 1 & -1 & -1 & 1 \\ -1 & 1 & 1 & -1 & 1 & -1 & -1 & 1 \\ 1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 \\ -1 & 1 & 1 & -1 & 1 & -1 & -1 & 1 \\ 1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 \\ 1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 \\ -1 & 1 & 1 & -1 & 1 & -1 & -1 & 1 \end{bmatrix}. \quad (26)$$

Similarly, using (9)

$$[X_{270^o}] = [S][J_8][x]^T[S]^T = [K_8][S][x]^T[S]^T = [K_8^I][X]^T = [X_H]^T. \quad (27)$$

We can also show (24) and (27) by using $[x]^T \Leftrightarrow [X]^T$, where the symbol $\Leftrightarrow$ indicates forward and inverse 2D-DST pair.

IV. Applications

A. Integer DCT for H.264

We use the integer DCT designed for the Fidelity Range Extension (FRExt) [3] of the H.264/MPEG-4 Advanced Video Coding (AVC) standard. The integer DCT is defined as follows:

$$[S^{FRE}] = [SF^{FRE}]\,[H^{FRE}] \quad (28)$$

where

$$[SF^{FRE}] = diag\{1/(16\sqrt{2}), 1/(17\sqrt{2}), 1/(8\sqrt{5}), 1/(17\sqrt{2}), 1/(16\sqrt{2}), 1/(17\sqrt{2}), 1/(8\sqrt{5}), 1/(17\sqrt{2})\}$$

and $[H^{FRE}]$ is defined by Eq. (14) in [11].

B. DCT and DST

The type 2 DCT for N = 8 and the type 1 DST for N = 9 are defined in matrix form as follows:

$$[S^{C2}]_{mn} = \sqrt{2/N}[k_m k_n]\cos[m(n+\tfrac{1}{2})\pi/N] \quad (29)$$

$m, n = 0, 1, \ldots, N\text{-}1$

$$[S^{S1}]_{mn} = \sin(mn\pi/N) \qquad m, n = 1, 2, \ldots, N \quad (30)$$

where $k_p = 1/\sqrt{2}$ for $p = 0$ and $k_p = 1$ otherwise.

C. Slant Transform

The slant transform [9] is defined as follows:

$$[S^{SL}] = [SF^{SL}]\,[H^{SL}] \quad (31)$$

where

$$[SF^{SL}] = \sqrt{1/8}\; diag(1, \sqrt{7/3}, 3\sqrt{5}, 17\sqrt{105}, 1, 1, 3\sqrt{5}, 3\sqrt{5})$$

and

$$[H^{SL}] = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & \frac{5}{7} & \frac{3}{7} & \frac{1}{7} & -\frac{1}{7} & -\frac{3}{7} & -\frac{5}{7} & -1 \\ 1 & \frac{1}{3} & -\frac{1}{3} & -1 & -1 & -\frac{1}{3} & \frac{1}{3} & 1 \\ \frac{7}{17} & -\frac{1}{17} & -\frac{9}{17} & -1 & 1 & \frac{9}{17} & \frac{1}{17} & -\frac{7}{17} \\ 1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 \\ 1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 \\ \frac{1}{3} & -1 & 1 & -\frac{1}{3} & -\frac{1}{3} & 1 & -1 & \frac{1}{3} \\ \frac{1}{3} & -1 & 1 & -\frac{1}{3} & \frac{1}{3} & -1 & 1 & -\frac{1}{3} \end{bmatrix}.$$

D. Hadamard Transform

The Hadamard transform [8] is defined by Eq. (5.107) in [10].

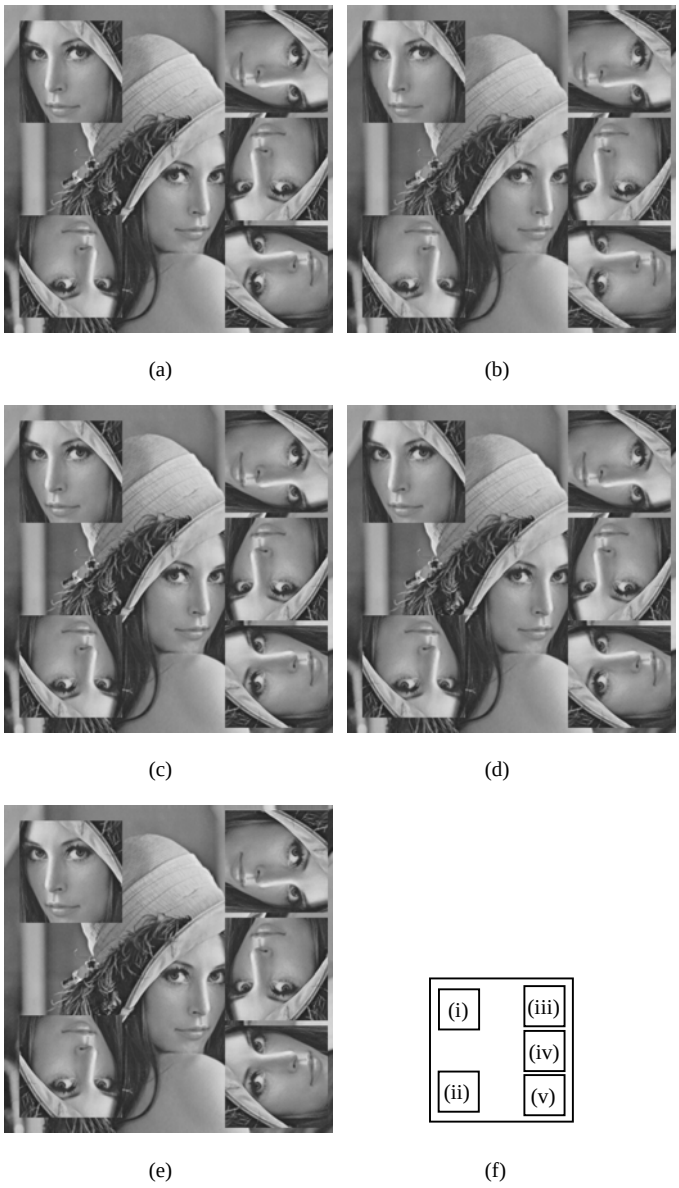

Figure 1. Mirroring or rotation of portion of Lena image in the spatial domain by manipulating the 2D-transform coefficients of the original block: (i) horizontal mirroring, (ii) vertical mirroring, (iii) rotation by 90°, (iv) rotation by 180°, and (v) rotation by 270° for (a) IntDCT of H.264, (b) Slant transform, (c) Hadamard transform (d) DST, and (e) DCT. Here the number of each block in images is shown in (f).

E. Simulations

Using Eqs. (16)-(26), the 2D-transform domain manipulation is utilized to obtain image mirroring and rotation by 90°, 180°, and 270° in spatial domain. Note that image mirroring and rotation by 90°, 180°, and 270° in spatial domain is accomplished by changing the signs of the 2D-transform coefficients of the original image appropriately. These operations are implemented on the Lena image (see Fig. 1).

Multi-Resolution Belief Propagation for Stereovision

Preeyakorn Tipwai and Suthep Madarasmi
Computer Engineering Department, King Mongkut's University of Technology Thonburi
126 Pracha-utid Rd., Bangmod, Toongkru, Bangkok 10140, THAILAND

***Abstract*-We propose a multi-resolution algorithm for stereo matching. The algorithm works with a grid matching and an inter-grid matching stereo model in terms of message passing in a Bayesian belief propagation (BBP) framework. The local smoothness and other constraints are expressed within each resolution scale grid and also between grids in a single paradigm. The matching within a single resolution grid contains data matching costs and smoothness costs. The inter-grid matching helps avoid the local minimum problem in finding the optimal solution by bringing features closer at the coarse level and yet providing a full-scale solution at the finest level. The results on real and synthetic images are presented, showing an increase in the accuracy of the disparity map.**

I. INTRODUCTION

The majority of machine vision algorithms work on 2-D cases. Stereo matching computes the third dimension by finding the matching features in each of the left and right images, and then measures the distances to objects containing these features by triangulation; that is, by intersecting the lines of sight from each camera to the object.

Considerable progress in stereo vision has been achieved by formulating the problem in terms of energy minimization. Lucas and Kanade [1] presented an iterative image registration technique with an application to stereo vision. They used the spatial intensity gradient of the images to find a good match using the Newton-Raphson's iterative method. The difficulty of this approach is in its requirement of considerable hand-guidance, so a method to automate the process is needed.

Marapane and Trivedi [2] proposed a multi-primitive hierarchical method for stereo matching. Each matching module uses a simple minimum distance based classifier to choose correspondences. Average contrast, average angle, and slope are used as attributes for comparing similarity of the linear features. Edge contrast and angle are also compared. However, an analysis found that the system is formulated as a nonsymmetrical matching process.

Boykov *et. al.* [3] proposed a method for computing dense visual correspondence based on general assumptions about scene geometry. For each pixel, the plausible disparity with the largest connected component is selected. A variable region of support is used to decrease false matches near the object boundaries. A suitable correlation measure method and sufficiently large window size are important, but a window may encompass more than a single smooth disparity region if the size is too large.

Tomasi and Manduchi [4] proposed a representation using intrinsic curves and transforming stereo matching into a nearest neighbor problem. The image positions are stored by their appearance instead of image intensities with the objective to store image points that look similar in the same place, so correspondences are trivially established. Occlusions are also easily found as points that lie isolated in some location. However, different image points can look the same, making memory locations crowded, and corresponding points in the images can look different, causing points that should be in the same memory location to vary.

Bayesian Belief Propagation (BBP) has recently become the choice algorithm for energy minimization in solving computer vision-related optimization problems. Good optimization algorithms for stereo vision based on BBP have been developed. Kolmogrorov [5][6], Wainwright *et. al* [7] and Meltzer *et. al* [8] applied the Tree Re-weighted Belief Propagation (TRBP) to the stereopsis problem. Sun *et. al* [9][10] proposed a variety of BBP for stereo matching with a line process for depth discontinuity and a binary process for occlusion handling. Belief Propagation methods produce highly accurate results in practice. However, several iterations are required to propagate data within a large neighborhood, and distant features are often not successful in propagating their constraints. Felzenszwalb and Huttenlocher [11] proposed a coarse-to-fine BBP approach with an added approximation to reduce the computational complexity inherent in the classical BBP algorithm. The top-down manner of the coarse-to-fine architecture helps the multi-stage process to escape a local minimum in the parameter space. This significantly speeds up the convergence process since the search space is narrowed for each subsequent finer level with a larger lattice. The problem in such approaches, though, occurs when the coarse level solution is incorrect, since the error will copied to the finer scale resulting in an incorrect solution at the finest level.

In this paper, we propose the use of a multi-resolution, coarse-and-fine, pyramid image architecture to belief propagation for stereo matching. It helps avoid the local minimum problem by bringing features closer at the coarse level and yet provides a complete solution at the finest level

II. BELIEF PROPAGATION

Figure 1 shows belief propagation as a Markov network. $I=\{I_p\}$ in solid circles are the *observed nodes* or data. $D=\{d_p\}$ in dashed circles are the *hidden nodes* or computed variables. In stereovision, I is data given by the stereo pair and D is the disparity image. The objective is to search for the values of the hidden variables D which provide the optimal solution, given the observed variables I. Therefore, using Bayes' Rule, the goal is to solve the following equation:

$$\arg\max_d P(D \mid I) = \frac{P(I|D)P(D)}{P(I)} \quad (1)$$

where *P(D|I)* is the conditional probability of *D* given *I*. *P(I|D)* is the conditional probability of *I* given *D* which is generally image formation model or the *data constraint*, and *P(D)* is the prior probability such as the *smoothness constraint*. *P(I)* is the evidence probability which may be assumed to be constant and can, therefore, be ignored.

Using negative log probabilities, the global optimization can be formulated in an energy minimization framework:

$$\arg\min_{d} E(D \mid I) = E(I \mid D) + E(D) \tag{2}$$

where *E*, in stead of *P*, is the cost or energy function.

Bayesian belief propagation (BBP) works by passing messages around within a predefined neighborhood. In Figure 1, m_p is called the local evidence, the message sent from an observed node I_p to the corresponding hidden node d_p. It is considered the data constraint revealing how much the value of the computed variable matches the data. Since I_p is known, m_p is a function of d_p, written as $U_p(d_p)$.

$$m_p = U_p(d_p) \tag{3}$$

m_{pq} is a message sent from a hidden node d_p to its neighbor d_q. The message carries the evidence from the observed node and messages from all other neighbors of the sender, combined with the smoothness between the sender and the receiver. First initialized using a uniform random distribution, it is then iteratively updated using the update rule in (4).

$$m_{pq}^{new} = \alpha \min_{d_p}\left\{ V_{pq}(d_p, d_q) + m_p + \sum_{k \in N(p) \setminus q} m_{kp} \right\} \tag{4}$$

where $V_{pq}(d_p,d_q)$ is the smoothness function between nodes d_p and d_q and $k \in N(p) \setminus q$ is all the other neighbors of the sender node d_p except the receiver neighbor d_q.

After passing messages for a number of iterations, the solution is computed by finding the maximum belief for each node *p*. However, as the messages are cost functions showing the error of the solution, the minimum disbelief must be used to represent the maximum belief. The disbelief of node *p* is obtained by the summation of all messages and evidence the node receives:

$$disbelief_p = m_p + \sum_{q \in N(p)} m_{pq} \tag{5}$$

The optimal solution is the one with the maximum belief.

$$d_p = \arg\max_{d_p}(disbelief_p) \tag{6}$$

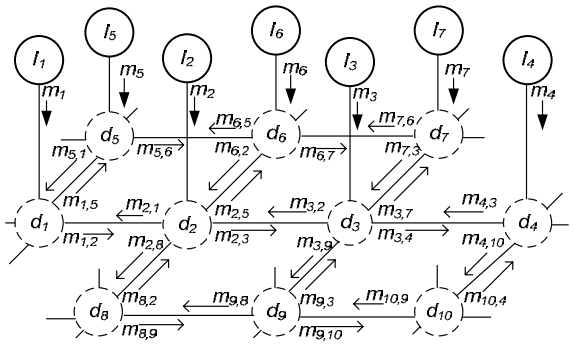

Figure 1. Belief Propagation Presented as a Markov Network.

III. Coarse-and-Fine Belief Propagation

The coarse-and-fine stereo matching includes grid matching and inter-grid matching. Let $I^0 = \{I_L^0, I_R^0\}$ be the original stereo images, where I_L is the left image and I_R is the right image. They are sub-sampled into N-1 coarser levels $I^n = \{I_L^n, I_R^n\}$, *n = 1,2,..N-1,* to make the image pyramid of *N* levels. Let $D^n = \{d_i^n\}$ be the scene property or disparity at level *n.* Within each grid the data constraint through differences in matched points and the smoothness constraint are both enforced to find the disparity labeling. In addition, another constraint called the *inter-grid* constraint requires the disparity at the contiguous coarse and fine levels to be consistent.

The data cost is expressed in terms of an energy function:

$$E(I \mid D) = \lambda_D \sum_{n=0,..,N-1} E^{DATA(n)} \tag{7}$$

where λ_D is the weight for the data constraint. $E^{DATA(n)}$ is the data constraint at grid level *n*, coarse or fine, defined by the summation of the energy at every pixel p given by:

$$E^{DATA(n)} = \sum_p \left(I_R^n(x_p, y_p) - I_L^n(x_p - d_p, y_p) \right)^2 \tag{8}$$

The prior includes grid smoothness and inter-grid consistency:

$$E(D) = \lambda_S \sum_{n=0,..,N-1} E^{S(n)} + \lambda_I \sum_{n=0,..,N-2} E^{I(n)} \tag{9}$$

where λ_S and λ_I are the smoothness and inter-grid weighing factors, respectively. At each grid level, the grid smoothness energy is defined by the smoothness prior:

$$E^{S(n)} = \sum_p \sum_{q \in N(p)} E_{pq}^S(d_p^n, d_q^n) \tag{10}$$

$E_{pq}^S(d_p^n, d_q^n)$ is the smoothness energy between nodes *p* and *q*, which are both at the same level *n*, computed from:

$$E_{pq}^S(d_p^n, d_q^n) = (d_p^n - d_q^n)^2 . \tag{11}$$

The inter-grid energy $E^{I(n)}$ measures the consistency between the disparities d_p at level *n* and d_q at it's adjacent coarser level *n+1*, between the coarse and fine levels. At each pixel *p* of fine level *n*, $E^{I(n)}$ is calculated by:

$$E^{I(n)} = \sum_p E_{pq}^I\left(d_p^{n+1}, d_q^n\right) \tag{12}$$

$$E_{pq}^I(x,y) = \begin{cases} 0, & |x \times S - y| < S - 1 \\ 1, & otherwise \end{cases} . \tag{13}$$

Message passing in the coarse-and-fine structure is illustrated in Figure. 2. The grid matching is in the messages m_{left}, m_{right}, m_{up}, m_{down}, which are sent to neighborhood pixels in the same grid level. The inter-grid matching is in the message m_{above} sent to corresponding pixel in the coarser level, and $m_{below1,2,3,4}$ sent to four corresponding pixels in the finer level.

A. Computing Local Evidence

The local evidence, or data constraint, at pixel *p* on level *n* can be computed via

$$m_p^n(d_p^n) = \left[I_R^n(x_p, y_p) - I_L^n(x_p - d_p^n, y_p) \right]^2 . \tag{14}$$

B. Computing Intra-grid Message

To send a message at the same grid level, the message is computed by

$$m_{pq}^{new}(d_p^n) \leftarrow \min_{dp} \lambda_S E_{pq}^S(d_p^n, d_q^n) + \lambda_D m_p(d_p^n) + \sum_{k \in N(p) \setminus q} m_{kp}(d_p^n) \quad (15)$$

, where $p=(x,y)$, m_{pq} is m_{left}, m_{right}, m_{up}, m_{down} *when* $q = (x+1,y)$, $(x-1,y)$, $(x,y+1)$, and $(x,y-1)$, respectively.

C. Computing Inter-grid Message

To send the inter-grid message, the message is calculated by:

$$m_{pq}^n(d_p^n) \leftarrow \min_{dp} \lambda_I E_{pq}^I(d_p^n, d_q^{n+1}) + \lambda_D m_p(d_p^n) + \sum_{k \in N(p) \setminus q} m_{kp}(d_p^n) \quad (16)$$

, where $p=(x,y)$ in level n, m_{pq} is m_{above}, when $q = (x/2,y/2)$ in level $n+1$, or

$$m_{pq}^n(d_p^n) \leftarrow \min_{dp} \lambda_I E_{qp}^I(d_q^{n-1}, d_p^n) + \lambda_D m_p(d_p^n) + \sum_{k \in N(p) \setminus q} m_{kp}(d_p^n) \quad (17)$$

, where $p=(x,y)$ on level n, m_{pq} is m_{below1}, m_{below2}, m_{below3}, m_{below4}, when $q=(2x,2y)$, $(2x+1,2y)$, $(2x,2y+1)$, $(2x+1,2y+1)$, respectively, in level $n-1$.

D. Belief Propagation Algorithm

The belief propagation algorithm is used to find a solution for the disparity image as described below:

1. For every level n, compute the data cost for every pixel by:

$$m_p^n(d_p^n) = \left[I_R^n(x_p, y_p) - I_L^n(x_p - d_p^n, y_p) \right]^2$$

2. All messages are initialized to 0.

$$m_{pq}^n(d_p^n) \leftarrow 0$$

3. For each iteration i = 1…T, update the following messages:

3.1 Intra-grid messages:

$$m_{pq}^n(d_p^n) \leftarrow \min_{dp} \lambda_S E_{pq}^S(d_p^n, d_q^n) + \lambda_D m_p(d_p^n) + \sum_{k \in N(p) \setminus q} m_{kp}(d_p^n)$$

3.2 Inter-grid message to the coarser grid level:

$$m_{pq}^n(d_p^n) \leftarrow \min_{d_p} \lambda_I g(d_p^n, d_q^{n+1}) + \lambda_D m_p(d_p^n) + \sum_{k \in N(p) \setminus q} m_{kp}(d_p^n)$$

3.3 Inter-grid message to the finer grid level:

$$m_{pq}^n(d_p^n) \leftarrow \min_{d_p} \lambda_S g(d_q^{n-1}, d_p^n) + \lambda_D m_p(d_p^n) + \sum_{k \in N(p) \setminus q} m_{kp}(d_p^n)$$

4. At level 0, compute disbeliefs for each pixel p:

$$disbelief_p^0(d_p^0) \leftarrow \lambda_D m_p(d_p^0) + \sum_{k \in N(p) \setminus q} m_{kp}(d_p^n)$$

5. Choose the value for disparity of each pixel p to the one with maximum belief or the minimum disbelief:

$$d_p^0 = \arg\min_{d_p} disbelief_p^0(d_p^0)$$

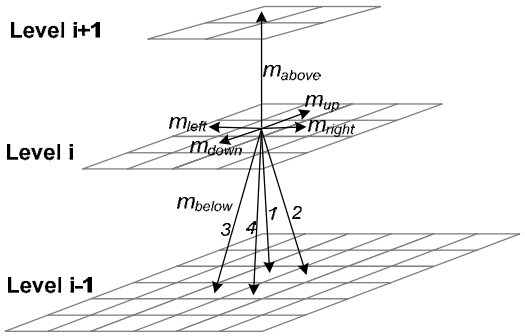

Figure 2. Message Passing in Coarse-and-Fine BBP.

IV. Experimental Results

We ran the coarse-and-fine Bayesian belief propagation algorithm on three types of stereo pairs which are those of random dot images, synthetic images, and real images.

Figure 3 shows the comparison of the stereo results from one level, coarse-to-fine, and our coarse-and-fine BBP. The results show that the coarse-and-fine algorithm can reduces some errors in the other algorithm.

The results for synthetic images are shown in Figure 4. The disparity images are shown in both coarse and fine levels, which appear to be so clean.

Figure 5 to 6 are the stereo results for real images. In figure 5 are the result for the tree images which looks very promising. Illustrated in Figure 6 are the intermediate results of the algorithm at different iterations, which show how the pixels propagate the right solution to the whole image. A result of Tsukuba stereo pair is shown in Figure 7. Compared to the ground truth image, our algorithm yields an accurate disparity image which has only some error in some non-texture areas.

V. CONCLUSION

We have presented a coarse-and-fine belief propagation algorithm for stereo vision to help get the distant features of the coarse level closer in order to not get stuck at a local minimum solution in the fine level. We present results for synthetic, random-dot, and real images, showing an increase in the accuracy of the disparity map. Our main contribution is in the mechanism for belief propagation in a multi-resolution grid. The algorithm is a connectionist one, since it manages to find a solution by only communicating within a neighborhood. Thus, it lends itself to parallel implementations for improved speed. In general the algorithm converges by the 2nd to 3rd iteration. Thus, the number of iterations is indeed very low.

Estimating Radar Cross Section by Anisotropic Diffusion

Sathit Intajag

King Mongkut's Institute of Technology Ladkrabang, Department of Instrumentation Engineering,
Faculty of Engineering, Ladkrabang, Bangkok, THAILAND 10520

Abstract- **Speckle effects are commonly observed in synthetic aperture radar (SAR) images, which apply to many fields, such as agriculture and forestry. The human eye is capable of deriving meaningful information from SAR images; however, an automatic or semi-automatic processing algorithm has difficulty distinguishing the objects in the images because of noise effects present in those images. This paper presents an estimation method for SAR images, which employs an anisotropic diffusion algorithm. In the proposed scheme, a SAR image is transformed into a logarithmic domain where the diffusion process is used to grow homogeneous regions in the noise environment until the regions reach some criteria for homogeneity; consequently, the segmented image in the logarithm domain is converted to the intensity domain by an exponential function. To grow radar cross section (RCS) regions the adaptive diffusion method is introduced with a tensor technique in which tensor data are varied with the neighboring pixels. Our diffusion algorithm will stop itself by a standard deviation divided by mean, which provides according to the homogeneity criteria. Results are shown on both synthetic and satellite SAR images. The evaluation of the proposed method employs the theoretical gain of equivalent numbers of looks (*ENL*).**

I. INTRODUCTION

Many land applications of SAR images [1, 2], such as agriculture or forestry, use information from intensity data. The accuracy of these applications requires methods for identifying changes between images gathered at different times or with a single set of image at a single time, in which preprocessing to reduce speckle is an essential step. Due to the image noise by coherent effects, the overlapping of signatures of various land categories, and the strong effect of the local topography, even forest mapping turns out to be very difficult.

Typically, when it comes to filtering speckle noise to estimate radar cross section (RCS), a spatial domain and many spatial filters are provided as described by Oliver and Quegan [3]. However, the anisotropic diffusion method has been developed to achieve a good trade-off between noise removal and boundary region preservation. Generally, the anisotropic diffusion model is formulated to eliminate additive noise. Speckle noise is multiplicative in nature; however, the multiplicative noise may be transformed to the additive noise by a logarithmic function [4, 5]. Furthermore, the proposed method modifies the diffusion process [6] for filtering the speckle noise by using the standard deviation divided by mean criteria to stop the iteration process.

The proposed scheme is a region-based estimation algorithm. The region-based methods postulate that neighboring pixels within the same RCS or region have similar intensity values, of which the split-and-merge [9] technique is probably the most well known. The general procedure is to compare a pixel with its immediate surrounding neighbors. If a criterion of homogeneity in RCS is satisfied, the pixel can be classified into the same region as one or more of its neighbors. In order to achieve success in estimation RCS method choosing the criteria for homogeneity is of the utmost importance.

Using anisotropic diffusion to smooth out noisy (in our assumption as the same to obtain RCS) is usually embedded with another mechanism such as watershed transformation [7] and thresholding technique [10]. In this paper, the anisotropic diffusion is employed to estimate RCS of SAR images in the logarithm domain. The diffusivity value of the diffusion process uses a structure tensor in order to discriminate textures. When the image regions have the same textures, they are grown and bounded by a diffusion mechanism. This estimation method is the same as region growing but without marker set or seeds. On the other hand, our diffusion algorithm can stop the iteration process within a standard deviation divided by mean criteria, which is provided according to the homogeneity criterion.

Section 2 presents the handling of backgrounds by the proposed method that consists of speckle noise modelling, anisotropic diffusion, and diffusion tensor. Section 3 describes the method of enhancing the SAR images in a logarithm domain. The experimental results of the despeckled images are given in Section 4 and the final Section is our conclusion.

II. RELATED WORKS

A. Speckle modeling

Generally, speckle noise is modeled with intensity and amplitude formats. The proposed method works on intensity data, which is transformed to a logarithm domain. The intensity of a SAR image $F_L(x, y)$ at a pixel coordinate (x, y), where the SAR image is assumed as the average of L looks, can be expressed by

$$F_L(x,y) = I(x,y)R_L(x,y) \tag{1}$$

where R_L is the speckle noise with L looks and I represents the radar cross section of the imaged surface [3].

The multiplicative model of speckle noise suggests performing a logarithmic transformation on the equation (1), giving

$$\tilde{F}_L = \tilde{I} + \tilde{R}_L \tag{2}$$

where $\tilde{F}_L = \ln(F_L)$, $\tilde{I} = \ln(I)$, and $\tilde{R}_L = \ln(R_L)$. From the transformation, $\tilde{R}_L$ becomes stationary white noise, we get the additive noise model, $\tilde{F}_L$ [4, 5].

An equivalent number of looks or *ENL* [11] is often used to estimate the speckle noise level in a SAR image, which is formulated by the ratio of mean to variation in the homogenous image area as given by:

$$ENL = E(F)^2 / V(F), \quad (3)$$

where $E(F)$ and $V(F)$ denote the mean and variance that are estimated from the homogenous area, respectively. In our scheme, *ENL* is employed to measure the degree of speckle reduction, by the meaning of: the higher the *ENL* value, the stronger the speckle noise reduction.

B. Anisotropic Diffusion

Anisotropic diffusion is derived for nonlinear diffusion. It was first proposed and has attracted much deserving attention in the field of image processing by Perona and Malik [12]. In their work, nonlinear diffusion was used to reduce noise while enhancing the true location of edge images. This diffusion is introduced with a space- and time-variant diffusion coefficient, $c(x, y, t)$, as formulated by

$$\frac{\partial f(x,y,t)}{\partial t} = div\left[c(x,y,t)\cdot\nabla f(x,y)\right] \quad (4)$$

where $f(x,y,t)$ is an image pixel value at discrete time steps (t^{th} iterations, for $t = 0$ the representation is the original data: $f(x,y,0) = f(x,y)$). *div* is the divergence operator and $\nabla f(x,y)$ denotes the gradient of images.

To allow the diffusion process to run smoothly from intra-region in RCS to inter-region of the another RCS and thus preserve edges, the region boundaries need to be identified. Obviously, the boundaries are not available a priori, and the best way to estimate the boundary locations by using an edge detector. Perona and Malik [12] claimed that the simplest gradient of images at time t ($\nabla f(x,y,t)$) works excellently; consequently, the diffusion coefficient, $c(x, y, t)$, is given by:

$$c(x,y,t) = g\left(\left|\nabla f(x,y,t)\right|\right) \quad (5)$$

The diffusivity function $g\left(\left|\nabla f(x,y,t)\right|\right)$ is provided to enhance the edges of objects in an image by smoothing the original image while preserving brightness discontinuities. Perona and Malik [12] defines the function as

$$g\left(\nabla f(x,y,t)\right) = \left(1 + \frac{\left\|\nabla f(x,y,t)\right\|^2}{K^2}\right)^{-1} \quad (6)$$

where K denotes a parameter controlling the diffusion strength. The enhancing process is obtained by gradient magnitude $\left|\nabla f(x,y,t)\right|$: where if $\left|\nabla f(x,y,t)\right|$ is large, then the diffusion will be low to preserve the edges. If $\left|\nabla f(x,y,t)\right|$ is small, then the diffusion will tend to smooth the pixel $f(x,y)$.

Catté *et al*. [13] used a Gaussian function (G_σ) with a small variance for convolution with the gradient magnitude term by replacing $g\left(\left|\nabla f(x,y,t)\right|\right)$ with $g\left(\left|G_\sigma * \nabla f(x,y,t)\right|\right)$. The regulation of Catté *et al*. [13] provides edge sharpening and is more stable than the Perona and Malik method. Form the Perona and Malik method, Weickert and Benhamouda [8] studied in more detail about the discrete implementations, a regularization factor.

C. Diffusion tensor

This is a technique to develop a directed diffusion by using local geometric structures. It is adapted from coherence enhancing diffusion (CED) proposed by J. Weickert in 1999 [6]. He suggested many useful properties of nonlinear diffusion under some general assumptions, which concern with the input images and some conditions imposed on the diffusion tensor, D, which was used to replace the diffusion coefficient, $c(x, y, t)$. A formulation of CED equation is expressed by:

$$\frac{\partial f(x,y,t)}{\partial t} = div\left[D\cdot\nabla f(x,y)\right] \quad (7)$$

The diffusivity tensor is a function of image gradient, where D is defined in a matrix framework as follows.

$$D = \begin{bmatrix} d_{11} & d_{12} \\ d_{21} & d_{22} \end{bmatrix} \quad (8)$$

This matrix is constructed by the smoothing perpendicular [17] of the image gradient and an integration scale ρ by using the convolution of an image $f(x, y)$ with a Gaussian kernel G_σ to obtain a smoothed version of the image with standard deviation σ, $f_\sigma(x,y) = G_\sigma * f(x,y)$, where * represents the convolution operator. Accordingly, the diffusivity tensor can be attained by a componentwise convolution of terms $\nabla f_\sigma(x,y)\left(\nabla f_\sigma(x,y)\right)^T$, which are partial derivatives, and a Gaussian G_ρ that is given as:

$$S_\rho\left(\nabla f_\sigma(x,y)\right) = G_\rho * \left(\nabla f_\sigma(x,y)\left(\nabla f_\sigma(x,y)\right)^T\right) \quad (9)$$

where T denotes a transposition of matrix. The structure tensor, S_ρ, is symmetric and positive semi-definite.

$$S_\rho = \begin{bmatrix} s_{11} & s_{12} \\ s_{21} & s_{22} \end{bmatrix} \quad (10)$$

In the CED [6], an integration scale ρ takes positive values. The diffusion process along coherent structures is based on the construction of a diffusion tensor whose eigen-directions coincide with the eigenvectors of the structure tensor and provide the different eigenvalues; namely,

$$\begin{aligned} \lambda_1 &= \alpha, \\ \lambda_2 &= \alpha + (1-\alpha)e^{\left(\frac{-C}{(\mu_1-\mu_2)^{2m}}\right)}, \end{aligned} \quad (11)$$

where μ_1 and μ_2 are the eigenvalues of the structure tensor and C, m, and α are parameters controlling the shape of the exponential form.

The CED method based on the structure tensor provides a local description for boosting up the ridge and valley [14], which is effective of enhancing images such as a fingerprint or a blood vessel [15]. In our paper, this diffusion method is modified to remove the speckle noise by preserving the information detail.

III. Estimate RCS by Anisotropic Diffusion

To smooth out the speckle noise by anisotropic diffusion, the proposed method uses logarithmic transformation to convert the multiplicative noise to additive noise. In practice, we employ a natural logarithm by adding the image data with 1 for convenience in calculation. The SAR image in an additive model as seen in Eq. (2) is an optimal model to process with the anisotropic diffusion methods. After the noise is smoothed out by the diffusion process, the image data is converted to the intensity domain by an exponential function.

The anisotropic diffusion, which is used to estimate RCS, is modeled by Eq. (7) when the diffusivity tensor D is

modified to reduce speckle noise in the logarithm domain and to discriminate textures in each region. In modification, the diffusion coefficient is constructed along boundaries of the homogeneous areas by using a local gradient of the smoothed image $f_\sigma(x,y)$. Generally, the Gaussian smoothing used for the structure tensor dislocates the edges in feature space leading to inaccurate results [16]. However, a nonlinear structure tensor based on a nonlinear matrix-valued diffusion method can tackle these dislocations.

The diffusion tensor *D* is decomposed as

$$D = \begin{bmatrix} d_{11} & d_{12} \\ d_{21} & d_{22} \end{bmatrix} = V^T \begin{bmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{bmatrix} V \tag{12}$$

where the parameters: λ_1 and λ_2 are conductivity values and *V* denotes the rotation matrix [17]. These parameters are calculated by a first-order derivative in the neighborhood of a coordinate pixel (*x*,*y*). In the proposed scheme, λ_1 and λ_2 represent conductivity of the gradient, expressed as

$$\lambda_2 = e^{-\frac{\|\nabla f_\sigma\|^2}{K^2}}, \quad \|\nabla f_\sigma\| = \sqrt{\left(\nabla_x f_\sigma(x,y)\right)^2 + \left(\nabla_y f_\sigma(x,y)\right)^2} \tag{13}$$
$$\lambda_1 = 0.2\lambda_2$$

where $\nabla_x f_\sigma$ and $\nabla_y f_\sigma$ are the gradients with respect to *x* and *y* directions, respectively. The parameter *K*, which is used to define λ_2, represents the controlling of the diffusion strength as the same in Eq. (6). The matrix *V* represents a local coordinate system, which is defined as

$$V = \frac{1}{\|\nabla f_\sigma\|} \begin{bmatrix} \nabla_x f_\sigma & -\nabla_y f_\sigma \\ \nabla_y f_\sigma & \nabla_x f_\sigma \end{bmatrix}. \tag{14}$$

In the RCS estimation algorithm, the diffusion process is completed by a standard deviation to mean criteria. The mean of RCS, $\hat{\mu}$, and standard deviation, $\hat{\sigma}$, are estimated in a homogeneous region, where $C_0 = \hat{\sigma}_0/\hat{\mu}_0$ is calculated before taking the diffusion process and $C_t = \hat{\sigma}_t/\hat{\mu}_t$ is formulated between the running of the diffusion process at the t^{th} iteration. When the ratio C_0/C_t is more than the defined value *R*, the iteration processes stop.

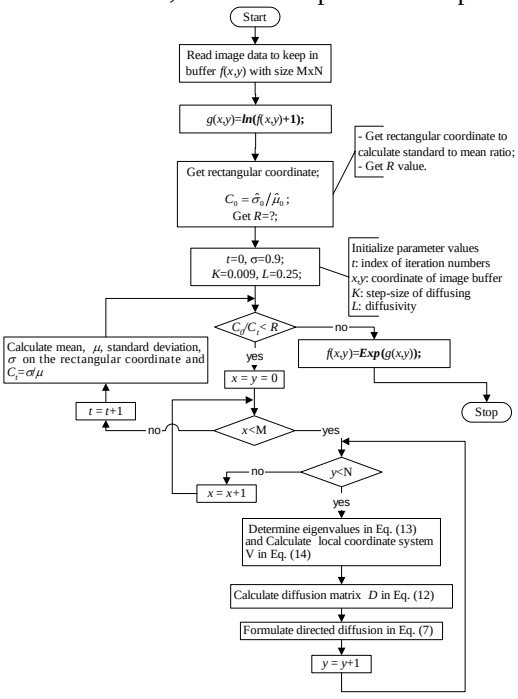

Fig. 1 RCS estimation algorithm

Fig. 1 illustrates our RCS estimation algorithm. The algorithm will get a SAR input and transfer the input data by taking logarithm. A user identifies a homogeneous region of the input data in rectangular coordinates and defines a homogeneity criterion *R*. The algorithm will calculate the standard to mean ratio, C_0, and go to the step of initialization of anisotropic diffusion parameters. Consequently, the diffusion process and measuring the homogeneity region will be started and operated until the ratio C_0/C_t is greater than the defined value *R*, and then the iteration processes are finished.

IV. Experiments and Results

Several illustrations and evaluations have been done on ERS-1/AMI and JERS-1/SAR satellite data [18]. These test data are selected from West-Thailand in Kanchanaburi province (coordinates 99°5′ E; 14°0′ N). The area consists of sparse forest, river, urban, and agricultural lands. Fig. 2(*a*) illustrates the ERS-1 image, which has a pixel spacing of 15 m and the image size, 256×256 pixels with 8 bits per pixel (taken on 22 November 1991). Fig. 3(*a*) shows the JERS-1 image with a pixel spacing of 12.5 m and the image size, 256×256 pixels with 16 bits per pixel (taken on 22 September 1992).

The experimentation results, which are depicted in Fig. 2(*b*~*d*) and 3(*b*~*d*), are processed by RCS estimation algorithm at a difference ratio of the homogeneous criteria, *R*. The homogeneous areas that are employed to estimate the standard deviation to mean values, are defined on the rectangular coordinates [(142, 84), (154, 100)] for Fig. 2 and [(27,170), (57, 193)] for Fig. 3. These results correspond with Table 2 and 3 that show the algorithm's parameters depending on the given value *R*.

Table 1 and 2 illustrate the numerical results of the RCS of each object from the ERS-1 and JERS-1, respectively. In the Tables, *R* is defined in the rough scale from 4 to 22. The *R* criterion provides the iteration processes with a halting mechanism, when the diffusion process propagates until the noise ratio is greater than the homogeneous criteria.

Table 1. The numerical results from ERS-1 image.

R	Iterations	Mean	Variance	*ENL*
-	-	39.39	33.90	45.77
4	195	21.85	2.61	182.97
6	292	21.80	1.10	433.45
8	389	21.83	0.69	692.03
12	625	21.84	0.30	1586.36
20	1409	22.00	0.10	5071.30
22	1639	22.03	0.06	7713.72

Table 2. The numerical results from JERS-1 image.

R	Iterations	Mean	Variance	*ENL*
-	-	62.37	72.04	53.99
4	416	33.52	6.28	178.90
6	575	32.59	2.79	380.67
8	725	32.38	1.46	716.65
12	1136	32.23	0.86	1210.25
20	1811	31.60	0.33	3000.51
22	1899	31.53	0.27	3746.68

The 3rd column of Table 1 and 2 provides the means of RCS, which represents water region in Fig. 2 and 3. In Fig. 2(*d*), the expected RCS of water region at *R*=22 equal to 22.03. For Fig. 3(*d*), the expected RCS of water region at *R*=22 equal to 31.35. As seen from the column of variance, the values decrease when *R* increase and that of the causes of the higher *ENL*.

Fig. 3. Despeckled results of JERS-1 image for different ratio *R*.

V. Conclusions

The RCS estimation of SAR images is important in an estimation for classification of agriculture, forestry and different terrain types, which was the motivation our research. The algorithm modifies the diffusion process by the decomposition of the diffusion tensor to improve the criterions of contour pixels and to grow the regions of each RCS object in optimum boundary. The superior performance of the adaptive diffusion method is in maintaining the homogeneous region boundaries in each region and booting up the boundary magnitude as seen from the *ENL* values in Table 1 and 2. The proposed algorithm can use the knowledge of SAR images to adapt the parameters of anisotropic diffusion for estimating RCS, such as the numbers of iteration and the growing region process were given by the homogeneity criteria.

***Abstract*-This paper presents determination of BOD by fitting model of time response curve from biosensor. Unlike previous method, the proposed method is a rapid, simple, compact and inexpensive determination of BOD measurement. The method consists of two phases: data collection and model fitting. In the data collection phases, we acquired data of eight degrees of added glucose and glutamic acid (GGA) substrate which covered the degree of water pollution. In the fitting phases, Iterative Least Square (ILS) is applied to fit the data to a Second Order Plus Dead Time (SOPDT) model. We compared the results to those obtained from recorder chart analysis by human experts. The technique requires less time consumption than BOD_5 and BOD_7. The algorithm is to be integrated into our on-going BOD analysis Machine.**

I. INTRODUCTION

BOD - biochemical oxygen demand is a method to measure a request of oxygen in a sample of water. It can be used to infer quality of the water or degree of pollution [1]. The BOD values indicate the amount of biodegradable organic material and the oxygen used to oxidise inorganic material such as sulphides and ferrous iron. The BOD test finds its main application in measuring waste load of treatment plant and evaluates the BOD removal efficiency of such treatment systems.

The BOD has been determined conventionally by taking a sample of water, aerating it, placing it in a sealed bottle, incubating for a period of time at $20 \pm 1\,^{\circ}C$ in the dark. The oxygen consumption in the water is determined at the end of incubation. For the American standard, the incubation time is five days and the BOD value obtained from this method is named BOD_5 [1] Whereas for the Swedish standard, the incubation time is set to seven days and the result is called BOD_7[2]. However, it has limitation of being time consuming and is not suitable for on-line measurement process. It is necessary to develop an alternative which requires less time for BOD evaluation. This could be achieved by biosensor.

The fast determination of BOD by biosensor is performed on a sample of water [4] confused with glucose and glutamic acid (GGA) [3, 6-8]. These approaches can provide quantitative or semi-quantitative analytical information using an integrated device.

The biosensor response curve from BOD measurement can be modeled using kinetic or dynamic models. The advantage of this method is a rapid, simple, compact and inexpensive determination of BOD measurement. It also uses less substrate than BOD_5 and BOD_7 and enabled possibilities of implementation for on-line monitoring applications. However, the conversion of difference current from the response curve to a BOD value is still done by experts on a chart recorder.

Since method of calculating BOD value depends on expertise of the human operators, it is a slow and complicated measurement process. From these drawbacks of the current method, this paper focuses on estimation and prediction of biosensor response curve by an Iterative Least Square (ILS) method on the time response curve. Typical response curve can be shown in Figure 1. The curve bears similarity to a time response of a Second Order Plus Dead Time (SOPDT) system; therefore, it is used as the model in our work.

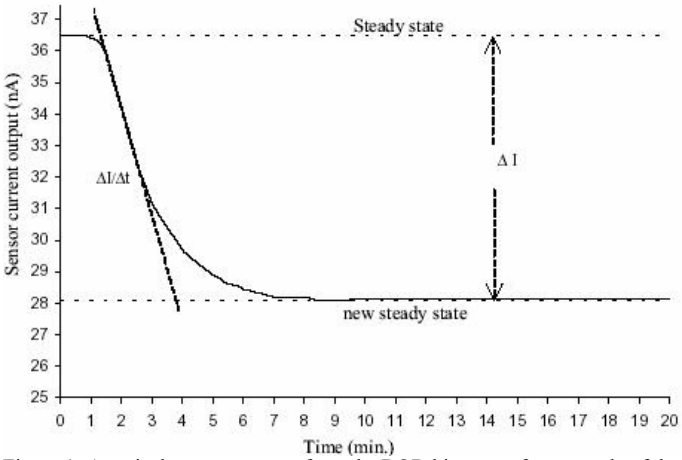

Figure 1. A typical response curve from the BOD biosensor for a sample of the synthetic wastewater. The initial current change ($\Delta I / \Delta t$) and current difference (ΔI) between two steady states were the sensor responses for sensor BOD measurements in the kinetic or dynamic models.

The paper is organized as follows. After general introduction presented in this section, our proposed method is described in Section II. In Section III, we present some experimental results. Finally, conclusion and future work are drawn in Section IV.

II. PROPOSED METHOD

The method consists of two phases: data collection and model fitting. In the data collection phase, we start by acquiring electrical current data from biosensor. In the fitting phases, we use iterative least square method to model a non-linear function. The time response of an SOPDT system is chosen as the model which includes four parameters.

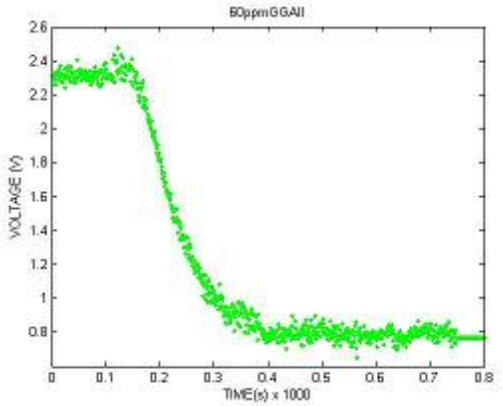

Figure 2. The change of electrical current using BOD sensor

A. Parameter Model Consideration

The change of signal is non-linear form. Before adding GGA, the signal is at a high and stable level. When GGA is added, the level of signal gradually decreases. Finally, the signal reaches another steady level. The decrease of signal level depends on the amount of added GGA. The response resembles the time response of an SOPDT which can be expressed as

$$y(t) = -k(1-(1+\frac{t-t_d}{\tau})e^{\frac{-(t-t_d)}{\tau}})u(t-t_d)+y_s \qquad (1)$$

this is function of SOPDT where k is the change in y(t) between the two steady states, τ is the system time constant, t_d is the delay time and y_s is the initial value of y(t). u(•) is the standard unit step function.

This model estimation is performed by an ILS estimator. The technique repeatedly applied a Least Square (LS) estimator to a liberalized form of non-linear function. Details are explained in the sequel.

B. Least Square Estimation

The method of least squares assumes that the best-fit curve of a given type is the curve that has the minimal sum of the deviations squared (*least square error*) from a given set of data. The LS is an optimization technique to find an approximate solution for system of linear equations which have no exact solution. It can be written as

$$\hat{\boldsymbol{\theta}} = (\mathbf{A}^T\mathbf{A})^{-1}\mathbf{A}^T\mathbf{b} \qquad (2)$$

where $\hat{\boldsymbol{\theta}}$ is the LS estimate of the equation $\mathbf{A}^{\mathrm{T}}\mathbf{y}=\mathbf{b}$. $(\mathbf{A}^T\mathbf{A})^{-1}\mathbf{A}^T$ is the pseudo inverse.

Since the response signal is non-linear, plain LS estimation can not be employed. So, we use Gauss-Newton algorithm to overcome the problem of plain LS estimation.

C. Iterative Least Squares

The LS finds its use in many applications and some researches try to overcome its limitation on linear function by applying several techniques to adjust the model for the LS [11-12]. The parameters of model are estimated iteratively until minimum error is reached [13-14]. Among these, Gauss-Newton algorithm can be used to solve this nonlinear least square problem.

A system of nonlinear equations can be written as

$$\mathbf{g_1}(\boldsymbol{\Phi}) \approx \mathbf{y}_1 . \qquad (3)$$

It can be approximated by Taylor series as

$$\frac{\partial \mathbf{g_1}}{\partial a}\Delta\boldsymbol{\Phi}_a + \frac{\partial \mathbf{g_1}}{\partial b}\Delta\boldsymbol{\Phi}_b + \cdots + \frac{\partial \mathbf{g_1}}{\partial n}\Delta\boldsymbol{\Phi}_n = \mathbf{y}_1 - \mathbf{g}_1\left(\boldsymbol{\Phi}^k\right). \qquad (4)$$

This form can be solved by LS estimator. Subsequent guesses $\boldsymbol{\Phi}^k$ for the parameter vector are produced by the recurrence relation

$$\boldsymbol{\Phi}^{k+1} = \boldsymbol{\Phi}^k - (\mathbf{J}_f(\boldsymbol{\Phi}^k)\mathbf{J}_f(\boldsymbol{\Phi}^k)^{\mathrm{T}})^{-1}\mathbf{J}_f(\boldsymbol{\Phi}^k)\mathbf{f}(\boldsymbol{\Phi}^k) \qquad (5)$$

where $\mathbf{f} = (\mathbf{f}_1 \ldots \mathbf{f}_n)$ and $\mathbf{J_f}(\boldsymbol{\Phi})$ are Jacobian of $\mathbf{f}$ at $\boldsymbol{\Phi}$. The matrix inverse is never computed explicitly in practice. we use

$$\boldsymbol{\Phi}^{k+1} = \boldsymbol{\Phi}^k + \boldsymbol{\Delta}^k \qquad (6)$$

and we compute update Δ^k by solving the linear system

$$\mathbf{J}_f(\boldsymbol{\Phi}^k)\mathbf{J}_f(\boldsymbol{\Phi}^k)^{\mathrm{T}}\boldsymbol{\Delta}^k = -\mathbf{J}_f(\boldsymbol{\Phi}^k)\mathbf{f}(\boldsymbol{\Phi}^k) \qquad (7)$$

where

$$\mathbf{J}_f(\boldsymbol{\Phi}^k) = \begin{bmatrix} \frac{\partial \mathbf{g_1}_{(x_1,y_1)}}{\partial \boldsymbol{\Phi}_1{}^k} & \frac{\partial \mathbf{g_1}_{(x_1,y_1)}}{\partial \boldsymbol{\Phi}_2{}^k} \cdots & \frac{\partial \mathbf{g_1}_{(x_1,y_1)}}{\partial \boldsymbol{\Phi}_n{}^k} \\ \vdots & \vdots & \vdots \\ \frac{\partial \mathbf{g_1}_{(x_n,y_n)}}{\partial \boldsymbol{\Phi}_1{}^k} & \frac{\partial \mathbf{g_1}_{(x_n,y_n)}}{\partial \boldsymbol{\Phi}_2{}^k} \cdots & \frac{\partial \mathbf{g_1}_{(x_n,y_n)}}{\partial \boldsymbol{\Phi}_n{}^k} \end{bmatrix} \qquad (8)$$

$$\boldsymbol{\Phi}^k = \begin{bmatrix} \Delta\boldsymbol{\Phi}_1 \\ \Delta\boldsymbol{\Phi}_2 \\ \vdots \\ \Delta\boldsymbol{\Phi}_n \end{bmatrix} \qquad \mathbf{f}(\boldsymbol{\Phi}^k) = \begin{bmatrix} \mathbf{y}_1 - \mathbf{g}_{1(x_1,y_1)}\left(\boldsymbol{\Phi}^k\right) \\ \vdots \\ \mathbf{y}_n - \mathbf{g}_{1(x_n,y_n)}\left(\boldsymbol{\Phi}^k\right) \end{bmatrix} \qquad (9)$$

$\mathbf{g}_{\mathbf{1}(x,y)}\left(\mathbf{\Phi}^k\right)$ is the model function around point (x, y) and $\mathbf{\Delta\Phi}_1 \ldots \mathbf{\Delta\Phi}_n$ is the parameter vector. The Gauss-Newton method is an iterative procedure and the parameter vector is initiated by an initial guess. Then the time response function of an SOPDT equation can be formed by

From equation (1), members of the Jacobian matrix can be found by

$$\begin{aligned}
\frac{\partial y}{\partial k} &= -(1-(1+\frac{t-td}{\tau})e^{\frac{-(t-td)}{\tau}})u(t-td) \\
\frac{\partial y}{\partial \tau} &= -k(\frac{t-td}{\tau^2})e^{\frac{-(t-td)}{\tau}}[1-(1+(\frac{t-td}{\tau}))]u(t-td) \\
\frac{\partial y}{\partial td} &= k\frac{(-e^{\frac{-(t-td)}{\tau}})}{\tau}[1-(1+\frac{t-td}{\tau})]u(t-td) \\
\frac{\partial y}{\partial y_s} &= 1
\end{aligned} \tag{10}$$

After substituting (10) into (8), it can be formed in linear equations as (2).

III. Experimental Result

The data collection to evaluate the performance of our proposed method was performed from sample water confused with added GGA of 5, 10, 20, 30, 40, 50, 60 and 70 parts per million. Eight degrees of GGA was added which covered the degrees of water pollution. Each degree of added GGA was evaluated three times. An example of the collected data is shown in Figure 3. Each data was modeled using ILS on the time response of an SOPDT. We compared the results to those obtained from recorder chart analysis by human experts.

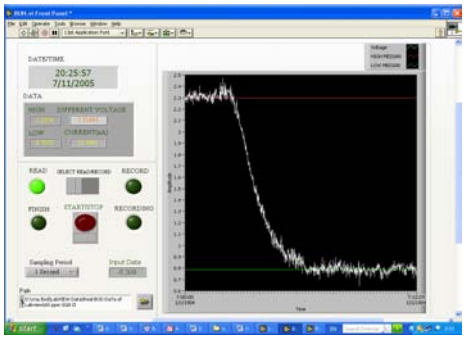

Figure 3. Data collection by LabVIEW program which used in data keeping. It spends time about fifteen minutes for data keeping and shows low, high, and different of voltage. The data is estimate by simple technique and convert to electrical current. It is automatic record.

Figure 4 shows performance of the estimation by our proposed method. The axis x and axis y of graph are time and voltage, respectively.

From experimental results, it can be seen that the estimate produced the best results. The error of estimation which compared with the results from expert is shown in Table I. The results were compared in nanoampere with an average of three measures for each GGA substrate. These results would be used to calculate the BOD value.

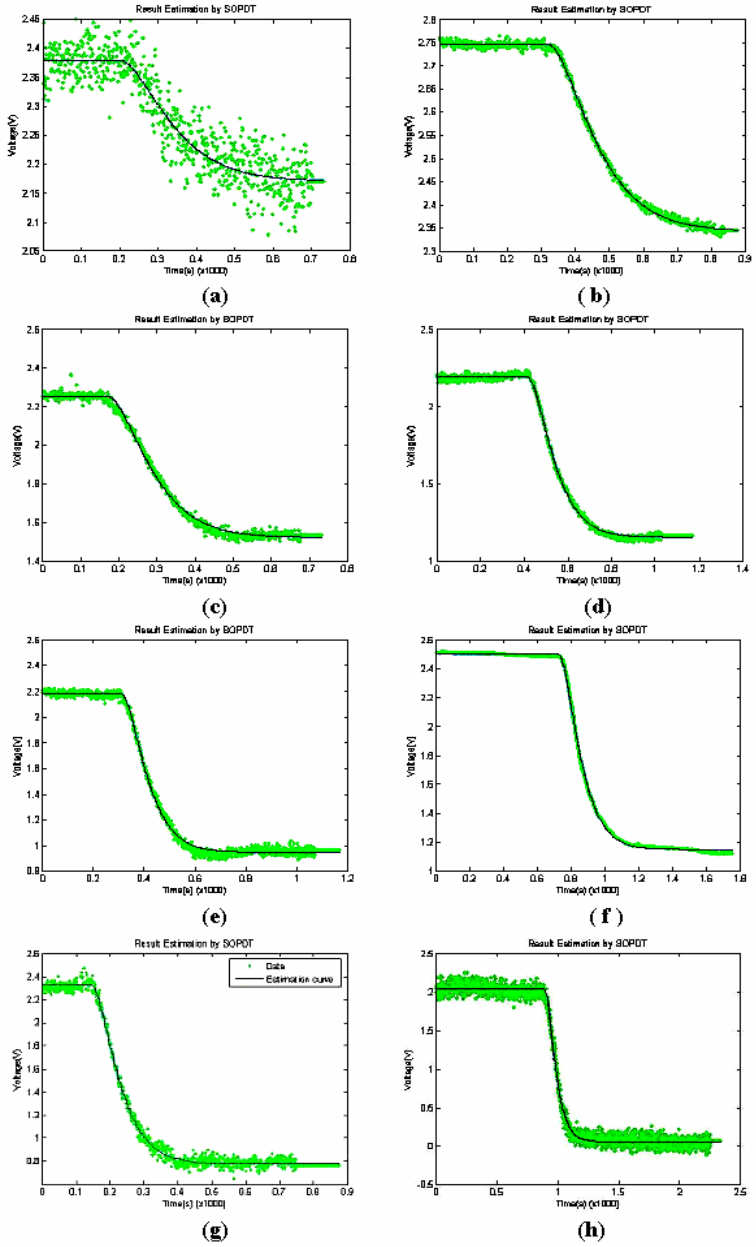

Figure 4. Results of estimation for each degree of added GGA by our proposed method which using MATLAB program. (a) 5 parts per million (b) 10 parts per million(c) 20 parts per million (d) 30 parts per million (e) 40 parts per million(f) 50 parts per million (g) 60 parts per million (h) 70 parts per million

IV. Conclusion and Future work

In this paper, we proposed a technique to estimate the timer domain response curve of current drawn from a BOD sensor. ILS estimation based on Gauss-Newton algorithm was applied. It requires less time consuming than that of BOD_5 and BOD_7. It also showed accurate results when compared with those from human expert. Moreover, our approach can be applied to model other nonlinear systems. The algorithm is to be integrated into our on-going BOD analysis Machine.

***Abstract*-This paper describes the design of adaptive video equalizer based on a linear-phase FIR filter with least mean square (LMS) algorithms. In color video waveform transmission, inequalities of delay between luminance and chrominance channel is a potential source of picture impairment. Delay inequalities cause horizontal registration errors and hue between the luminance-chrominance content of picture and will make picture look smeared. As the simulation results, the modulated 20T sine-square pulse test signal with color sub-carrier 4.43 MHz for PAL system is utilized. It can be seen that the proposed adaptive equalizer based on linear phase FIR filter can equalized the chrominance delay distortions without causes gain error and provides a wide range of time-delay control.**

I. INTRODUCTION

In recent years, adaptive filtering has been receiving a great deal of attentions in the area of communications, sonar, radar, mechanical design, and biomedical electronics. Adaptive filters are self-designing system, which can adjust them to difference environments, so the use of adaptive filter provides a significant performance over the use of a fix filter. Basic classes of adaptive filtering applications are recognized, namely adaptive equalizer. Therefore, in this paper design the adaptive equalizer using LMS adaptive algorithm, which has always been attractive to the researchers in adaptive signal processing because of its simplicity and its robustness to numerical errors [1].

Unlike the IIR digital filter design problem, whereas it is not possible to design an IIR transfer function with exact linear-phase. So, many researches are always possible to design FIR digital filters with exact linear-phase [2]. In color video system, the linear distortions divided into the gain distortion only, group-delay distortion only and both gain & group-delay distortions. Adaptive amplitude chrominance distortion is described in ref. [3]. In this paper, we examine specially occurrence the group-delay distortion only hence it's necessary linear-phase FIR filter. As the effects of group-delay error are the picture look less sharp, look smeared and causes to utilize the color hue.

In addition, the pulse and bar test signal which has been used to measure linear waveform distortion in TV system is a special 20T sine-squared pulse with a 4.43 MHz color sub-carrier for PAL system [6], [8]. As a result, the proposed adaptive equalizer can be equalized the group-delay distortion in good agreement.

II. LINEAR PHASE FIR FILTER BASED ON LMS ADAPTIVE ALGORITHM

A. Linear Phase FIR Digital Filter

In this section, we pointed out why it is important to have a transfer function with a linear-phase property. It turns out it is always possible to design an FIR transfer function with an exact linear-phase response, whereas it is not possible to design an IIR transfer function with exact linear-phase. We first consider the realization of FIR digital filters. Recall that a causal FIR filter of order N is characterized by a transfer function $H(z)$ [2].

$$H(z) = \sum_{k=0}^{M} h(k) z^{-k} \tag{1}$$

where $h(k)$ are samples of its impulse response, a polynomial in z^{-1} of degree M . In the time domain, the input-output relation of the above FIR filter is given by

$$y(n) = \sum_{k=0}^{M} h(k) x(n-k) \tag{2}$$

where $y(n)$ and $x(n)$ are the output and input sequences, respectively. A linear-phase FIR of order M is either characterized by a symmetric impulse response

$$h(n) = h(M-n) \tag{3}$$

or by an antisymmetric impulse response

$$h(n) = -h(M-n) \tag{4}$$

The symmetry (or antisymmetry) property of a linear-phase FIR filter can be exploited to reduce the total number of multipliers into almost half of that in the direct form implementations of the transfer function.

To see this, consider the following manipulations of the discrete convolution equation, assuming that M is an even integer corresponding to type I or type III system [4]:

$$y(n) = \sum_{k=0}^{M/2-1} h(k)x(n-k) + h(M/2)x(n-M/2) + \sum_{k=0}^{M/2-1} h(M-k)x(n-M+k) \quad (5)$$

For type I system, we use (3) to obtain

$$y(n) = \sum_{k=0}^{M/2-1} h(k)(x(n-k) + x(n-M+k)) + h(M/2)x(n-M/2) \quad (6)$$

Equation (6) implies structures with $M/2$ coefficient multipliers rather than the M coefficient multipliers of the general direct form. Fig. 1 shows the direct form structure for a linear-phase FIR system when M is an even implied by (6).

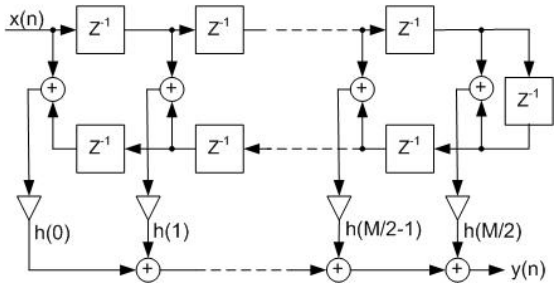

Figure 1 Direct form structure for a linear-phase FIR system when M is an even.

B. LMS Adaptive Algorithm

One of the most well known algorithms in adaptive signal processing is the Least Mean Square (LMS) adaptive algorithm proposed by Widrow and Hoff [1]. The most commonly used structure in the implementation of adaptive filter is the transversal structure given by

$$y(n) = \mathbf{w}^T(n)\mathbf{x}(n) \quad (7)$$

where,

$$\mathbf{w}(n) = [w_0(n) \quad w_1(n) \quad ..... \quad w_{N-1}(n)]^T \quad (8)$$

$$\mathbf{x}(n) = [x(n) \quad x(n-1) \quad ..... \quad x(n-N+1)]^T \quad (9)$$

where $\mathbf{w}(n)$ is tap-weight vector of FIR filter, $\mathbf{x}(n)$ is input vector, and the error signal $e(n)$ is written as

$$e(n) = d(n) - y(n) \quad (10)$$

where $d(n)$ is desire signal.

The conventional LMS algorithm is a stochastic implementation of the steepest-descent algorithm. It simply replaces the cost function $\xi = E[e^2(n)]$ by its instantaneous coarse estimate $\hat{\xi}(n) = e^2(n)$. Substituting $\hat{\xi}(n) = e^2(n)$ for ξ in the steep-descent recursion (10), and replacing the iteration index k by the time index n, we obtain

$$\mathbf{w}(n+1) = \mathbf{w}(n) - \mu\nabla e^2(n) \quad (11)$$

where ∇ is the gradient operator defined as the column vector

$$\nabla = \left[\frac{\partial}{\partial w_0} \quad \frac{\partial}{\partial w_1} \quad ..... \quad \frac{\partial}{\partial w} \right] \quad (12)$$

We note that the *i*th element of the gradient vector $\nabla e^2(n)$ is

$$\frac{\partial e^2(n)}{\partial w_i} = 2e(n)\frac{\partial e(n)}{\partial w_i} \quad (13)$$

Substituting (10) in the last factor on the right-hand side of (13) and noting that $d(n)$ is independent of w_i, we obtain

$$\frac{\partial e^2(n)}{\partial w_i} = -2e(n)\frac{\partial y(n)}{\partial w_i} \quad (14)$$

Substituting for $y(n)$, we get

$$\frac{\partial e^2(n)}{\partial w_i} = -2e(n)x(n-i) \quad (15)$$

Using (13) and (15), we obtain

$$\nabla e^2(n) = -2e(n)x(n) \quad (16)$$

Substituting, this result in (11). So that we have LMS algorithm as follows

$$\mathbf{w}(n+1) = \mathbf{w}(n) + 2\mu e(n)\mathbf{x}(n) \quad (17)$$

where μ is the step-size parameter.

III. Chrominance-to-Luminance Gain & Delay Distortions

In color video waveform transmission, linear distortions cause by gain distortion only, group-delay distortion only and both gain & group-delay distortions. The pulse and bar test signal, which has been used to measure linear waveform distortion in TV systems, by a special 20T sine-squared pulse. This pulse is formed by the linear addition of a 20T-pulse to the pulse modulated on the color sub-carrier can be expressed as follows [6].

$$x(n)=\begin{cases}\dfrac{1}{2}\sin^2\left(\dfrac{\pi t}{40T}\right)+\dfrac{A}{2}\sin^2\left(\dfrac{\pi(t-\tau}{40T}\right)\cos\omega_c t & ;|t|\le 20T\\ 0 & ;|t|>20T\end{cases} \tag{18}$$

where A is the gain of 20T sine-squared pulse, τ is delay time, T = 0.1 μs. For the Phase Alternating Line (PAL) system t is instantaneous time, $\omega_c = 2\pi f_c$ and the color sub-carrier $f_c = 4.43$ MHz.

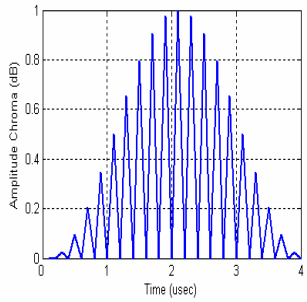

Figure 2 The Modulated 20T sine-square pulse test signal

Fig. 2 shows the undistorted modulated 20T sine-square pulse test signal, which we defined gain or $A=1$ and the delay time or $\tau = 0$. In this paper, we will defined $A=1$ but adjust τ value, because we examine specially occurrence the group-delay distortion shown in Fig. 3.

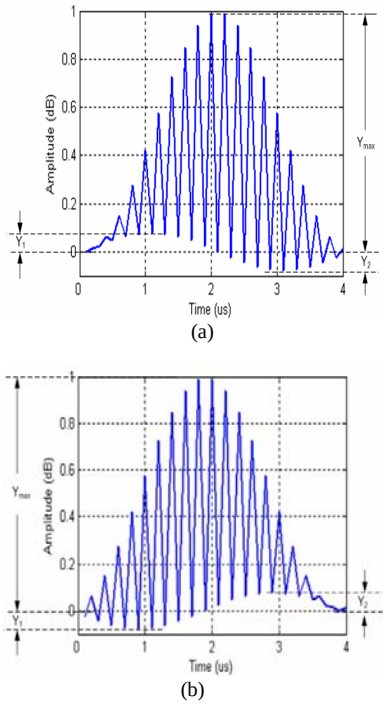

Figure 3 Group-delay distortion of the modulated 20T sine-square pulse.

From Fig. 3 (a) shows the modulated 20Tsine-square pulse is occurring a group-delay distortion only at $\tau = 200$ ns, that the peak pulse height $y_1 = 0.08$ and $y_2 = -0.08$ or $Y_1 = Y_2$ we obtain unity gain ($A = 0$ dB) given by

$$\tau = \frac{4T_0}{\pi}\sqrt{-y_1 y_2} \tag{21}$$

where y_1 and y_2 is the normalize of the single peak the following as

$$y_1 = \frac{Y_1}{Y_{\max}} \tag{22}$$

$$y_2 = \frac{Y_2}{Y_{\max}} \tag{23}$$

Fig. 3 (b) shows group-delay distortion only at $\tau = -200$ ns, that the peak pulse height $y_1 = -0.08$ and $y_2 = 0.08$. The baseline shape will indicate whether chrominance is lagging or leading luminance. The group-delay distortion will cause color hue and make the picture look smeared [7].

IV. Simulations And Results

A. *Design of Adaptive Equalizer*

Fig. 4 shows block diagram of an adaptive equalization of group-delay of chrominance distortion by using linear-phase FIR filter and LMS adaptive algorithm. Herein, $x(n)$ is input signal, which have been occurred the chrominance group-delay distortion by using the modulated 20T sine-square pulse test signal. $d(n)$ is the desire signal or no group-delay error. $y(n)$ is the output signal, which is modified the group-delay distortion, and $e(n)$ is the error signal [9].

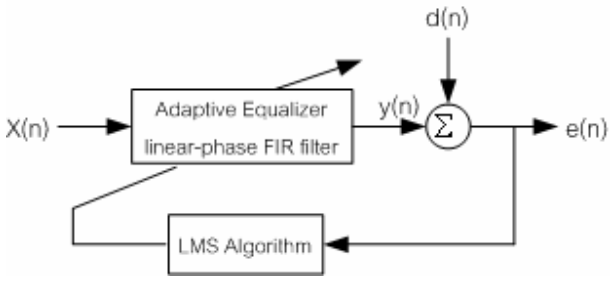

Figure 4 Block diagram of an adaptive equalization of chrominance signal

The linear-phase structure was discussed section, and the equation of adaptive equalizer linear-phase FIR based on LMS adaptive algorithm is given as

$$y(n) = \sum_{i=0}^{N/2-1} w_i(n)(x(n-i)+x(n-N+i)) + w(N/2)x(n-N/2) \tag{22}$$

B. Experimental Results

Herein, the proposed adaptive equalizer linear-phase FIR with LMS adaptive algorithm is used to correcting the distorted modulated 20T sine-square pulse test signal, which have been occurred the chrominance group-delay distortion only.

We first consider the chrominance delay inequalities between luminance-chrominance without gain error $(A=1)$ [9]. We determine the group-delay distortion only at 200 ns and -200 ns, which the baseline will be a symmetrical positive and negative peaks indicate the presence of group-delay distortion only shown in Fig. 5 (a) and (c) respectively. In this case, other parameters chose are $N=50$, and step-size $\mu=0.02$. Fig. 5 (b) and (d) show the output signal is equalized by using adaptive linear-phase FIR digital filter with LMS adaptive algorithm As the results, the proposed adaptive equalization can be equalized the chrominance delay distortion, which the baseline will be flat indicates no group-delay distortion..

Next, we used the input signal is the modulated 20T sine-square pulse has the both low-gain chrominance distortion at -2 dB ($A<1$) and group-delay distortion at +300 ns as shown in Fig. 6 (a), and the both high-gain chrominance distortion at 2 dB ($A>1$) and group-delay distortion at -300 ns as shown in Fig. 6 (c). The both of figure have the baseline are an asymmetrical positive and negative peaks indicate the presence of the both gain and group-delay distortion. Fig. 6 (b) and (d) show the low gain chrominance distortion only at -2 dB ($A_l=-2$ dB) and high gain chrominance distortion only at 2 dB ($A_h=2$ dB), respectively.

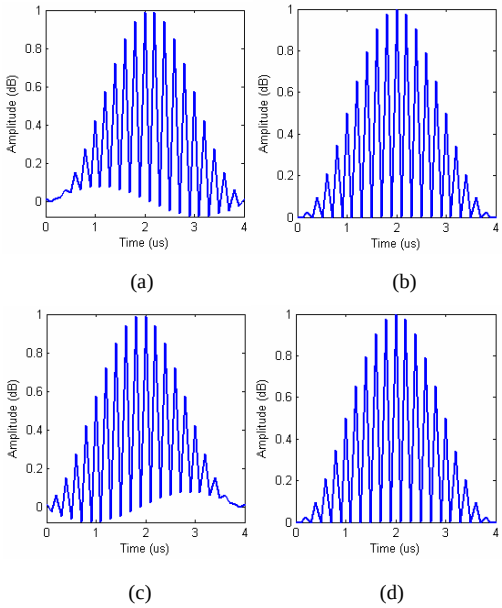

Figure 5 Group-delay distortion of chrominance signal equalized by using adaptive linear-phase FIR digital filter with LMS algorithm.

As the result, the proposed adaptive equalizer can be equalized the chrominance delay distortion only, which the baseline will be enhanced and compressed the amplitude chrominance indicates the presence of gain distortion only.

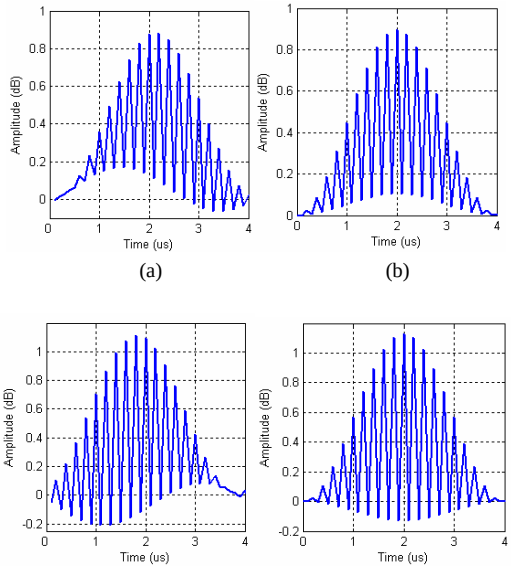

Figure 6 Gain and Group-delay distortion of chrominance signal equalized by using adaptive linear-phase FIR digital filter with LMS algorithm.

V. CONCLUSION

In this paper, an adaptive video equalizer is designed by using a linear-phase FIR structure with LMS adaptive algorithm. It is shown that the proposed adaptive equalizer can be equalized the chrominance group-delay distortion at color sub-carrier 4.43 MHz for PAL system. From the simulation results, the symmetry of linear-phase FIR filter with even order degree is adopted. Therefore, its can be exploited to reduce the total number of multipliers into almost half of that in the direct form. As the results, the modulated 20T sine-square pulse is used to examine the characteristics of the proposed adaptive equalizer. Simulation results show the performance achievable.

Bangkok 10330, Thailand

***Abstract*-Quantum dot molecules (QDMs) were grown on nanopropeller templates which were obtained by thin-capping-and-regrowth MBE process. Thin-capping-and-regrowth was done on as-grown quantum dots (QDs) at low temperature. All processes are self-assembled method which provides defect-free structures. The length of nanopropeller templates was extended by applying several cycles of thin-capping-and-regrowth as well as by using proper thin-capping thickness. Longer nanopropellers result in the possibility of growth of longer chains of QDMs if QDs are grown with suitable thickness in final cycle. Chains of QDMs stretch along [1 $\bar{1}$ 0] crystallographic direction. With their alignment in one specific direction, chains of QDMs demonstrate optical anisotropy. The polarization dependence of photoluminescence (PL) spectrum of QDM chains was measured. The QDMs grown with difference conditions were compared in term of degree of anisotropy. The optical anisotropy increases when length of aligned QDs is increased. However, it is reduced when the density of QDMs become high.**

I. INTRODUCTION

Quantum dots have been attracting interest for applications in optoelectronic devices and quantum computing as well as the fundamental physics of QDs. Their unique physical properties lead to high performance optoelectronic devices, for example, QDs lasers have low threshold current density, high temperature stability, high gain etc.[1] Because of their applicability of optoelectronic devices in fibre-optical communication, polarization dependence of QDs photoluminescence is required as one fundamental optical property. The polarization-uncontrolled laser has problems such as increasing of relative intensity noise which leads to a deterioration of bit error rate.[2] Polarized emission property of QDs was proposed to be arised from asymmetric shape, anisotropic composition and anisotropic strain of QDs.[3-5] Recently, coupling of aligned QDs was introduced that it also contributes to polarization anisotropy.[6]

QDs can be modified to form laterally close-packed QDs, which are so-called quantum dot molecules, by the GaAs-thin-capping and regrowth of InAs-QDs at low temperature on the as-grown QDs.[7] QDMs obtained by this technique have formation pattern of QDs stretching along [1 $\bar{1}$ 0] crystallographic direction. The advantage of this growth process, which is a self-assembled technique, is the possible growth of defect-free nanostructure. In our previous work, we proposed the modified MBE growth process for extending the length of QDMs.[8] The thin-capping-and-regrowth done for several cycles with proper thin-capping thickness was applied for this purpose. In this paper, we reported further experimental result i.e. the polarization-dependence PL intensity of long chain of QDMs. Polarization-dependence measurement system was set up by modifying the conventional PL measurement system. A half wave plate was placed in front of samples to adjust the polarized direction of incident laser and polarizer was placed between samples and a monochromator. The light emerging from polarizer is corresponding to Malus's law and was measured by a detector.

II. QUANTUM DOT MOLECULE CHAINS

After oxide desorption under As_4 overpressure of 8×10^{-6} Torr, 300 nm of GaAs buffer layer was grown on GaAs(100) substrates with growth rate of 0.6 ML/s at 580 °C. Afterward, the substrates were cooled down to 500 °C. This temperature which was used as a reference temperature was checked by RHEED-pattern transition from (2x4) to (2x2) reconstruction. 1.8 ML of InAs was deposited to form QDs using low growth rate of 0.01 ML/s. The growth interruption time of 30s was applied to obtain uniform QDs before the substrates were reduced to 470 °C. The QDs were thin-capped by GaAs and the growth interruption of 25 s was applied at retaining temperature of 470 °C. After that, InAs QDs were regrown with different depositions of InAs thickness. The thicker thin-capping thickness was deposited, the more InAs amount was required to form QDs. The thickness was estimated by observing RHEED transition into clear spotty pattern. As the results, the necessary thickness of InAs for the cases of the samples thin-capped with 6, 9, 12 and 15 ML of GaAs are 0.6, 0.75, 0.82 and 0.875 ML, respectively. After QDs-regrowth and annealing for 25 s, the QDs locating at the center of nanopropellers are nucleated above the QDs buried in GaAs thin-capping layer due to the seeding effect of strain as well as both of nanopropeller's blades stretch along [1 $\bar{1}$ 0] crystallographic direction due to strain anisotropy. Thin-capping-and-regrowth processes were done for several cycles in order to extend length of nanopropeller's blades.

The samples thin-capped with 9, 12 and 15 ML of GaAs and regrown QDs with InAs were used to compare the surface of samples by atomic force microscope (AFM). The nanopropeller length is statistically summarized in Fig.1 as

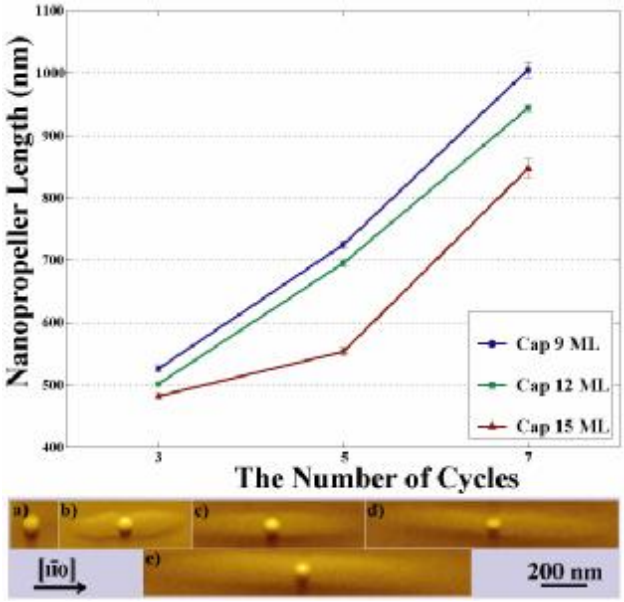

Figure 1. Nanopropeller length as a function of the number of cycles of thin-capping-and-regrowth for thin-capping thickness of 9 ML, 12ML and 15 ML. And AFM images of as-grown QDs and nanopropeller from 9ML-thin-capping for 1,3,5 and 7 cycles in a), b), c), d), and e)

well as the AFM images of as-grown QDs and nanopropeller QDs from 9ML-thin-capping for 1,3,5 and 7 cycles are shown in Fig.1 a), b), c), d) and e), respectively.

Corresponding to all thin-capping thicknesses, the nanopropeller length is increased when capping-and-regrowth process is more repeated. Considerably, the length of nanopropellers with thin-capping thickness of 9 ML is consistently longer than the length of nanopropeller with thin-capping thickness of 12 and 15 ML. However, the length fluctuation is lowest at thin-capping thickness of 12 ML and is highest at thin-capping thickness of 15 ML. For example, the standard deviations of length of nanopropellers with thin-capping of 9 ML, 12 ML and 15 ML for 7 cycles are 185.6, 123.6 and 196.36 nm, respectively.

The chains of QDMs were achieved by depositing further InAs in the last cycles. The additional QDs are likely to locate on the nanopropeller's blade templates. The chains of QDMs ordering along [1 $\bar{1}$ 0] direction can be attained by depositing with appropriate InAs amount. The QDMs from 1 cycle of 9ML-thin-capping-and-regrowth which originate from isolated nanopropellers contain 10 QDs per group in average. And the numbers of QDs per QDM form 5 cycles of thin-capping-and-regrowth and final-cycles regrowth thickness of 1.5 ML are 25 and 22 for thin-capping thickness of 9 ML (sample1 shown in Fig.2 a)) and 12 ML (sample2 shown in Fig.2 b)), respectively. The QDs densities of QDMs chains increase from densities of as-grown QDs (3.2×10^{9} cm^{-2}) and nanopropeller QDs (1.8×10^{9} cm^{-2}) to 2.7×10^{10} cm^{-2} and 2.24×10^{10} cm^{-2} for sample1 and sample2, repectively. When final-cycles regrowth thickness increase to 1.8 ML (sample3 shown in Fig.2 c)), the QDs density is raised up to 3.38×10^{10} cm^{-2}.

III. Polarization Dependence of QDM Chains

All samples used to perform PL measurement were capped with 10 nm of GaAs at 470 °C. And the substrate temperature was ramped up to 500 °C while the growth of GaAs was suspended. Further 90 nm of GaAs was grown when substrate temperature was stable.

All samples were excited by Ar^{+} laser at wavelength of 488 nm. The peaks of PL spectra of sample1, sample2 and sample3 are at 1.17 eV and full widths at half maximum are 50 meV at 77 K. In order to measure polarization dependence of the peaks, The polarized direction of laser were adjusted by retarding a halfwave plate and a polarizer was used to filter light emerging from the samples before the light entered into monochromator. The polarized direction of laser was adjusted to obtain the highest excitation of electron in QDMs by observing PL intensity at the peaks. After that, the polarizer was retarded to determine the highest intensity and set that

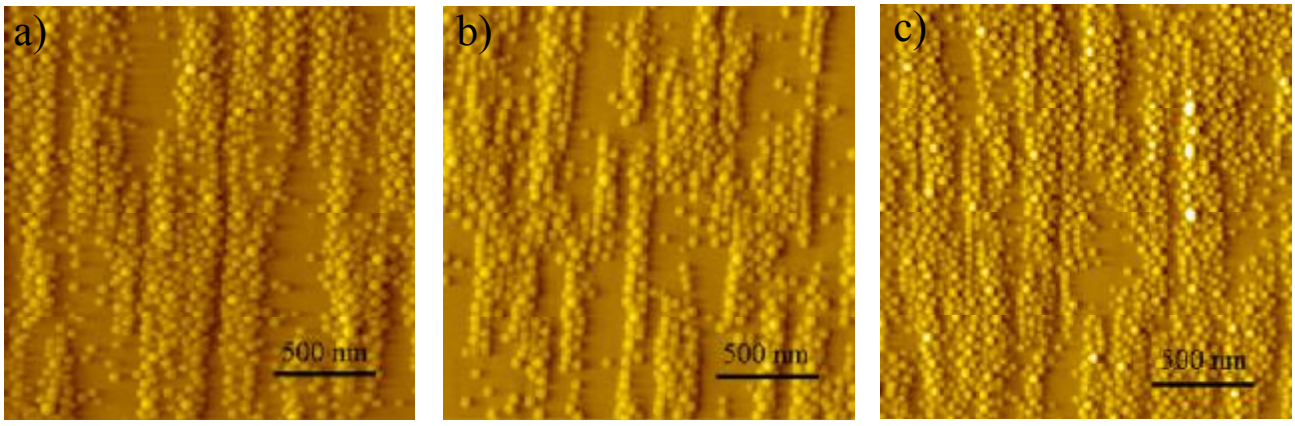

Figure 2. The AFM image of QDMs from 5 cycles of thin-capping-and-regrowth with 9 ML and 12 ML of thin-capping thickness and 1.5 ML of final-cycles regrowth thickness in a) and b), repectively and with 9 ML of thin-capping thickness and 1.8 ML of final-cycles regrowth thickness

direction to be angle of zero.

The polarization dependence of PL peaks from as-grown QDs was not observed in this experiment. QDMs in sample1, sample2 and sample3, however, demonstrated clear polarization dependence. The degree of linear polarization P defined by

$$P = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}}$$

where $I_{\max}$ and $I_{\min}$ are the maximum and minimum PL intensity. The degree of polarization at PL peaks of sample1, sample2 and sample3 are 35.15%, 29.72% and 21.35%. The PL spectrum of sample1 at each angle from 0° to 90° are shown in fig.3 as well as the peak intensity of PL spectrum was plotted on the upper right side as a function of polarization angle θ. The results of peak intensity of PL spectrum exhibit existence of two orthogonal components of PL peak intensity. The peak intensity of PL spectrum was thus fitted by

$$I = A\sin^2(\theta + \delta) + B\cos^2(\theta + \delta)$$

where A and B correspond to the peak intensities of PL spectrum in each of their component and δ correspond to the deviation angle due to zero-angle setting error. A and B imply for the PL intensity in polarization direction along [1 $\bar{1}$ 0] and [1 1 0] directions, respectively. The optical anisotropy of QDM chains is resulted from the difference in the square of the magnitude of the wave vectors between [1 $\bar{1}$ 0] and [1 1 0] directions. It is arised from the difference in amount of coupled QDs in each direction.

The measurement results of the peaks of PL spectrum can be comparatively explained. Sample1 have stronger polarization dependence than sample2. That is in an agreement with the AFM result that nanopropeller templates

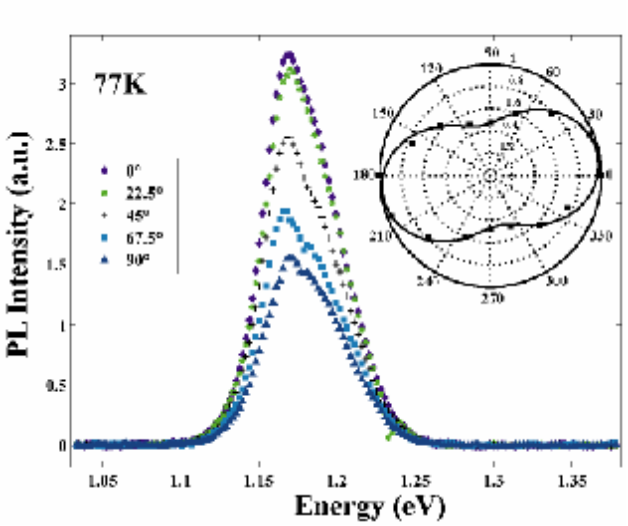

Figure 3 PL spectrum of QDMs from 9ML thin-capping and regrowth for 5 cycles (sample1) which polarized in angle of 0° to 90° and peak of PL spectrum as a function polarized angle

of sample1 are longer than that of sample2. It also implies that the number of coupled QDs aligning along [1 $\bar{1}$ 0] direction in sample1 is greater than that in sample2. In contrast, sample3 have weaker optical anisotropy, because sample3 have high density of QDs which lead to greater amount of coupling in [1 1 0] direction.

IV. Conclusion

Nanopropeller used for QDM template can be extended by applying many cycles of thin-capping-and-regrowth and proper selection of thin-capping thickness as the parameters of thin-capping-and-regrowth process. Polarization dependence of QDMs was observed in PL spectrum of QDMs. Alignment of coupled QDs along [1 $\bar{1}$ 0] rather than [1 1 0] is the origin of optical anisotropy. Longer nanopropeller template with proper overgrowth thickness gives longer ordering of ODs as well as stronger anisotropy. On the other hand, if the density of QDs which is resulted from the density of as-grown QDs and overgrowth thickness is too high, the anisotropy will be limited.

***Abstract*- The 3D shapes encountered in designing in dentistry and maxillofacial applications. It is difficult to design and edit some features of crowns, some part of skull and anatomical model for rapid prototyping.**

Therefore, this paper presents 3 dimensional deformable mesh using thin plate spline through the following 4 steps: The first step, the program was written to open, display and allow the user to interact with the 3D STL file by using Borland C++ Builder ™ and OpenGL library. Second step, the deformable region was manually defined by locate the surface control points. Then the surface control points were fitted and the patch surface were created automatically using cubic spline technique. Third step, the control points in the patch surface were manipulated in the direction as required. The last step, the control points manipulation can change the shape of the 3D object using the thin plate spline algorithm.

The results from the research have shown that the 3D deformable mesh by applying thin plate spline technique can do either restrict a deformation to a limited local region or also create a new shape by making very large area deformations as well. Therefore 3D deformable mesh is powerful alternative, which can make a small deformation in an exiting shape and modify the shape without affecting its original overall characteristics.

I. INTRODUCTION

In the past, dental crown design has been done by manual process along with expertise of dental crown designer to get dental crown with shape resemble to actual teeth. However, manual process cannot fulfill the growing demands of dental crown from increasing number of aging people. Therefore, the computer design for dental crown has become the new trend after there is a commercial CAD/CAM product for dental crown design such as CEREC™ 3D CAD/CAM system [1] for designing

However, it is quite difficult to design and manipulate dental crown shape due to natural complexity of 3D structure, which takes time to modify the shape of the dental template to have the shape that suit for each patient.

This paper presents a technique for 3D deformable mesh aided dentistry based on thin plate spline technique [2]. With this algorithm, the users are allowed to see the movement of 3D mesh, in the direction that they have been decided. Therefore, the users who needs to developed software for dental designer; CAD/CAM editing application; virtual animation or further study in 3D would find this technique more informative and useful. In recent years, some algorithms for deformable mesh model have been proposed [3][4]. Some approaches construct surfaces that interpolate from 2D data [5]. Others provide means for the direct drawing of surfaces like commercial CAD/CAM software. An alternative to these shape change techniques is the warping or deformation of existing shapes like the technique proposes in the research.

However, mostly 3D deformable mesh techniques are applied in the research or CAD/CAM technology areas. The techniques are also available in dentistry application but they are expensive commercial software such as 3shape dental designer™ [6], GeoMagic Dental ™ [7] and so on.

II. METHODS

A. 3D STL Viewer & User Interaction

First step, the graphics user interface of 3D deformable mesh has been designed using C++ Builder® and OpenGL library. The users are allowed to interact with the 3D object by rotating, zooming and panning as shown in Figure 1.

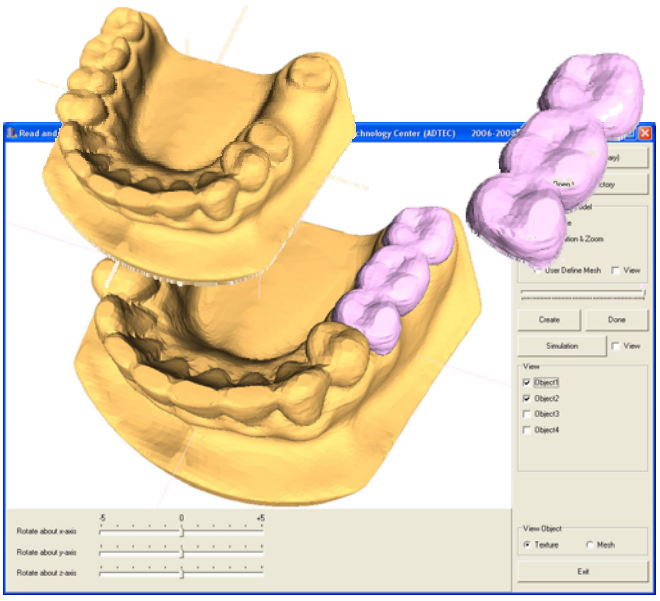

Figure1: The 3D visualization of dental cast and crown.

This software is also allowed to open the 3D object up to 100 objects with the different color set in the same time as well. The 3D STL data format has been used in this research.

B. Surface Control Points and Cubic Spline fitting

Next step is to define the area to perform dental crown shape manipulation by applying surface control points and then apply cubic spline interpolation to fit the landmarks with the mesh of

3D dental model. The landmark placement will be 4 x 4 landmark set to form a mesh of 3 x 3 on 3D object as shown in Figure 2.

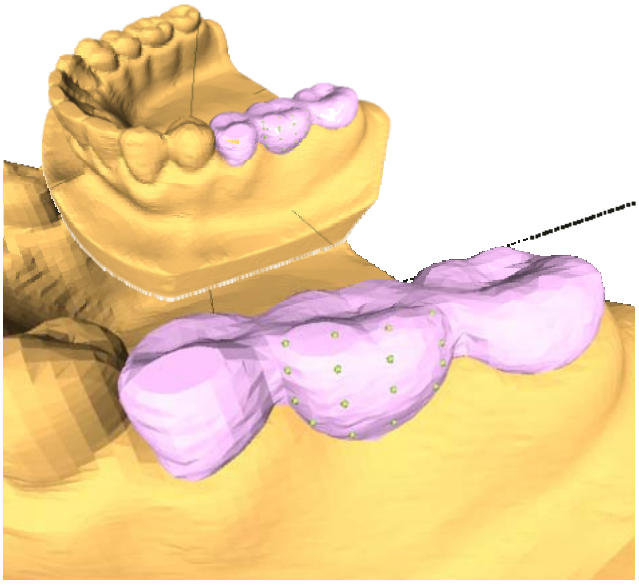

Figure2: Manual Location of Landmarks onto the 3D Object.

After landmark placement, the next step is to perform 3D cublic spline interpolation to form a mesh and create minor landmarks between major landmarks in very smooth way in both horizontal and vertical. For this experiment we have chosen the natural spline technique [8]. The results of cublic spline interpolation can be shown in Figure 3.

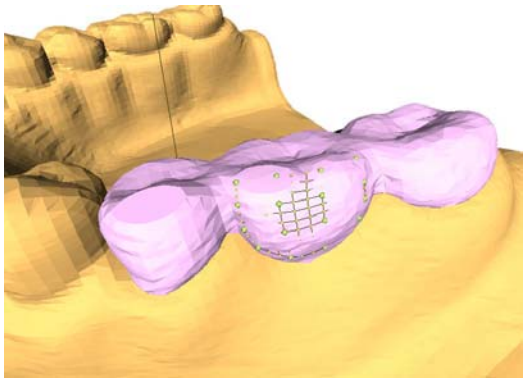

Figure 3: Automatic creating of the patch surface using cubic spline technique.

C. Adjusting the Surface Control points

The next step after performing 3D cubic spline interpolation is to manipulate the surface control point by moving the set of landmark to the direction that need the change of the 3D object shape as shown in Figure 4. This is the way to set the shape change landmarks for performing 3D thin plate spline

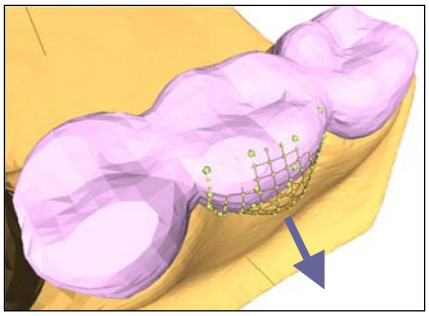

Figure 4: Adjusting of the patch surface in order to move to the required direction.

D. 3D Deformable Mesh using Thin Plate Spline

After manipulating surface control points by applying cubic spline interpolation and adjust the patch landmarks, the next step is to manipulate the mesh of the object by 3D thin plate spline to perform image manipulation by calculating the linear affine factor A and nonlinear weighting factor W from 2 set of landmarks from initial positions X which has been modified into matrix P and final positions V according to the following equations.

$$\begin{bmatrix} K & P \\ P^T & zeros(4,4) \end{bmatrix} \begin{bmatrix} W^T \\ A^T \end{bmatrix} = \begin{bmatrix} V \\ zeros(4,3) \end{bmatrix} \quad (1)$$

$$K = \begin{bmatrix} 0 & U(r_{1,2}) & \dots & U(r_{1,N-1}) & U(r_{1,N}) \\ U(r_{2,1}) & 0 & \dots & U(r_{2,N-1}) & U(r_{2,N}) \\ \dots & \dots & \dots & \dots & \dots \\ U(r_{N-1,1}) & U(r_{N-1,2}) & \dots & 0 & U(r_{N-1,N}) \\ U(r_{N,1}) & U(r_{N,2}) & \dots & U(r_{N,N-1}) & 0 \end{bmatrix} \quad (2)$$

$$U(r)_{r>0} = |r|, r = \sqrt{(P_{xi}-x)^2 + (P_{yi}-y)^2 + (P_{zi}-z)^2} \quad (3)$$

X is a matrix of initial position (the landmarks from step B) which can be expressed as

$$X = \begin{bmatrix} x_1 & y_1 & z_1 \\ \dots & \dots & \dots \\ x_N & y_N & z_N \end{bmatrix} \quad (4)$$

P is the modified matrix for X with the additional matrix one of N x 1

$$P = \begin{bmatrix} ones(N,1) & X \end{bmatrix} = \begin{bmatrix} 1 & x_1 & y_1 & z_1 \\ \dots & \dots & \dots & \dots \\ 1 & x_N & y_N & z_N \end{bmatrix} \quad (5)$$

V is a matrix of the final positions (the landmarks from step C) which can be expressed as

$$V = \begin{bmatrix} x_1' & y_1' & z_1' \\ \dots & \dots & \dots \\ x_N' & y_N' & z_N' \end{bmatrix} \quad (6)$$

The solution for both weighting factor W and affine factor A can be expressed as the following equation

$$\begin{bmatrix} W^T \\ A^T \end{bmatrix} = \begin{bmatrix} K & P \\ P^T & zeros(4,4) \end{bmatrix}^{-1} \begin{bmatrix} V \\ zeros(4,3) \end{bmatrix} \quad (7)$$

W is a matrix of the weighting factors for non-rigid (nonlinear) registration which can be expressed as

$$W = \begin{bmatrix} w_1 & \dots & w_N \end{bmatrix} = \begin{bmatrix} w_{x1} & \dots & w_{xN} \\ w_{y1} & \dots & x_{yN} \\ w_{z1} & \dots & w_{zN} \end{bmatrix} \quad (8)$$

A is a matrix of the affine factors for rigid and linear transformation (e.g. Rotation, Translation, and Scaling) which can be expressed as:

$$A = \begin{bmatrix} a_1 & a_x & a_y & a_z \end{bmatrix} = \begin{bmatrix} a_{11} & a_{1x} & a_{1y} & a_{1z} \\ a_{21} & a_{2x} & a_{2y} & a_{2z} \\ a_{31} & a_{3x} & a_{3y} & a_{3z} \end{bmatrix} \quad (9)$$

Use weighting and affine factors to define function of coordinate $f(x, y, z)$ everywhere in the plane as shown in (1), (2), and (3)

$$f(x, y, z) = a_1 + a_x x + a_y y + a_z z + \sum_{i=1}^{N} w_i U(P_i - r) \quad (10)$$

The result on 3D thin plate spline calculation can be shown in Figure 5. Figure 4 is showing the direction of mesh movement for patch surface manipulation.

The original crown with texture will be shown in Figure 5(A) while the original crown displayed in mesh can be seen in Figure 5(C). The final form of crown with texture after applying 3D thin plate spline following to the moving patch surface can be seen in Figure 5(B) while the final form of crown with mesh can be displayed in Figure 5(D).

IV. Discussions and Conclusions

The results after performing mesh deformation with cubic spline interpolation and thin plate spline have shown that it can deform dental crown, mandible and skull at the targeted area without distorting other areas.

Further improvements will be focused on faster image distortion algorithm [9] along with better segmentation of target area which require the generation of new vertices and form new triangles in between the old vertices.[10]

***Abstract*-A license plate localization (LPL) is a key that bring a good final result for automatic license plate recognition system (ALPRS). Switching algorithm for Thailand license plate localization is presented. Eleven plate detection techniques were used to generate candidate plate regions based on gradient and color. All of Thailand license plates can be detected, including plates complex problem. Experimental results correspond to 99.07%, 0.93% and 1.48% for correct extraction rate, missed detection rate, and false alarm rate, respectively. However, some problems still occur due to similar texture of grilles, logos, headlights, and plate.**

I. INTRODUCTION

An automatic license plate recognition system (ALPRS) has many applications such as law enforcement, toll collection, and car parking systems. ALPRS involves three steps: license plate localization (LPL), text segmentation (TS), and text recognition (OCR). In this paper, the focus is on LPL as it is a key step which determines the accuracy of the final ALPRS results.

There are many types of Thailand license plate such as private car, pickup truck, rental car, diplomat car, etc (see Table I). These plates differ in size, color, and format. In this paper, an LPL approach which can detect all types of Thailand license plates is presented. For national security reason, military and royal plates are not included in this research work.

Existing LPL systems can only detect limited types of license plate. Difficulty arises when old plates, dirty plates, damaged plates, and complex scene such as vehicle with large or complex bumper, are encountered. Other problems include fast moving vehicles and changing outdoor environments. The proposed approach utilizes important characteristics of license plate to form switching algorithm for license plate localization.

Well known plate region extraction techniques include binarized image approach [1], edge and gradient detection [2][3], plate color [4][5], and text detection approach [6]. The binarized image approach requires a good threshold value and often fails if intensities of plate and bumper are alike. Edge and gradient technique generates many candidates in complex scene which leads to ambiguity in segmentation. Color-based approach often fails if colors of plate and bumper are similar or when lighting condition is unstable. Text detection also fails if the text is connected to screws or merged with borders.

TABLE I

STYLES OF THAILAND LICENSE PLATE UNDER CONSIDERATION

Plate Type	Character/ plate color	Size (WxH cm)	Category	Example
A1	Black/graphic	34x15	Private car (not more 7 persons) (graphic plate)	
A2	Black/white	34x15	Private car (not more 7 persons)	
A3	Green/white	34x15	Pickup truck	
A4	Blue/white	34x15	Private car more 7 persons	
A5	Red/white	34x15	Private Tuk tuk	
A6	White/light green	34x15	Corporate rental car	
A7	Black/yellow	34x15	Taxi	
A8	Green/yellow	34x15	3-wheel Tuk tuk	
A9	Blue/yellow	34x15	4-wheel Tuk tuk	
A10	Red/yellow	34x15	Large regional bus	B1	Black/white	30x15	Private car (old generation)	B2	Black/white	30x15	Private car (old generation)	
B3	Black/red	30x15	New car waiting to be registered	C1	White/Blue	38.7x11	International organization car	C2	Black/white	38.7x11	Diplomat car	
D1	Black/white	43x21	Truck	
D2	Black/yellow	43x21	Local bus	
E1	-	-	Modified plate (unlawful)	
* There are four character formats for A1 to A10 : XX-X, XX-XX, XX-XXX, XX-XXXX

II. LICENSE PLATE LOCALIZATION SYSTEM

The LPL system consists of two parts, candidate plate detection and plate verification. Firstly, eleven plate detection techniques are used to determine candidate plates. The plate verification part is explained in Section IV. If a plate is not verified, the next of the eleven detection algorithms is used. The LPL system and its details are shown in Figure 1.

III. CANDIDATE PLATE DETECTION

An image sub-sampling is carried out prior to plate region detection. Plate candidate regions are then determined. There are eleven plate detection techniques using color and gradient

density. A switching algorithm selects which techniques to use in the detection, see Figure 1(b).

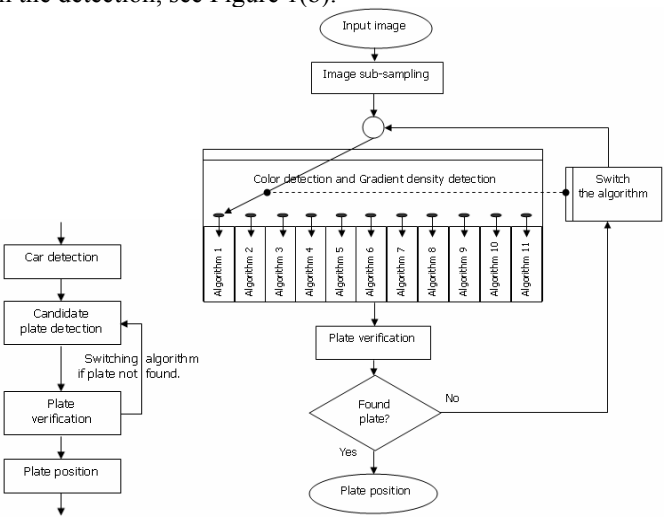

Figure 1. LPL system and its details
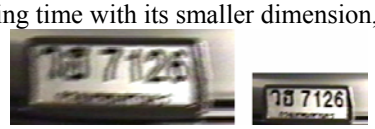
a) LPL system b) detail of LPL

A. *Image Sub-Sampling*

Comb-type problem is often found in captured images where cars move quickly. Sub-sampling the image, keeping only odd or even lines from both horizontal and vertical directions, can solve this problem. Moreover, sub-sampled images result in faster processing time with its smaller dimension, see Figure 2.



a) b)

Figure 2. Image sub-sampling
a) original image b) sub-sampled image

B. *Colors Detection*

There are five background colors on Thailand license plate: white, yellow, red, light green, and blue. HSV color model is a logical model for color detection. However, this model is unstable in white, gray, and black. This instability problem can be solved using chromatic thresholding [10], see Figure 3. Subsequently, HSV color model can be used to detect yellow, red, light green, and blue background. Detected background colors can then be encoded, see Table II. In chromatic thresholding, cylindrical area is defined in RGB cube covering gray scale part of the model. This cylindrical area can be used to detect white, gray, and black.

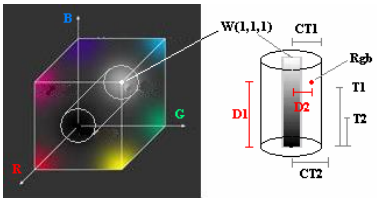


Figure 3. Rgb color model and cylindrical model

$$D_1 = \sqrt{\|\overline{RGB}\|^2 - \left(\frac{\overline{RGB}\cdot\overline{W}}{\|\overline{W}\|}\right)^2} \quad (1)$$

$$D_2 = \frac{\overline{RGB}\cdot\overline{W}}{\|\overline{W}\|} \quad (2)$$

From (1) and (2), D1 is the distance from origin on black (0,0,0) to $\overline{RGB}$ diagonal axis and D2 is the perpendicular distance from of $\overline{RGB}$ to diagonal axis. $\overline{RGB}\in(0,1)$, $\overline{W}=(1,1,1)$. Color code of these gray points (as shown in Table II.) can be determined as shown in (3) where $CT1=0.1250$, $CT2=0.2499$, $T1=0.8627$, $T2=0.5$.

$$colorcode = \begin{cases} 1 & if \quad D_1 > T_1 \quad and\ D_2 \le CT_1 \\ 2 & if \quad T_2 \le D_1 \le T_1 \quad and\ D_2 \le CT_1 \\ 3 & if \quad D_1 \le T_2 \quad and\ D_2 \le CT_2 \\ 0 & Otherwise \end{cases} \quad (3)$$

Subsequently, HSV values of yellow, red, light green, and blue can be determined by a standard conversation [7].

The colors are encoded using (4) where $H \in (0,360)$, $S,V,R,G,B \in (0,1)$, $YT1=21.6$, $YT2=64.8$, $YT3=0.4$, $RT1=21.6$, $RT2=327.6$, $RT=0.4$, $LGT1=140.4$, $LGT2=187.2$, $LGT3=0.35$, $BT1=187.2$, $BT2=252$, $BT3=0.35$.

$$colorcode = \begin{cases} 4 & if \quad YT_1 \le H \le YT_2 \quad and \quad S > YT_3 \quad and \quad colorcode \ne 1,2,3 \\ 5 & if \quad H \le RT_1 \text{ or } H > RT_2 \quad and \quad S > RT_3 \quad and \quad colorcode \ne 1,2,3 \\ 6 & if \quad LGT_1 < H < LGT_2 \quad and\ S > LGT3 \quad and \quad colorcode \ne 1,2,3 \\ 7 & if \quad GT_1 < H < BT_2 \quad and \quad S > BT_3 \quad and \quad colorcode \ne 1,2,3 \end{cases} \quad (4)$$

Finally, binary image of each color code is formed (see (5)).

$$\text{Binary Image}(Color) = \begin{cases} 1 & if \quad ColorCode = Color \\ 0 & Otherwise \end{cases} \quad (5)$$

C. *Gradient Density Detection*

Gradient density of the plate image can be calculated from the red channel in (6). Intensities in red channel show clearly the differences between plate characters and background of Thailand license plates.

$$\text{Gray Image}(x_i, y_j) = RGB[\text{Red}(x_i, y_j)] \quad (6)$$

Since gradient of texts in license plate will dominate in horizontal direction, a window of size $1 \times N_1$ is run over the image, where $N_1 = 4$, for gradient detection and noise reduction (see (7)).

$$\text{Gradient Image}(x_i, y_j) = \frac{\sum_{k=0}^{(N/2)-1} \text{GrayImage}(x_{i+k}, y_j) - \sum_{k=N/2}^{(N-1)} \text{GrayImage}(x_{i+k}, y_j)}{N/2} \quad (7)$$

Next, high gradient density regions are determined, see (8).

$$DensityGradientDetection(x_i, y_j) = \frac{\sum_{k=0}^{7} Gradient\ \text{Image}(x_{i+k}, y_j)}{7} \quad (8)$$

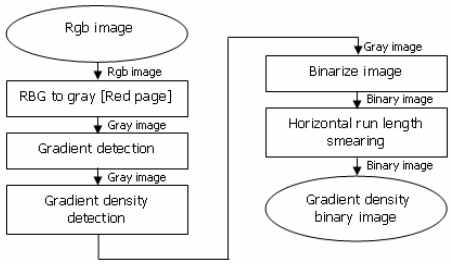

Figure 4. Block diagram of gradient density detection

The gradient density image is binarized. The color and gradient density selection uses threshold value equal to 50. And the gradient density selection uses threshold value equal to 30, see (9).

$$DensityGradientBinary\ \text{Image}(x_i, y_j) = \begin{cases} 1 & if \quad DensityGradientBinary\ \text{Image}(x_i, y_j) \ge Threshold \\ 0 & Otherwise \end{cases} \quad (9)$$

Finally, horizontal run length smearing [7] with gradient density binary image are used to fill gap of gradient with threshold value of 15, see Figure 4.

D. Switching Algorithm for Candidate Plate Detection

From eleven pre-processing algorithms for candidate plate detection using switching method in Table III, they can be categorized into three groups as follows.

1. Color and gradient density selection.
2. Color selection.
3. Gradient density selection.

Color and gradient density selection provides high accuracy result because color and gradient data are the main features of license plate. However, the accuracy depends on color integrity and gradient density. The color selection uses only color data to detect candidate plate region as some of the plates have little gradient. If the color of the plate is similar to that of the vehicle bumper, this method will fail since license plate region and bumper region will be joined together. In outdoor environment with changing light conditions, gradient density selection is more tolerant to changing light condition than color data. Segmentation problem will occur in a license plate with complex scene as many spurious gradients will be generated.

The algorithms order by efficiency and frequency of successful plate detection of Thailand license plate are shown in Table III.

TABLE II
BACKGROUND COLOR CODES

Code	Color
0	Unclassified
1	White
2	Gray
3	Black
4	Yellow
5	Red
6	Light green
7	Blue

TABLE III
ORDER OF SWITCHING ALGORITHM

Order	Algorithm
1	White color and gradient density selection (WGS)
2	Yellow color and gradient density selection (YGS)
3	Red color and gradient density selection (RGS)
4	Light green color and gradient density selection (LGGS)
5	Blue color and gradient density selection (BGS)
6	White color selection (WS)
7	Yellow color selection (YS)
8	Red color selection (RS)
9	Light green color selection (LGS)
10	Blue color selection (BS)
11	Gradient density selection (GDS)

The first to fifth algorithms are color and gradient density selection as shown in Figure 5. The binary image from the color detection will be processed horizontal run length smearing with threshold value of gap 15. After that, we uses AND operation between the binary image and gradient density binary image. The output of this is candidate plate. Finally, the candidate plate feeds to plate verification process.

The sixth to tenth algorithms are color selection algorithms. The process is similar to Figure 5 except the And operation as shown in Figure 6(a).

The eleventh algorithm is gradient density selection, see Figure 6(b). The method uses the gradient density binary image with processing in horizontal to vertical histogram [9] to confirm position of candidate plate. The horizontal to vertical histogram can reduce the noise of gradient.

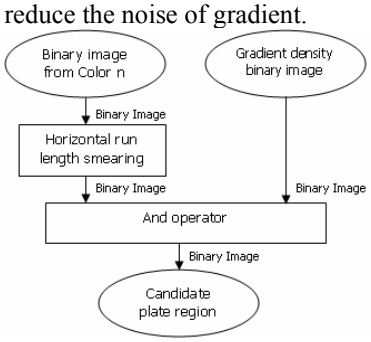

Figure 5. Block diagram of color and gradient density selection

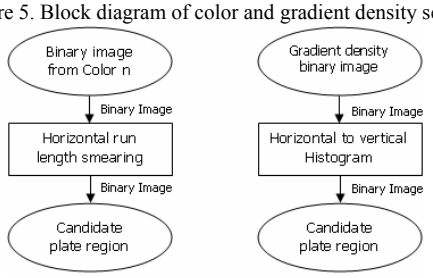


a) b)

Figure 6.Block diagram of color and gradient density selection
a) Color selection b) Gradient density selection

IV. PLATE VERIFICATION

In case of there are more than one candidate regions, the candidates will be verified. Component labeling is carried out to determine the position and properties of their regions. The plate verification technique can be divided into three steps.

1) The width and aspect ratio of height/width are checked to reduce candidate plate regions. The width varies in range 56-125 pixels and respect ratio of height/width varies in range 0.14-0.52.

2) Detect the average number of objects in horizontal line. A threshold is determined for each candidate region using iterative thresholding selection [7]. The iterative thersholding selection conditions are:

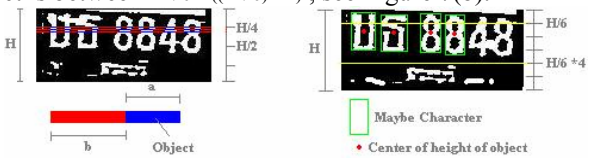
Threshold value is initialized to 127 in all algorithms, except algorithms that pass red, light green or blue steps in switching algorithm.

For red, the threshold is set at 20% of P-tile method [7].

For light green or blue, the threshold is set at 80% of P-tile method [7].

The image from light green and blue must be binary inverse because the color of character is white. Next, objects in binary image that are smaller than 10 pixels are removed. Then, number of objects along 3 horizontal lines is counted. The three lines are called L_1, L_2 and L_3. The position of L_1 object starts at $H/4$ and the total height of all lines are limited to $H/2$,see Figure 7(a). Each line is 1 pixel apart. Only objects with $1 \le a \le 8$ and $b \le 18$ will be counted. Then, average number of objects along the three lines must be between 6 to 14 objects. Otherwise, if it is between 3 and 6, then 3 to 8 objects within this region must be considered for being a character. Number of objects that maybe text will be counted when height of

object is between 20 to 24 pixels with aspect ratio of width/height between 0.14 to 0.96. And the center of height of object is between $H/6-((H/6)\times 4)$, see Figure 7(b).



a) b)

Figure 7. Plate verify step 2.

a) Horizontal line scan image b) Maybe character image

3) The last step, width of plate is considered by region growing [8] which it must be between 50 to 125 pixels. The region growing uses the seed point from binary image. In this experiment, a windows of size 1x10 is used starting at $x=(w/2)-7$, $y=H/2$ and sliding the window to bottom until all pixels in window are background (pixel="0"). Then shift window 1x10 to bottom 1 pixel and put seed point in gray image to process region algorithm with eight neighbors. The region growing uses threshold of 70 and expands area of growth to Left-2, Right+4, Top-3 and bottom+7.

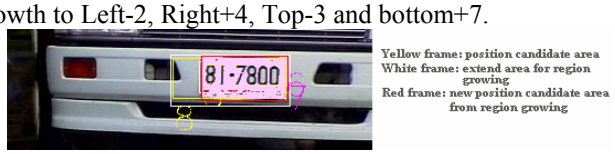


Figure 8. Result from region growing

V. Experimental Results

The proposed method was evaluated at three locations: the Bangkok express way and two semi-indoor parking lots with controlled light source. Manual vehicle detection was used in express way test and photo sensors were used in parking lot tests. For the second parking lot, all of the license plates were setup for testing on one car. The program was written in Visual C++ 6.0 in a Pentium 4 2.4GHz/1GB RAM with IDS falcon card capture (768x576 pixels).

Experimental results are shown in Table V. These results correspond to 99.07%, 0.93% and 1.48% for correct extraction rate, missed detection rate, and false alarm rate, respectively. Computation time varied between 0.39 to 1.266 seconds, depending on the number of detection techniques used. Frequency of detection algorithms used are shown in Table IV.

Grilles, logos, and headlights of vehicles have similar characteristics that of license plates. The thresholds in proposed method support for license plate detection with many sizes, colors and formats, so false alarms happened.

VI. Conclusion and Future Work

A switching algorithm for Thailand license plate localization is presented. Eleven plate detection techniques were used to generate candidate plate regions based on gradient and color. All of Thailand license plates can be detected, including some other complex plate localization problems. Experimental results show high accuracy. However, some problems still occur due to similar texture of grilles, logos, headlights, and plate.

***Abstract*-This paper studies the performance of deploying a normalized cross correlation pattern matching algorithm in independently tracking three desired regions on thermal imagery. In our experiment with five subjects under test, we observe that the orientation angles of the subject along three axes can be tracked with a wider angle in color-based than in gray-based thermal images. However, as there are three color planes in the color-based thermal image, the measured learning time is about twice of that in the gray scale-based thermal image. For the searching time, both color and gray scale-based thermal images show similar performance of ~ 8 ms per tracking zone using the Duo Core technology.**

I. INTRODUCTION

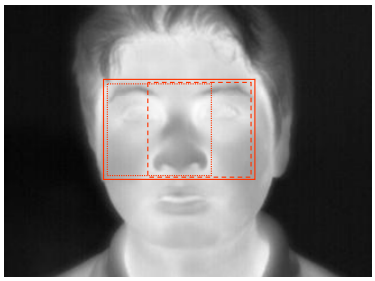
As the price of a thermal imaging camera is gradually going down, thermal images have been exploited in several applications in order to investigate some interesting parameters through the change of the object temperature. Especially, it has been deployed to distinguish in real time a person who might affect from severe acute respiratory syndrome at the airport check point [1] and to analyze the subject's deceptive level during crime investigation [2-3]. For these applications, an independent tracking approach of the desired areas on the subject's face is very important. Because there are some difficulties in locating and tracking desired regions of interest in the thermal image, complicated feature extraction and feature tracking techniques are required. These include the use of a threshold adjustment [4], a multicast multifeature fuzzy connectedness framework [5], and a rigorous data training-based support vector method [6]. Although these tracking techniques promise to provide good tracking results, the operating time is slow due to their complicated computing processes, which is not appropriate to use for independently searching several zones in real-time applications. Hence, it would be highly desirable to have a simple image matching technique and yet still provides an acceptable tracking performance.

II. OUR EXPERIMENTAL DEMONSTRATION

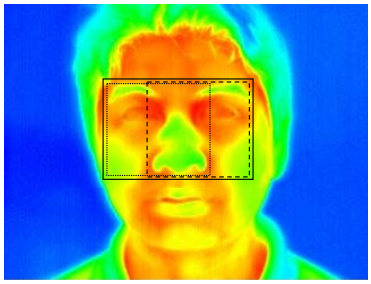
Keeping in mind that geometric features of the subject's face taken from a thermal imaging camera is difficult to observe, we choose to use a holistic or appearance-based approach to identify our desired zones. In this method, it generally operates directly on a pixel intensity array without the detection of facial features [7]. One of the appearance-based pattern matching algorithms is the normalized cross correlation (NCC) technique. In this case, a normalized amplitude of the NCC is used in order to distinguish the desired areas from their surrounding regions and it can be calculated as follows [8].

$$R(i,j)=\frac{\sum_{x=0}^{L-1}\sum_{y=0}^{K-1}\left[w(x,y)-\bar{w}\right]\left[f(x+i,y+j)-f(i,j)\right]}{\left\{\sum_{x=0}^{L-1}\sum_{y=0}^{K-1}\left[w(x,y)-\bar{w}\right]^2\right\}^{1/2}\left\{\sum_{x=0}^{L-1}\sum_{y=0}^{K-1}\left[f(x+i,y+j)-f(i,j)\right]^2\right\}^{1/2}}, \quad (1)$$

where $\bar{w}$ is an array intensity value of the pixels in the reference template w and it is computed only once. w(x,y) and f(x,y) are the subimage having KxL pixels and the image having MxN pixels ($M \geq K$, $N \geq L$), respectively. i and j vary from 0 to M-1 and from 0 to N-1, respectively.



(a)



(b)

Fig.1 An example of our thermal image taken in (a) gray scale palette and (b) rainbow palette. Small dash line, large dash line, and solid line indicate our regions of interest 1, 2, and 3, respectively.

In our study, we have recorded thermal images at a measured speed of 20 frames/second (fps) (or 50 ms in one frame) by using a far-infrared (i.e., 7.5-13 μm wavelength band) camera having an uncooled focal plane array-based microbolometer with its thermal sensitivity of 0.080 mK, a 24°×18° field of view, and a 320×240 active pixels. We also divide our study into two cases. One is to perform the NCC on the gray scale-based thermal image while another case is to do the same on the color-based thermal image. In addition, there are three tracking zones as shown in Fig.1. One zone covers the right eye and the nose and the second zone encompasses the left eye and the nose. These two areas have approximately 81×76 pixels. The last zone includes two eyes and the nose and it has about 119×76 pixels. Five subjects (i.e., A, B, C, D, and E) as shown in Fig.2 are tested and our study is investigated under a notebook computer having an Intel DuoCore 1.83GHz with 512 MB RAM. In addition, an NCC threshold is set to 0.6 in a full scale range of 1.0.

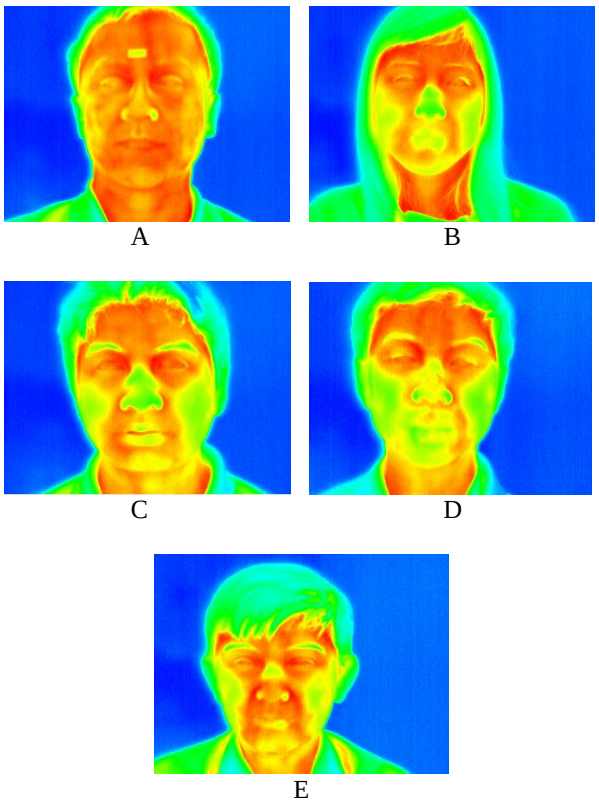


Fig.2 Color-based thermal images of our five subjects under study.

As our experiment aims to study only the performance of using the NCC to independently match and track three separate regions of interest, we manually locate these three desired regions in each subject. In addition, maximum rolling angle, maximum pitch angle, and maximum rotation angle for each subject are investigated as shown in Fig.3. We can see that

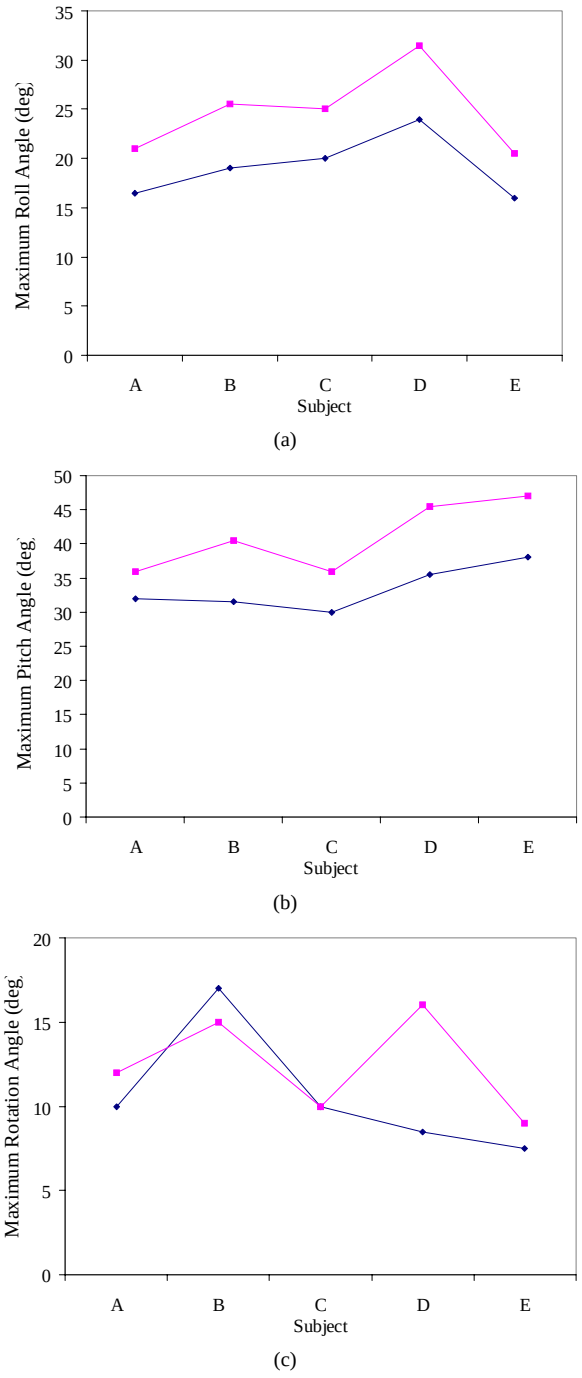

Fig.3 Maximum located orientations of the subject's regions of interest when the subject (a) rotates from left to right, (b) tilts from top to bottom, and (c) inclines from left to right.

when the subject rotates his/her face from left to right along the roll axis as shown in Fig.3(a) or tilts from top to bottom along the pitch axis (see Fig.3(b)), the NCC matching method shows a better 5-7 deg tracking angle in color-based thermal images. For the case of inclining subject's face from left to right as shown in Fig.3(c), the NCC matching method gives similar

performance for both gray scale-based and color-based thermal images. Apart from the maximum orientation of the subject, pattern learning and matching times are also important parameters. An average measured pattern learning time for color-based thermal images is 5,616 ms while it is only 2,796 ms for gray scale–based thermal images. The average measured searching time on three separate zones of 25 ms (or ~8 ms per zone) is achieved for both color palettes. This result implies that if we deploy this NCC for independently matching and tracking three different zones on the subject's face during recording data, a recording speed is expected to reduce from 20 fps to 13 fps. However, if we consider only one tracking zone, this algorithm will slightly alter the recording speed from 20 fps to 17 fps, thus very practical to use in real time applications.

III. CONCLUSION

This paper shows that a simple and widely used NCC pattern matching algorithm can be deployed to independently track the desired zones on the thermal image, especially, in the roll and pitch axes. It can also be applied for both gray scale- and color-based thermal images, and still offers similar searching speed via a DuoCore-based CPU. As the color-based thermal image has three different color planes, tracking orientation of the subject is more robust but with slower learning time. In a practical point of view, our experimental result for five subjects confirms that merely the NCC can be used during recording thermal imaging data without affecting too much on the recording speed. In the future, we will employ an appropriate thresholding algorithm to help us automatically and systematically define three desired regions of interest. We will also increase the number of subjects and will statistically analyze the result.

ABSTRACT

Since cutting-edge ubiquitous devices need power conscious high-speed operation, embedded software approaches so far taken do not always continue to play the key role in ubiquitous computing. Single chip processors are most promising solutions for overall demand of ubiquitous devices. We have so far developed a hardware cryptography-embedded multimedia mobile processor, HCgorilla and its software support system. In this article, we focus on the hardware of HCgorilla. Firstly, we show the structure of HCgorilla. The architecture, implementation, and verification are described in detail. Then, we evaluate the hardware in view of area, the number of devices, power consumption, and clock speed.

Keywords: Hardware cryptography, multimedia, moblie, ubiquitus, single chip processor.

1. INTRODUCTION

Internet owes its outstanding expansion in recent years to the development of handheld multimedia devices. The latest cellular phones are embedded with various functions like GPS, music, and the game, etc [1, 2]. The performable features of these devices have mainly relied on embedded software. However, such approach obviously contradicts power conscious design.

Cutting-edge ubiquitous devices need power conscious, high-speed, secure, and user friendly processing. ICT techniques corresponding to these demands are as follows. Java is one of the most promising solutions for user friendly multimedia processing. Power consciousness for mobility must be satisfied together with high speed for quick response. Not only so called security chip but also data protection is important to practically prevent privacy, prevention, intrusion, etc.

In order to fulfill demands for the Java execution of power conscious high speed and the cryptography of large quantity of multimedia data, it is expedient to develop a single VLSI processor system with built-in functions covering those schemes [3]. We have so far developed multimedia mobile processor named gorilla [4, 5], hardware cryptography-embedded processor named RAP (random addressing-accelerated processor) [6, 7], and a hardware cryptography-embedded multimedia mobile processor named HCgorilla [8-17].

In this article, we focus on the hardware of the latest version of HCgorilla. Firstly, we show the structure of HCgorilla. The architecture, implementation, and verification are described in detail. Then, we evaluate the hardware in view of area, the number of devices, power consumption, and clock speed.

This work has been financially supported in part by the president of Hirosaki University and the dean of the Faculty of Science and Technology of Hirosaki University.

2. PROCESSOR STRUCTURE

Our strategies for developing HCgorilla are as follows.

a. Making use of practically simple structure for a full-length RNG (random number generator). For this aim, LFSR (linear feedback shift register) is best suited. This requires trivial additional chip area and power dissipation. A tiny *n*-bit LFSR produces the huge *n*-th power of 2 random numbers.
b. Cooperating with Java compatible media processing. This makes it possible for HCgorilla to have efficient performance for media processing as well as cryptography.
c. Following H/S co-design in order for HCgorilla to have many PC-like sophisticated features as well as the role for ubiquitous computing.

Table 1 summarizes architectures related to HCgorilla. Firstly, one of our previous works for downsizing, power reduction, and speedup in ubiquitous computing was the development of a series of Java-embedded multimedia processor and a multimedia mobile processor core, gorilla. Another previous work was the development of RAP. Considering the unification of RAP and gorilla has advantageous potential for multimedia security, we have developed a hardware cryptography-embedded multimedia mobile processor architecture, HCgorilla.

In order to lighten the burden on hardware design, the ISA (instruction set architecture) of HCgorilla is made compact. The ISA of HCgorilla consists of 2 SIMD (single instruction stream multiple data stream) mode cipher instructions and 61 Java compatible media instructions.

The cipher instructions are the random addressing instructions *rsw* and *rlw*. Java instructions like *bipush, iadd, isub* are carefully selected from the 202 Java bytecodes for ever growing usage of Java in mobile fields [18]. Each instruction is composed of a 1-byte opcode and 0 to 2 1-byte operands. Since ISA succeeds various aspects of Java, opcodes are Java bytecodes. Operands are grammatically equal to opcodes but are actually dependent on them.

Table1: *Exploration of hardware cryptography-embedded multimedia mobile processors*

Name	Architecture								Microarchitecture				
	ISA		Core parallelism										
	No. of instructions	Format	No. of cores	ILP	Pipelining			Hardware crypto-graphy	Control	Chip	Process	Clock Speed (MHz)	Current status
					Regular		Waved						
					Degree	Number							
gorilla.1	16	JVM	2	2-degree	8	2 media pipes	2-wave EX	Not available	Wired logic	gorilla035	0.35μm	240	4.9-mm chip
gorilla.2					7					gorilla035v2		200	Synthesis
RAP	17	RISC	1	Not available	5	1 cipher pipe	Not available	SISD		Not available	FPGA	45	FPGA
HCgorilla.1	18	JVM	2	2-degree	8	2 cipher-embedded media pipes	Not available	SISD		HCgorilla035	0.35μm	150	4.9-mm chip
HCgorilla.2	63				7	3 (2 media pipes and a cipher pipe)	2-wave EX	SIMD		HCgorilla018	0.18μm	400	2.8-mm chip
										HCgorilla018 v2			Synthesis
										HCgorilla018 v3			5.9-mm chip

According to ISA, the latest version, HCgorilla018v3 has double core structure as shown in Fig. 1. Each core has two media pipes and a cipher pipe. These pipes are partly wave-pipelined. This results in the formation of heterogeneous pipelines. The register file plays the role of a pseudo-streaming buffer. The register file and data cache are quasi 2-port I/O. Although the register file and data cache are physically shared by the two cores considering hardware resource, they are logically divided. Each division is allocated to a corresponding core.

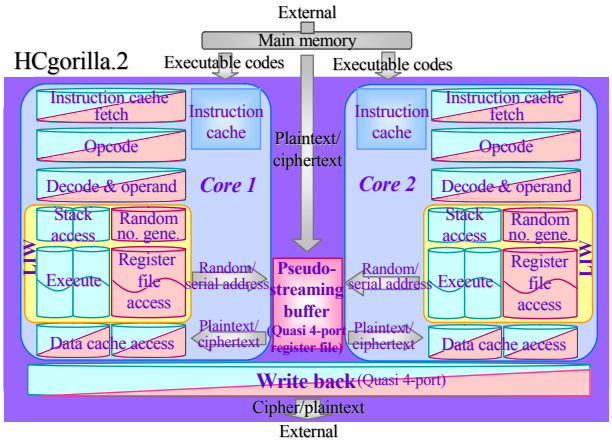

Fig. 1: *Organization of HCgorilla018v3*

The cipher pipes are built in RNGs. They are connected to data cache that writes the content of a specified register file location in data cache directly addressed by RNG output. The cipher pipe enables multimedia stream cipher due to an extremely long cycle of random numbers. It is easily produced by making RNG with LFSR.

The architectural aspects of HCgorilla are summarized as follows.

a. Direct connection of a built-in RNG and a data cache without additional chip area and power dissipation.
b. Interpreter type Java CPU to enhance sophisticated multimedia processing.
c. Multicore and LIW (long instruction word) to swiftly deal with large quantity of multimedia data. LIW is not so broad like VLIW (very long instruction word). Yet, LIW is effective to enhance multimedia communication.
d. Microprogramming techniques for respective cores that cover PicoJava in conjunction with LIW.
e. Wave-pipeline for execution units that brings about PC-like high speed and low power dissipation proper to mobile devices.

We have been developing HCgorilla018 by using 0.18-μm CMOS standard cell technology. Design environments we have used are basically Synopsys and Cadence tools. Fig. 2 shows the resultant logic synthesis of HCgorilla018v3.

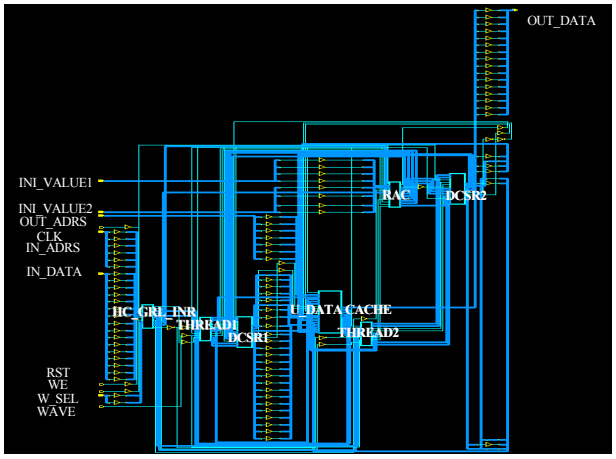

Fig. 2: Logic synthesis *of HCgorilla018v3*

Fig. 3 shows the verification of the hardware parallellism of HCgorilla that is under a dual mode bidirectional processing at 400MHz. The horizontal axis shows time in nanosecond. For the sake of well understanding the timing relation, the pipelined structure is added in the above. The test bench of this simulation describes dual mode processing that activates both cores and LIW. LIW covers two media streams. While core 1 simultaneously executes the SIMD mode encryption and the two arithmetic operations (*add* and *sub*), core 2 executes the SIMD mode decryption and other arithmetic operations (*or* and *and*). The encryption within core 1 works for 32 1-byte graduation elements stored in the register file. On the

other hand, the arithmetic operations by using Java instructions work for stacks. Thus, the encryption and the arithmetic operations are completely independent.

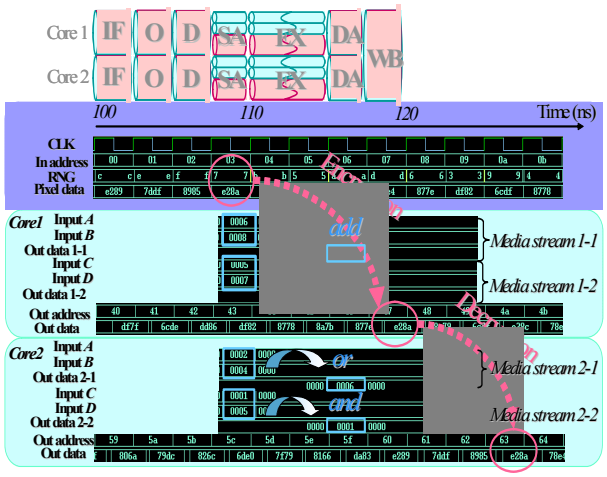

Fig. 3: *Simulation of the 400-MHz operation of HCgorilla018v3*

3. PROCESSOR EVALUATION

HCgorilla018v3 is evaluated in view of various aspects. Related chips are compared. The difference of process technology and chip area is taken into account of by scaling them. Fig. 4 shows the area of HCgorilla018v3 and related chips. Cache and register file occupies wide area in any case.

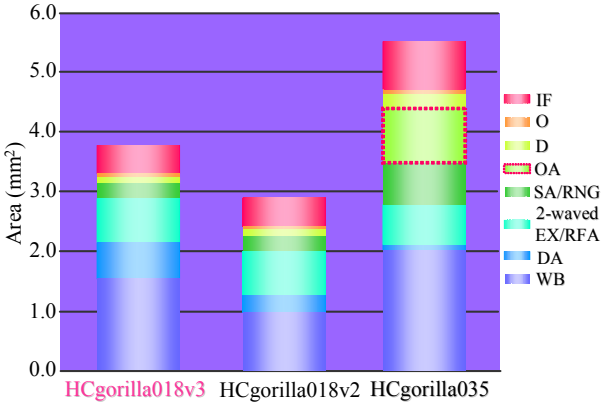

Fig. 4: *Area of HCgorila018v3 and related chips*

Fig. 5 shows the number of transistors of HCgorilla018v3 and related chips. The dotted line shows scaling by using chip core size ratio between HCgorilla018v3 and HCgorilla018v2. The usage of the chip core size in this scaling is because we are setting core utilization as large as possible in any case. From the estimation shown by the dotted line, HCgorilla018v3 is made compact.

Fig. 6 shows the power consumption of HCgorilla derivatives. The parameters *A*, *B*, and *C* represent test programs. In the case of SIMD mode encryption and decryption, each core executes the random addressing instructions *rsw* and *rlw*, respectively. In the case of Java and SIMD mode cipher, it runs a test program whose threads simultaneously execute Java instructions, *rsw* and *rlw*.

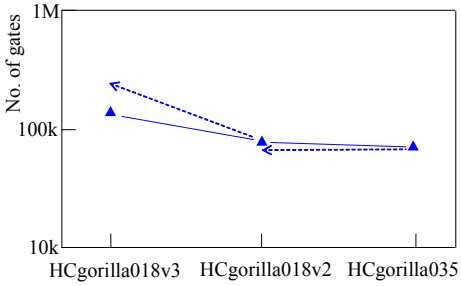

Fig. 5: *Number of gates of HCgorilla018v3 and related chips*

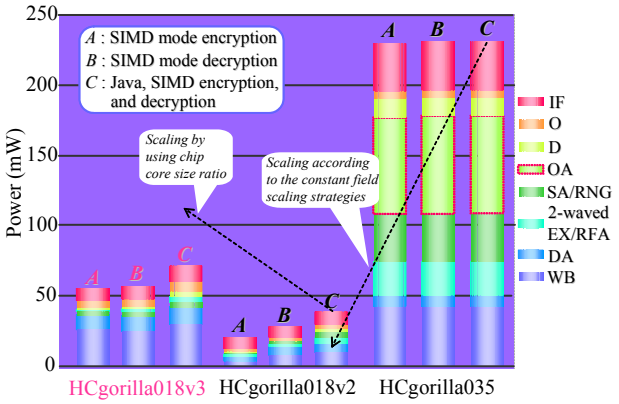

Fig. 6: *Power consumption of HCgorilla018v3 and related chips*

Dotted lines in fig. 6 show the effect of process technology and chip core size. Scaling between HCgorilla018v3 and HCgorilla018v2 has been done by using chip core area ratio. Then, scaling between HCgorilla018v2 and HCgorilla035 has been done according to core area ratio and constant field scaling strategies [19]. From the estimation shown by the dotted lines, HCgorilla018v3 has architectural improvement on the power reduction.

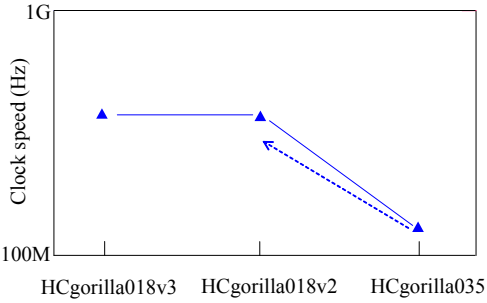

Fig. 7: *Clock speed of HCgorilla018v3 and related chips*

Fig. 7 shows the clock speed of HCgorilla018v3 and related chips. The dotted line between HCgorilla035 and HCgorilla018v2 is drawn by scaling according to the

constant field scaling strategies. This shows the architectural design effort of HCgorilla.2.

4. CONCLUDING REMARKS

In order to make power conscious, high-speed, secure, and user friendly ubiquitous devices, we have developed HCgorilla018v3. This is the latest version of the hardware cryptography-embedded multimedia mobile processor, HCgorilla. It has the parallelism of double core and six pipes. HCgorilla018v3 has been compactly designed in view of chip area and number of devices. HCgorilla018v3 has further improved multimedia mobility. It consumes less power and operates at higher clock. It also has both Java and cryptographic streaming capability.

The next step of this study will be as follows.

1. Further expanding the register file and data cache from the practical viewpoint of streaming SIMD.
2. Real chip implementation and its evaluation. The chip implementation requires effort to suppress the increase of power dissipation and the decrease of clock speed.
3. Combining HCgorilla and cutting-edge other single chip processors like security chips. They compliment each other.

HDL Design and Verification of Digital Signal Processor for 2.4 GHz ZigBee Radio Receiver

T. Demeechai
Mahanakorn University of Technology
Department of Telecommunication Engineering
51 Cheum-Sampan Road, Nongchok
Bangkok 10530, Thailand

***Abstract*-This paper describes design and verification of a digital signal processor of a receiver for the IEEE 802.15.4 PHY or ZigBee radio at the 2.4 GHz ISM band. This design achieves an improvement over a recent work, as the resulting circuit requires smaller silicon area and potentially lower power.**

I. INTRODUCTION

The IEEE 802.15.4 standard and ZigBee wireless technology are designed to satisfy the market's need for a low-cost, standard-based and flexible wireless network technology, which offers low power consumption, reliability, interoperability and security for control and monitoring applications with low to moderate data rates. The IEEE 802.15.4 standard specifies the physical (PHY) and medium access control (MAC) layers at the 868 MHz, 915 MHz and 2.4 GHz ISM bands [1], [2]. This paper presents a design and verification of a digital signal processor for a radio receiver conforming to the IEEE 802.15.4 PHY at the 2.4 GHz ISM band. This processor receives a digitized form of an IF signal obtained after quadrature downconversion and outputs the detected PHY payload. More information on the specification of this processor can be found at the author's URL [3]. The present work is indeed an improvement over a recent work [4], in which the author has participated.

In this paper, a brief introduction of the related standard is given first. The design principle and verification method are then explained. Results on the verification and estimated silicon area on an FPGA are also presented before the paper is concluded.

II. PROTOCOL DATA UNIT AND MODULATION SCHEME

According to the IEEE 802.15.4 PHY standard, the physical layer protocol data unit (PPDU) is a packet that consists of three concatenated components. The first component in the PPDU is the synchronization header (SHR) which allows a receiver to synchronize and lock onto the bit stream. The second component is the PHY header (PHR) which contains frame length information. The third component is the PHY payload which carries the data of the PHY packet. The SHR is composed of a preamble field that provides synchronization information to a receiver and a start-of-frame delimiter (SFD) field that indicates the end of the SHR. The preamble field is composed of 32 binary zeros. The SFD field is a fixed octet, i.e., a fixed eight-bit binary pattern. The PHR is an octet which contains a seven-bit frame length field that specifies the total number of octets contained in the PHY payload. The PHY payload has a variable length and carries the data of the PHY packet. For all packet types of length five octets or greater than seven octets, the PHY payload contains the MAC sublayer frame.

The IEEE 802.15.4 PHY at the 2.4 GHz band employs a spread-spectrum offset quadrature phase-shift keying (OQPSK) with half-sine pulse shaping as the modulation scheme. However, since signal obtained from OQPSK with half-sine pulse shaping can be deemed as a minimum-shift keying (MSK) signal, MSK with a suitable encoding can be employed instead of the OQPSK. In the modulation scheme, during each four-bit data symbol period, four information bits are used to select one of 16 nearly orthogonal pseudo-random (PN) sequences to be transmitted. The PN sequences for successive data symbols are concatenated, and the aggregate chip sequence is modulated onto the carrier at 2 Mchip/s using MSK. Since MSK is employed instead of the OQPSK, the 16 PN sequences mentioned above must be properly derived from Table 20 of [1]. Note also that each PN sequence derived will have 32 chips, where there are 31 chips uniquely identifying a four-bit symbol.

III. DESIGN PRINCIPLE

There are two major components in the processor: an FM demodulator and a symbol detector as shown in Figure 1.

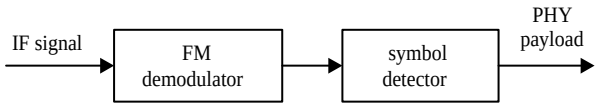

Figure 1. Block diagram of the processor.

The FM demodulator receives a digitized form of an IF signal obtained after quadrature downconversion and outputs a signal representing an estimate of the instantaneous frequency of the IF signal. The symbol detector receives the estimated instantaneous frequency signal and performs acquisition and tracking of symbol timing as well as detection of successive symbols for each PPDU.

For the FM demodulator, the IF frequency of 2 MHz is assumed. Due to quadrature downconversion, there are 2 IF signals, i.e., I-phase and Q-phase signals, as shown in Figure 2. Both of them are represented in digital form by a stream of five-bit two's complement numbers at 8 Msample/s, and accordingly the system clock frequency is 8 MHz. The two IF signals are processed independently by component FM demodulators, and the outputs are then combined simply by addition. A classical FM demodulator is adopted for each component FM demodulator.

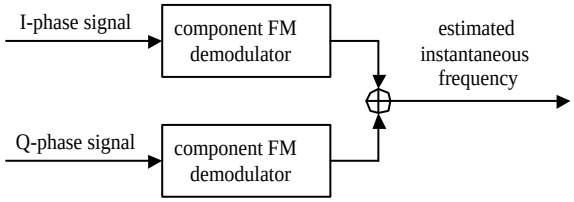

Figure 2. Block diagram of the FM demodulator.

The symbol detector has two modes of operations, i.e., the acquisition mode where the detector attempts to lock onto the received signal timing and the tracking mode where the acquired timing is fine-tuned while successive symbols are detected. Switching between the two modes behaves as shown in Figure 3.

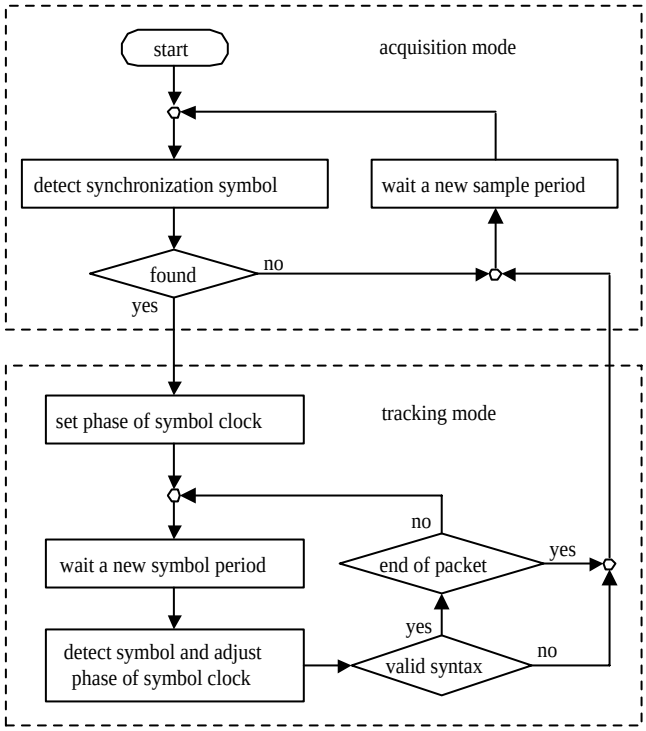

Figure 3. Symbol detector flow of operations.

The detector is in the acquisition mode when start, until a synchronization symbol is detected. Once a synchronization symbol is detected, the detector enters the tracking mode. When entering the tracking mode, the phase of a symbol-rate clock that represents the received signal timing at a resolution of one sample period is set. In the tracking mode, for every symbol period, a successive symbol is detected and the phase of the symbol-rate clock is adjusted. The operation mode will switch from the tracking mode to the acquisition mode, if the last symbol detected is the last symbol of the packet or the successive symbols detected violate the PPDU format. It may be noted that such a violation is possible only before the SFD is detected and it occurs when a detected symbol that follows a synchronization symbol is neither a synchronization symbol nor constituting the SFD.

Realization of the symbol detector is based on the structure shown in Figure 4.

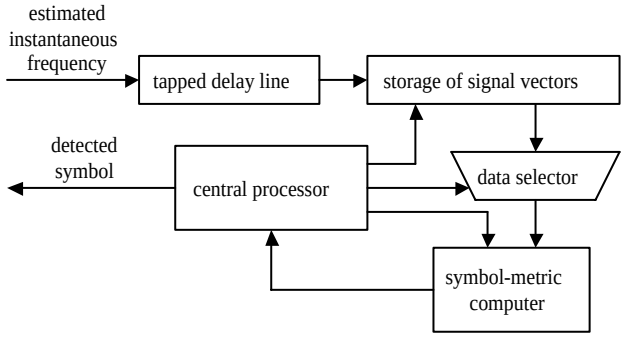

Figure 4. Symbol detector structure.

The tapped delay line is a parallel-output shift register that implements a sliding-window storage of the input. The operations of the symbol detector rely only on the likelihood metrics of 16 candidate symbols, computed from the received signal at properly determined time intervals. A single symbol-metric computer based on the matched-filter principle is employed for the computation of all the likelihood metrics.

In the acquisition mode, the storage of signal vectors and the data selector bypass the output of the tapped delay line to the symbol-metric computer, so that the tapped delay line and the symbol-metric computer act as a sliding correlator for the synchronization symbol. Once in the acquisition mode the output of the symbol-metric computer is significant that signifies presence of a synchronization symbol, the received signal timing is acquired, and the symbol detector enters the tracking mode with the phase of the symbol-rate clock set accordingly.

For every symbol period in the tracking mode, the storage of signal vectors keeps three signal vectors. Each of the three vectors is to be inputted through the data selector to the symbol-metric computer in the process of symbol detection and symbol-rate clock-phase adjustment. The first vector corresponds to the received signal over a symbol period that is

synchronized with that of the previously detected symbol. This vector is used in symbol detection, based on a selection of the best among 16 candidate symbols. It takes 16 system clock periods to accomplish the selection by the central processor. The second and third vectors correspond to the received signals over the symbol periods that are one-sample-early and one-sample-late compared to that of the first vector. Based on an early-late synchronization style, these vectors are used in the process of fine-tuning the acquired timing that adjusts the phase of the symbol-rate clock. It takes 4 system clock periods to accomplish the fine-tuning. Noting that a symbol period equals 128 system clock periods, we should see that the symbol detector activity is quite low in the tracking mode that processes the major part of the data packet.

It may be noted that, although this design is based on the same algorithm as the recent design [4], the symbol detector of this design uses a sequential-processing architecture instead of a parallel-processing one. Compared to the recent design, the use of sequential processing in this design results in a substantial reduction of registers and combinatorial circuits. The number of required slices on a Virtex-II FPGA for this design is found to be 464, that is quite small compared to the 4,039 slices required by the recent design. In addition, because the recent design uses a bank of 16×3 matched filters that are all-time active, the present design also results in a substantial reduction of circuit activity. Therefore, the present design achieves an improvement, as the resulting circuit requires smaller silicon area and potentially lower power.

IV. VERIFICATION

This design is completed as a set of VHDL source codes and has been verified at the HDL level as shown in Figure 5.

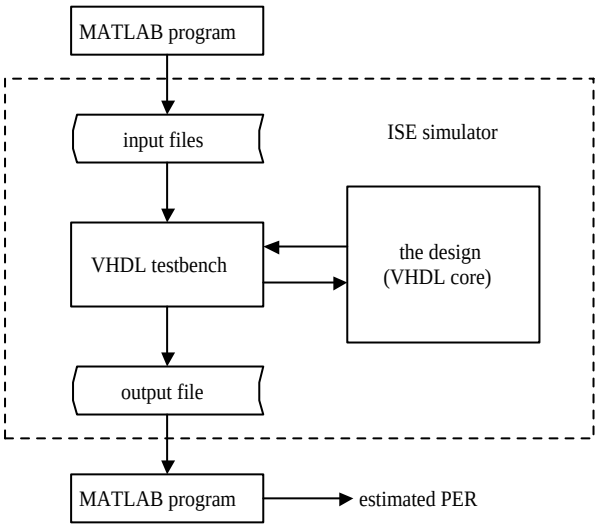

Figure 5. Design verification.

A MATLAB program was used to make input files that store an integer representation of the quantized I-phase and Q-phase IF signals, according the following criteria: (1) the frame length is 20 octets; (2) the two IF signals are corrupted by independent Gaussian noise processes; (3) the power spectral densities of noise and signal are the same; (4) the quantizer is of uniform-type with five-bit two's complement representation, and therefore the quantizer output is an integer that ranges from -16 to 15; (5) the quantizer input is automatic-gain-controlled such that its average power is $(q^{-1}(15))^2/2$, where $q^{-1}(\cdot)$ is the associated uniform dequantizing function. A VHDL test bench was simulated to get the input data from the input files for the core, get the detected data frames from the core output, and write the results to an output file from which the packet error rate (PER) can be estimated. Thanks to the Xilinx university program for the donation of the ISE platform that includes the ISE simulator. Table I shows the simulation results on the detection performance.

TABLE I
DETECTION PERFORMANCE

input SNR (dB)	no. of transmitted packet	no. of packet errors	PER (%)
2.1	2000	21	1.05
2.2	3000	28	0.94

It should be noted that, while Annex E.2.2 of [1] states that a typical low-cost detector implementation is expected to meet the 1% PER requirement as SNR values of 5-6 dB, this design meets the requirement at SNR of 2.2 dB for the above simulated environments.

V. CONCLUSIONS

In this paper, design and verification of a digital signal processor that receives an IF signal and outputs the detected PHY payload for a 2.4 GHz ZigBee radio receiver have been presented. This design employs a sequential-processing architecture, which results in an improvement over a recent work. Namely, the resulting circuit requires smaller silicon area and potentially lower power.

Abstract - **This work proposes a design of, SX4, a resource efficient 32-bit processor. SX4 is designed for a limited resource embedded system. The performance of SX4 has been improved by the "instruction packing" method. The measurement on the performance improvement is evaluated. Instruction packing reduces the code size by 33.0% at the same time it improve the speed of the processor by 17.1%. The proposed design has been realized on a FPGA device. SX4 processor requires 10,020 equivalent gates. Its maximum frequency is 63 MHz. In term of cycle consumed, it compares very well to commercial 32-bit Xilinx's microprocessor, Micro Blaze.**

I. INTRODUCTION

Nowadays, the embedded devices are playing important role in daily life. Computer exists in many things, such as mobile phone and automatic vending machine. As a result, the research in this area has many objectives: to improve the performance, to minimize code size, to minimize power consumption or to reduce cost of production depend on their functional purposes.

According to its working environment, the embedded devices have to be built to fit its surrounding conditions. A modern mobile phone needs a high performance processor for its multimedia applications, while most of the other devices don't require such high performance.

This is the main motivation of the work, to develop a resource efficient processor with adequate performance. The main focus of this work is to apply instruction packing method to reduce the size of executable code and also to improve the performance of a processor. The performance improvement is possible due to the reduction in number of cycle in fetching instructions. Such method is done by putting more than one instruction into same memory address space, which reduces the code size. As the code segment and data segment of the proposed processor share the same memory bus, instruction packing eases the memory bottle neck problem by reducing instruction traffic between processor and memory. Moreover, the proposed method requires little amount of additional resource so that the enhanced processor is still very resource efficient. Pipelining is another option for improving the processor's performance but it requires large modification on processor's data path which can violate the resource efficient criteria.

II. PROCESSOR DESIGN

SX4 is a 32-bit processor with no pipelined execution. Its design is based on the design of stack-based processor, SMC [1]. Fig. 1 demonstrates system overview of the proposed processor. Additional perpherals are attached to the system via memory-mapped I/O. SX4's instruction set is also based on SMC's ISA. SMC's zero-address instructions, which operate with data on top of stack, are replaced by one-address instructions in SX4 so that there is no stack-based operation in SX4. The processor operates with memory as shown in Fig. 1. One part of memory is writable; another part is read only (ROM). The ROM stores the code segment.

A. Data path

This processor data path is improved from the previous stack-based processor, SMC. (see Fig. 2) The processor has 32-bit data width. It consists of five registers: PC (program counter), IR (instruction register), AC (Accumulator), FP (frame pointer) and BUFFER.

B. Instruction Set Architecture

SX4 uses three instruction formats: Short, Long1 and Long2.(see Fig. 3) The Short format instruction, which is 16-bit wide, consists of two parts: 8-bit opcode and 8-bit operand. The long instruction formats are 32-bit wide. Long1 format has 8-bit opcode and 24-bit operand. Long2 format has 4-bit opcode, 20-bit operand and another extra 8-bit operand.

SX4 instructions can be divided into four categories: arithmetic&logic, data manipulation, control and misc (see Table I). Unary instruction operates on AC. The binary instruction needs one more element, which depended on the addressing mode. It can be either an immediate value of the operand or a local variable stored in the activation record. LD and ST access global memory. GET and PUT access local variables. CALL creates a new activation record. RET restores the previous activation record and returns to the caller.

The processor's operation is similar to an accumulator machine. This design uses an activation record, instead of general purpose registers. Although the activation record is slower than register, but there is some benefit of using the activation record. Firstly, it reduces size of the processor. Moreover, the activation record eliminates register saving and restoring during a function call.

Normally, the SX4 processor takes one cycle for instruction fetch and one more cycle for executing the instruction. But for some complex instruction, execution needs two cycles to

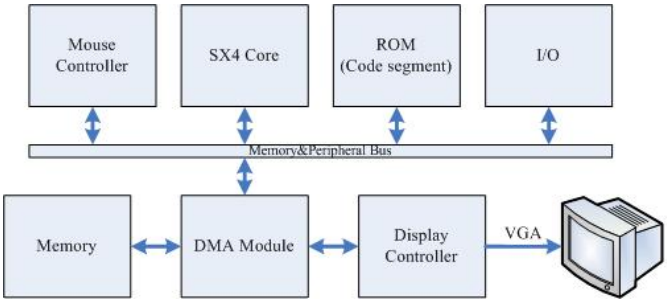

Figure 1. System overview of the proposed processor.

complete. As a result, overall performance of SX4 is around 2 to 3 cycles per instruction.

III. INSTRUCTION PACKING

As mentioned earlier, the embedded devices are designed to fit their working environment. In this paper, we introduce an instruction packing method, which causes little impact to the resource of a processor. The resource increased from including the instruction packing is less than 10% of the original design while it reduces code size and cycle consumed in program execution.

Instruction packing is done by putting two short instructions in the same memory address space (see Fig. 4). As two instructions are stored in one word, the processor will have two instructions after one instruction fetch. There is a case in which two short instructions can not be packed together. The instruction, which is the destination of CALL or JMP, cannot be placed in the most significant half word (31^{st} – 16^{th} bit). This is due to the proposed design's architecture does not suport half word directional in CALL and JMP instruction. Says, the program can not jump to the instruction placed in the most significant half word. As a result, such instructions can not be packed with the earlier instruction. Fig. 4 illustrates example of such case. The GET LED_addr instruction is the destination of the later IJX instruction, therefore it can not be packed with the earlier LIT 0 instruction. Hence, NOP instruction is packed with the LIT 0.

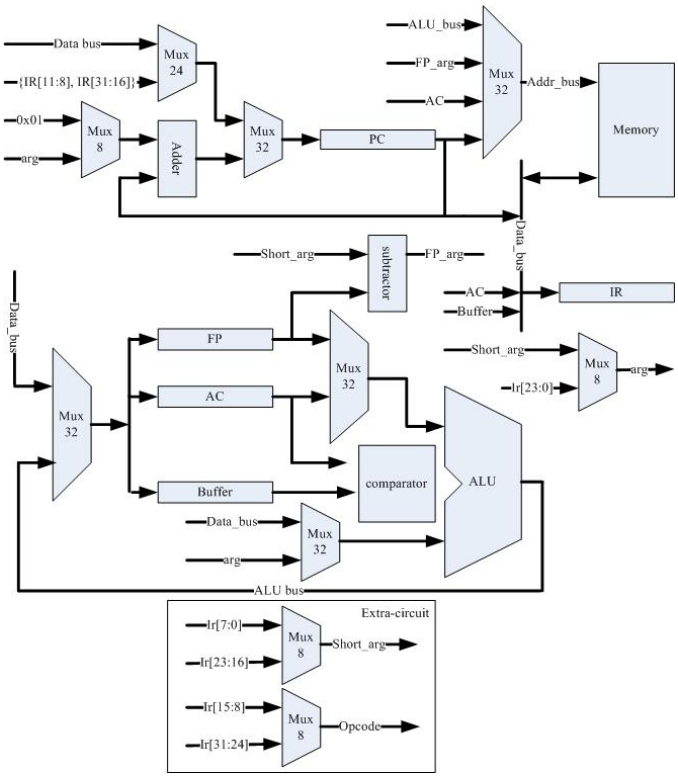

Figure 2. The data path of the proposed processor.

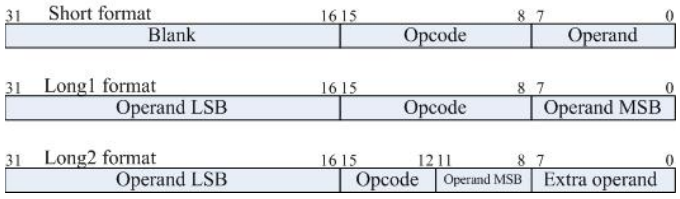

Figure 3. The proposed ISA format.

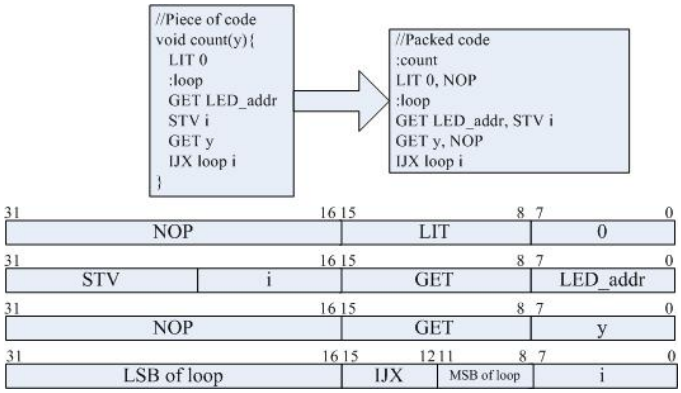

Figure 4. Example of instruction packing.

In the best case, instruction packing can reduce the program size by 50% and improve processor's throughput by 25%. This method also reduces program's code size. To include instruction packing on SX4, there is a small modification of the control unit. The data path needs two 8-bit MUX to select which half word is used. The extra circuit is shown in Fig. 2.

A complier plays a role in packing the code for the processor. Improvement in performance also depends on how well the code has been packed.

TABLE I
THE LIST OF THE PROPOSED PROCESSOR'S INSTRUCTIONS.

Instruction category	Instruction
Arithmetic&logic	ADD, SUB, MUL*, DIV*, BOR, BAND, BXOR, MOD*, ADDI, SUBI, MULI*, DIVI*, BORI, BANDI, BXORI, MODI*
Data manipulation	LD, ST, LDL, STL, LDX, STV, GET, PUT, INC, DEC
Control	JMP, JT, JF, JMPL, JTL, JFL, IJX, CALL, RET
Misc.	LIT, LITL, NOP

* indicates the instruction has not yet been implemented.

See the following function written in a machine code as follow:

```
add:
    get a  // 2 cycles consumed
    add b // 2 cycles consumed
    ret 3   // 3 cycles consumed
```

The code above can be optimized by packing GET and ADD instruction together as follow:

```
add:
    get a add b // 3 cycles consumed
    ret 3   // 3 cycles consumed
```

As a result, the packed code runs one cycle faster than the unpacked code, hence the performance improved by 14%.

IV. MEASUREMENT

In this section we test the processor with a suite of benchmarks. There are seven programs used in the measurement. There are seven test suites used in this paper: Bubble, Merge, Quick, Fibonacci, Hanoi, Sieve and AES.

Bubble: bubble sort 100 items of data. The initial data is ordered in descending order.

Merge: merge sort 100 items of data. The initial data is ordered in descending order.

Quick: quick sort the descending ordered data. The following number indicates number of data items.

Fibonacci: calculate the value of Fibonacci 10. The program is written in recursive function.

Hanoi: solves the 6 disks Hanoi problem.

Sieve: finds all prime numbers which less than 100.

AES: AES (Advance Encryption Standard) (128, 128) bit key block cipher [2].

To test the processor, we divide the measurement into three steps. Firstly, the instruction packed SX4 is compared to the original SX4 (see Table II, III). The test result shows that the SX4 executes packed code faster than unpacked code by 17.1% averaging over all benchmarks. Also packed program code size is 33.0% smaller than unpacked programs.

Secondly, code size comparison between packed SX4 program and other processors' (see Table IV, V). One of them is the stack-based processor [1]. The stack-based ISA is widely known to achieve a compact executable code [3].

TABLE II
THE COMPARISON BETWEEN
PACKED CODE SIZE AND UNPACKED CODE SIZE.

Test program	Unpacked code size (Byte)	Packed code size (Byte)	Size reduce
Bubble	96	64	33.3%
Merge	388	224	42.3%
Quick	200	168	16%
Fibonacci	100	68	32%
Hanoi	180	116	35.6%
Sieve	152	92	39.5%
AES	1,336	912	31.7%

The total equivalent gates needed in Micro Blaze system, the processor and 8kbytes of block ram is 315,528 gates. The Micro Blaze alone needs about 55,000 gates. The test program is written in C programming language and compiled by gnu C compiler. We use Xilinx On-Chip Peripheral Timer/Counter to measure the number of cycle consumed during execution. The numbers of cycle shown in Table V are the number of cycle that Micro Blaze takes to finish the test program and stop the timer. In term of cycle, the SX4 compares very well with Xilinx Micro Blaze. If running at the same frequency, the proposed processor will be about 15% slower than Micro Blaze, except for Fibonacci and Hanoi test suite. Because of the use of activation record, SX4's function call is very simple and fast. Therefore, SX4 defeats Micro Blaze on heavily recursive call programs. SX4 code size is about 60% of the Micro Blaze code size. In term of performance, Micro Blaze's maximum frequency is 91 MHz while the proposed design's is 63 MHz.

V. RELATED WORK

Processor proposed in paper [1] uses stack-based instruction approach to achieve the resource efficient criteria. Its operations take elements on the top of stack so it does not require general purpose registers. Performace is the major weakness of the stack-based processor. Many methods, include instruction packing [4] , are applied to improve the performance. But the stack-based operations, which require a lot of memory accesses, have limitted the processor's performance.

There are many approaches in instruction packing. One of them is the use of Instruction Register File (IRF) [5, 6]. IRF

TABLE III
THE PERFORMANCE COMPARISON BETWEEN
PACKED CODE AND UNPACKED CODE.

Test program	Unpacked code Cycle consumed	Packed code Cycle consumed	Speedup
Bubble	327,706	282,953	13.7%
Merge	34,712	27,888	19.7%
Quick			**14.8%**
20 items	5,388	4,575	15.1%
60 items	32,948	28,116	14.7%
100 items	82,908	70,856	14.5%
Fibonacci	3,875	3,112	19.7%
Hanoi	4,398	3,708	15.7%
Sieve	2,341	1,859	20.6%
AES	59,710	50,640	15.2 %

TABLE IV
THE COMPARISON BETWEEN
PACKED CODE SIZE AND THE STACK-BASED PROCESSOR CODE SIZE.

Test program	Stack-based code size (Byte)	Packed code size (Byte)	Comparison
Bubble	124	64	51.6%
Quick	187	168	89.8%
Fibonacci	50	68	136%
Hanoi	153	116	75.8%
Sieve	137	92	67.2%
AES	650	912	140.3%

keeps the frequently occurring pair of instructions in the program. This approach indicates multiple instructions by indexing the IRF.

Similar to instruction packing, code compression aimed for reducing the code size. The well-known code compression examples are ARM Thumb [7] and MIPS16 [8]. The special instruction set is designed to offer small code size. Number functions are unavailable in code compression mode. As a result, the performance of the processor drop while operating in code compression mode.

TABLE V
THE COMPARISON BETWEEN
THE PROPOSED PROCESSOR AND XILINX MICRO BLAZE.

Category	Xilinx Micro Blaze	Proposed processor	Comparison
Circuit size (Equivalent gate)	315,528* 55,000**	10,020	3.2% 18.2%

Maximum frequency (MHz)	91	63	0.69

* 8kbyte of Block ram is included in the equivalent gate count.
** approximated equivalent gate count of Micro Blaze processor. Block ram is excluded.
*** indicates external memory is used to hold the Micro Blaze program's Stack/Heap section.

VI. CONCLUSION

The design presented here of a 32-bit processor with instruction packing achieves the main objective, to design a resource efficient adequate performance processor. We divide the conclusion into three points of view. First of all, in term of resource consumed, the proposed design has been realized on a Xilinx Spartan3 FPGA device. It consumes 10,020 equivalent gates. Secondly, in term of code size, the result is still satisfactory. SX4's code size is obviously smaller than the conventional 32-bit processor. The proposed processor code size also comparable to the stack-based processor [1], which is a 16-bit processor. Finally, the number of cycle of SX4 executing the benchmark suites are comparable to a commercial processor, Micro Blaze. However, the maximum frequency of the SX4 is significantly lower than Micro Blaze's. To be fair, these results are based on small set of benchmarks and should be taken as preliminary result. Our current work is expanding on this result to include larger and more diversed benchmark suite and better code generation quality.

g49jsr@cp.eng.chula.ac.th, prabhas@chula.ac.th

***Abstract*-This work presents an AES encryption circuit implemented by a special type of machine called "Hardware Multiplexing" (HWMX). Hardware Multiplexing is a kind of reconfigurable embedded processor. By using dynamic reconfiguration concept, HWMX operates AES Algorithm correctly with efficient resources. HWMX consists of two cores 1) Register Bank and 2) Reconfigurable Core. The first part stores temporal results for next round computation. The second part, an important core of HWMX, processes as a reconfigurable system. This approach allows HWMX to pursue AES encryption application by splitting AES circuit into four segments and execute one segment per round, putting the temporal result of each segment into Register Bank. By using time-multiplexing hardware the resource consumed is less than a conventional circuit.**

I. INTRODUCTION

Presently, the embedded system plays critical role of computation in everyday life. At the same time, application is becoming more complex. Therefore, circuit area must be enlarged to provide more complex functionality. As a result, the circuit size could not match for budgetary environment. Hardware Multiplexing (HWMX) is a good solution for embedded systems with limited resources.

HWMX does have contribution to economic resources and its flexibility makes it suitable for embedded systems. Moreover, AES encryption is an instance of problem that we are interested in. This work demonstrates how to apply the concept of Hardware Multiplexing to implement an AES encryption circuit efficiently.

II. RELATED WORKS

The paper [1] describes the fundamental concept of Hardware Multiplexing which it provided the simulation result. This work also provides the simulation result. The simulation compares between HWMX and a general processor which illustrates HWMX's advantages.

In [2], a reconfigurable AES core using FPGA is represented. Their work presents a reconfigurable component for saving resources, S-Box. The S-Box is an important part of ByteSub process. It uses large area because of ByteSub look-up table (Encryption/Decryption). To reduce ByteSub look-up table area, a reconfigurable S-Box would be used ByteSub value stored in S-Box counts on whether it is Encryption or Decryption. This concept saves 50% of overall resource area. However, the reconfiguration of entire data path (not only S-Box) which relies upon current function is the core concept of HWMX.

Another work [3], proposed a design of Reconfigurable AES Encryption/Decryption for mobile terminals. It made up of Reconfigurable Crypto-Unit (RCU) and Reconfiguration Control Logic (RCL). The RCU has the multiplier which supports encryption, decryption, error correction and error detection. The RCU obtain control signals from the RCL. The RCL is reconfigured by Control Unit. Consequently, the RCU and the RCL give overall system more flexibility.

When a computation task is larger than the available area, it is needed to be partitioned. The work [4] proposed methods to partition a design into reconfigurable blocks. This work states two partition methodologies, Level-Based partition and Clustering-Based partition. If Level-Based partition is applied to a task, the independent subtasks will be put into reconfigurable area. On the other hand, The Clustering-Based partition will put dependent subtasks into reconfigurable area. As a result, Level-Based partition spends a little time of execution delay but it has expensive communication time and vice versa for Clustering-Based partition.

III. OPENCORE AES IP-CORE

We compare our work with an Opencore AES engine. The work [6] meets Rijndael's specification and has publicly available information (Fig. 1).

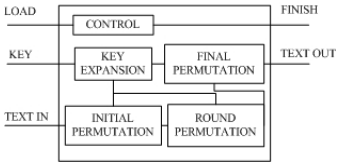

Figure 1. Opencore AES architecture which finishes its task by 12 cycles. It starts when completely load 128-bits key and 128-bits data into machine.

Opencore AES IP-Core has five modules integrated into a structure. There are four modules that are connected to each other. A group of modules does transformation and computes a RoundKey per each round. The Opencore Encryption cipher

consumes chip area about 40,000 equivalent gates. This synthesized result comes from FPGA Xilinx spartan3 xcv200.

IV. Overview of AES Encryption and Hardware Multiplexing

This section describes a basic background of AES Encryption. Moreover, some fundamental concept of how to apply HWMX to the AES core would be described.

A. AES Encryption Background

AES encryption [5] is an iterated block cipher with a variable block length and a variable key length. The block length can be independently specified to 128, 192 or 256 bits. The round transformation is composed of four different transformations. From Rijndael's proposal we obtain Table I.

TABLE I
FOR 1ST -TO 9TH OF AES ENCRYPTION USES LEFT SIDE TABLE, BUT FINAL ROUND USES RIGHT SIDE.

Round(State, RoundKey){
ByteSub(State);
ShiftRow(State);
MixColumn(State);
AddRoundKey(State);
}
	FinalRound(State,RoundKey){
	ByteSub(State);
	ShiftRow(State);
	AddRoundKey(State);
	}

* The intermediate cipher result is called *State.*

B. Hardware Multiplexing Architecture

HWMX contains two essential components, Register Bank (RB) and Reconfigurable Data Path (RDP), as show in Fig. 2.

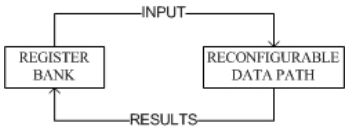

Figure 2. RB and RDP work together by sharing input, output and temporal result.

From Fig. 2, HWMX manages process cycles around RB and RDP. RB keeps three types of data, input, output and temporal results. These data comes from RDP's unit, which links with Control Unit. The Control Unit outputs fix sequence of control signal to RB and the Control Unit issues commands to the sequence ROM as a pointer to the desired sequence. (See Fig. 3)

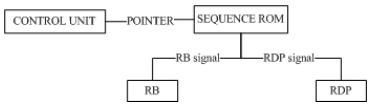

Figure 3. Control Unit send pointer to sequence ROM for RB signal and RDP signal.

The RDP realized the AES circuit by dividing it into four modules, Transposer, KeyExpansion, cipherSB and cipherMX. At any time, the RDP will be configured as one of these modules (Fig.4).

As you see in Fig. 4, there are two types of execution that is Initial Round and Others Round (1^{st}-10^{th} Round). Initial Round is a round which provides data ready to be executed in next round. In 1^{st}-10^{th} Round, all of processes will change. These rounds calculate the final result when they reach 10^{th} round. Execution sequence is discussed in detail again in EXECUTION section.

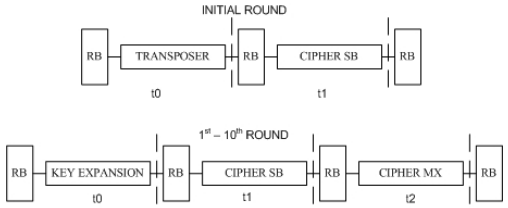

Figure 4. AES Encryption instance has two types of loop that has to be executed along the encryption.

V. Implementation

This section presents briefly the details of HWMX architecture and then shows the AES Encryption. HWMX has two main cores. There are Double Register Banks and Reconfigurable Data Path, called RDP.

Double Register Banks: Each bank contains sixteen 32-bit registers. These cores are designed to store any temporal results that come from RDP and then RDP will fetch these temporal results to compute next results.

Reconfigurable Data Path (RDP): RDP has a self-reconfigurable capability. It changes its circuit to maximize utilization and minimize resource usage. The idea to achieve this encryption by minimum resources consumption is to break an entire circuit into smaller fragments. If a fragment is too large that means circuit spends expensive resource but if a fragment is too small that means circuit wastes time. In this paper, AES Encryption circuit is divided into four modules, a Transposer, a CipherSB, a CipherMixColumn and a KeyExpansion. We assume method of reconfiguration by using Multiplexer. Reconfiguration happens when Multiplexer swaps itself to connect to other modules. By this assumption, the reconfiguration time is zero. Because there is no known practical and fast reconfiguration method at present, this assumption is amounted to a best case scenario.

VI. Experiment

We illustrate how an AES circuit based on HWMX work by comparing it to two conventional designs, one in based on a general purpose processor and the second one is an AES engine.

Traditional CPU: the CPU fetches instructions, and then decodes them. After that, The CPU executes instructions. All of these steps run on the same data path, no matter what operations are.

The AES engine: the special purpose AES engine has its circuit designed specific for the task. It has fast data-flow style execution which can be parallelized. It can be much faster than a general purpose processor trade in by the size of the circuit.

The AES based on HWMX: a HWMX circuit changes its data path (the reconfigurable unit) from time to time to share resource among different part of computation. It can trade off the speed with the size of the circuit. Table II shows the sequence of multiplexing the reconfigurable units. This is a sequence of data paths that it uses to find the result. (See Table II)

TABLE II
TABLE II SHOWS THE SEQUENCE HWMX OF EXECUTION. INITIAL ROUND PREPARES DATA INPUT READY TO PROCESS NEXT ROUND. 1st-10th ROUND DOES ENCRYPTION TO FIND OUTPUT.

Initial Round	1st-10th Round
Transposer cipherSB	KeyExpansion cipherSB cipherMX*

*cipherMX in final round would not do mix column operation.

First of all, RDP selects the Transposer module (Fig. 5) to be used. It fetches input data and input key from RB. After it finishes matrices transpose operation ,it stores the results into RB. The cipherSB module (Fig. 6) replaces the Transposer module. To prepare encryption, the cipherSB does addRoundKey. When it gets the end of addRoundKey process, RDP begins encryption. The AES encryption iterates the intermediate results for 10 rounds (see Table II). Each round has the same sequence. Firstly, the KeyExpansion module (Fig. 7) is the first module which RDP selects. The KeyExpansion module causes a new Round Key that other modules need to manipulate the Round Cipher. The KeyExpansion module finds a Round Key, and then it places them into RB. Thereafter, the cipherSB would replace the KeyExpansion module. Instead of doing addRoundKey process again, the cipherSB does ByteSub. The intermediate results from the cipherSB would be stored to RB. Finally, the cipherSB transforms itself to the cipherMX module (Fig. 8). At the beginning, the cipherMX module fetches data, and then executes shiftRow, mixColumn and addRoundKey. These set of operation which consist of the KeyExpansion, the cipherSB and the cipherMX module would be executed that sequence until they reach 10th round encryption. Furthermore, the final result is store into RB. Fig. 5-8 illustrate each component.

VII. CONCLUSION

The following paragraphs compare among HWMX, Traditional CPU and AES engine. Any advantages and disadvantages would be discussed.

Figure 5. Inside the Transposer module, matrix transpose module transforms input to ready-to-use form.

Traditional CPU: a general purpose processor has its performance disadvantage due to its generic data path. However, the processor can perform other general purpose task as well.

The AES engine: an AES engine is built to be specific encryption hardware. Certainly, this approach has highest performance. On the other hand, it consumes the largest area when compares to others and can not do anything but AES Encryption.

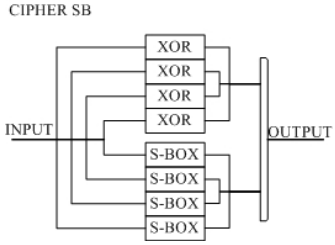

Figure 6. Inside cipherSB module, there are four S-Boxes and four XORs module to find ByteSub result.

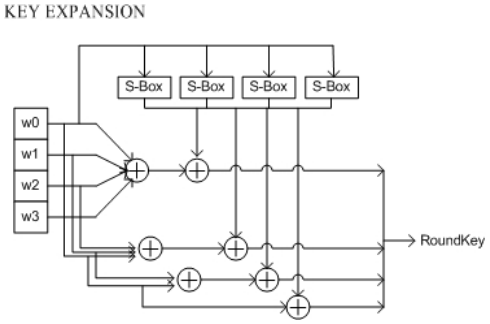

Figure 7. KeyExpansion module is the most complicated module, so this reason is why KeyExpansion is the largest part.

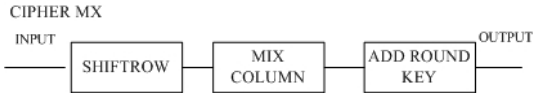

Figure 8. The cipherMX module consists of three sub-modules to do three operations, ShiftRow, MixColumn and AdddRoundKey.

The AES based on HWMX: HWMX does the AES encryption by RDP. RDP has the advantage of a flexible data path by reconfigurable ability. The ability of partition hardware into a smaller fragment helps to overcome the resource problem. Although the speed of HWMX is traded off with the resource, it can be designed to be "in-between" the performance of the general purpose processor and the special engine. This flexibility is shown in Table III.

This paper demonstrates a design of AES circuit based on HWMX concept. The comparison is made between the proposed design, AES engine, and a general purpose processor, Intel 8051 [8], which has a published performance figure. From Table III, HWMX spend around 10 thousand gates less than AES engine three times and two times for Intel 8051 [5]. The reason that HWMX is smaller than any other because its core, RDP. However, its speed is still slower than the specific AES Encryption engine. The Bottleneck

Communication is a major problem according to nature of Level-Based partition. Each module that RDP change operates on 128-bits bus but HWMX bus is Double 32-bits bus. Therefore, it wastes 2 cycles to load data into each module. Nevertheless, if HWMX has 128-bits bus instead, it will be much faster. Anyway, that is not the sole purpose of HWMX. HWMX idea is more general than a circuit that does only AES encryption.

TABLE III
RESOURCES AND CYCLES USAGE SUMMARY SHOW THAT HWMX TAKE AN ADVANTAGE ON EQUIVALENT GATES.

	Equivalent gates	128-bit Encryption Cycles	Freq (MHz).
HWMX	10830	202	75.644
AES engine	40621	12	137.299
Intel 8051	38203* 37902**	48780* 4878**	12.00* 18.906**

* original 8051 [5], ** Oregano 8051 [8]

VIII. FUTURE WORKS

In this paper, HWMX never do the physical dynamic self-reconfigurable circuit. The technology of hardware has not reaches the actual self-reconfigurable yet. Presently, we are working on a study of integrating two Xilinx spartan3 boards, one is master and other is slave. Master board consists of Double Register Banks and Microblaze. Slave board is reserved only for RDP. Master board handles storing temporal results and request to Microblaze for reconfiguration. Microblaze, then, put bitstream that store in it memory into slave board via JTAG.

***Abstract*-We use symbolic model checking to verify a VHDL design. This paper mainly focuses on Computational Tree Logic (CTL) for model checking problem. We have explained these two terms "CTL" and "model checking" for providing a clear idea about these two. Most importantly we have explored the ways of uses of CTL formulae in the case of model checking. The importance of the model checking, the ways of specifying properties in CTL and some most commonly used CTL formulae in checking are also stated. Also the uses and importance of fairness constraints in CTL formula and the conversion of CTL operators have also been included in this paper. Lastly, we have given an example of the processes of model checking.**

I. INTRODUCTION

Hardware systems are generally specified as a set of interacting finite state machines (FSMs). Network protocols and CPU controllers are such systems that their base structures consist of finite state machines. Therefore, checking the correctness of these systems is a major issue in the digital system design and the verification.

Current techniques for testing FSMs are simulations and testing. But the problems with the simulation are: it can not run for ever; it will be many times slower than the simulated system; can be very expensive; and there is no guarantee that all the possible runs will be simulated. Testing also suffers from similar disadvantages. There are some additional disadvantages such as, not all (infinite) inputs can be presented; input patterns needs to be automatically generated; no guarantee that bad inputs will be presented; and especially messy for concurrent systems like multi-component systems. These two can reveal the presence of bugs but can never establish the absence of bugs. This is a fundamental limitation for safety-critical systems. For these reasons, the application of model checking is increasing day by day. Model checking uses transition systems (*Kripke Structure*) to model systems and *temporal logics* to specify properties. It makes the verification problem reduced to graph algorithmic problems that can be fully automated [1, 2, 3, 6] and relatively easy to use. It is very successful in verifying hardware communication protocols and other many *embedded systems.* It is increasingly popular in industry. Besides, there are some robust tools such as SPIN, SMV, COSPAN, VIS, SMART etc. that can be easily and effectively used as verification tools. But the problem is that as the number of interacting components increases the size of the transition system increases exponentially which creates a very serious problem namely the state explosion problem.

The use of modeling checking in place of simulation or testing is now common in most of the cases of hardware, software, concurrent systems, reactive systems design verification. This checking uses *temporal logic* (mainly CTL) to specify the properties to be verified. In our paper, we have explored a brief idea on how we can use Computational Tree Logic (CTL) for model verification purpose. We have explained about the model, the CTL formula, the necessity of *fairness* in CTL formula and lastly a full elaborative example of model checking.

II. SYMBOLIC MODEL CHECKING

Symbolic CTL model checking is a formal verification technique which has proven itself practical in the verification of hardware specifications and implementations. A design of N latches is considered as a state machine containing 2**N states, and the temporal logic CTL is used to reason about the design. Symbolic representation and manipulation of the design allows the state machine to be traversed without explicitly building it, thus making the technique feasible for N=100 and more. The foremost step to verify a system is to specify the properties that the system should have. For example, we may want to show that some concurrent processes never deadlock. These properties are represented by *temporal logic*.

Computational Tree Logic (CTL) is one of the versions of *temporal logic*. It is currently one of the popular frameworks used in verifying properties of concurrent systems [4]. In this paper; we take consideration of only this type of logic for model checking. Once we know which properties are important, the second step is to construct a *formal model* for that system. The model should capture those properties that must be considered for the establishment of correctness. Model checking includes the traversing the state transition graph (*Kripke Structure*) and verifying that if it satisfies the formula representing the property or not, more concisely, the system is a model of the property or not. Each CTL formula is either true or false in a given state of the *Kripke Structure*. Its truth is evaluated from the truth of its sub-formulae in a recursive fashion, until one reaches atomic propositions that are either true or false in a given state.

A formula is satisfied by a system if it is true for all the initial states of the system. Mathematically, say a *Kripke*

Structure K = (S, S0, R, AP, L) (system model) and a CTL formula Ψ (specification of the property) are given. We have to determine if $K \models \Psi$ holds (K is a model of Ψ) or not. $K \models \Psi$ holds iff $K, s0 \models \Psi$ for every $s0 \in S0$. If the property does not hold, the model checker will produce a counter example that is an execution path that can not satisfy that formula.

III. STANDARD CTL FORMULAE

Formulae in standard CTL are built from atomic propositions which correspond to variables in the model being verified, standard Boolean operators (e.g., AND, OR, XOR, NOT), and temporal operators. Each temporal operator consists of two parts: a path quantifier (*A* or *E*) and a temporal modality (*F*, *G*, *X*, *U*). There are two different path quantifiers: *A* indicates that the modality defines a property that should be true on all the possible paths and *E* indicates that the property needs only hold on some paths. The temporal modalities describe the ordering of events in time along a path and have the following meaning:

$F\phi$: (reads ϕ holds sometime in the future) is true on a path if there exists a state in the path where formula ϕ is true.

$G\phi$: (reads ϕ holds globally) is true on a path if ϕ is true at every state in the path.

$X\phi$: (reads ϕ holds in the next state) is true on a path if ϕ is true in the state reached immediately after the current state in the path.

$\phi \cup \psi$: (reads ϕ holds until ψ holds, called strong until) is true on a path if ψ is true in some state in the path, and ϕ holds in all preceding states.

The semantics of the CTL operators are stated below:

K, s |= EX (Ψ) there exists s' such that s → s' (R(s, s')) and K, s' |=Ψ. It means that s has a successor state s' at which Ψ holds.

K, s |= EU (Ψ1, Ψ2) iff there exists a path L = s0, s1, … from s and k >= 0 such that: K, L(k) |= Ψ2 and if 0 ≤ j < k, then K, L(j) |= Ψ1.

K, s |= AU(Ψ1, Ψ2) iff for every path L = s0, s1, … from s there exists k >= 0 such that: K, L(k) |= Ψ2 and if 0 ≤ j < k, then K, L(j) |= Ψ1.

AX (Ψ): It is not the case there exists a next state at which Ψ does not hold i.e. for every next state Ψ holds.

EF (Ψ): There exists a path L from s and k >= 0 such that: K, L(k)|=Ψ.

AG (Ψ): It is not the case there exists a path L from s and k>= 0 such that: K, L(k)|= Ψ i.e. for every path L from s and every k >= 0;K, L(k)|=Ψ

AF(Ψ) : For every path L from s, there exists k>= 0 such that: K, L(k)|= Ψ.

EG(Ψ): It is not the case that for every path L from s there is a k >= 0 such that K,L(k)|=Ψ. It means that there exists a path L from s such that, for every k>= 0: K, L(k) |= Ψ.

Some basic CTL operators among those stated above are shown graphically for easy understanding in Figure 1. In this figure, if it is assumed that in the filled states, the formula *f* holds then we can say that the formula EF*f*, AF*f*, EG*f* and AG*f* are satisfied in the initial states (a) in the figures 1.a, 1.b, 1.c and 1.d, respectively.

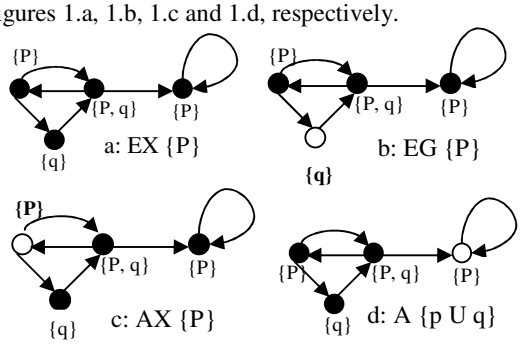

Figure 1: Basic CTL Operators

IV. CTL FORMULA CONVERSION

For a universal *CTL* formula, all states in a design that are reachable from the initial states should be checked. However for an existential *CTL* formula only one case from the initial states should be found that satisfies the formula. It is clear that algorithms of existential *CTL* formula can be implemented easier than universal *CTL* formula, so universal formulae are converted to existential formulae. Therefore all universal path quantifiers are replaced with the appropriate combination of existential quantifiers and *Boolean* negations. Also "*finally*" operators are converted to "*until*" operators. This returns a new formula that shares absolutely nothing with the original formula (not even the strings). The "*original Formula*" field of each new sub-formula is set to point to the formula passed as an argument. In addition, if and only if the original formula is of type *AG, AX, AU, AF, or EF*, the "*converted flag*" is set. These conversions are as below:

TABLE I
CONVERSION OF CTL FORMULAE

Formulae	Converted Formulae
AX f	*~ EX (~f)*
EF f	*E (True U f)*
AG f	*~ EF(~f)*
AF f	*~ EG (~f)*
A (f U g)	*~E[~g U (~f ∧ ~g)] ∧ ~EG ~g*

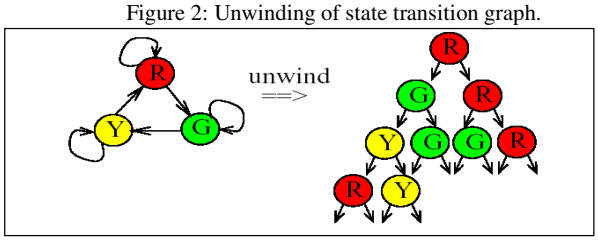
V. UNWINDING

We usually use the Computation Tree Logic (CTL) for specifying these kinds of formula for model checking. It is one of the versions of *temporal logic*. State Transition Graph (STG) is used to derive the computation trees. Now the question is that how we can build a tree from the STG? The graph structure is unwound into an infinite tree rooted at the initial state. Figure 2 shows an example of unwinding a graph (traffic-light controller; R, G and Y indicate RED, GREEN and YELLOW respectively) into a tree. All possible computations of the system being modeled are represented by the paths in the tree. Formulae in CTL refer to the computation tree derived from the model. CTL is classified as branching time logic because it has operators that describe the branching structure of this tree.

The formula *EG (RED)* is true as there is at least one path which in all its states; there is RED (the path *R, R, R*

…….). The formula E *(RED U GREEN)* is also true as there is at least a path (*R, R, G……*) where all the states hold *R* until we reach a state with *G*. But the formula *AF (GREEN)* is false as there is at least one path in which no state is with the atomic proposition *G*.

Figure 2: Unwinding of state transition graph.



VI. Expressing Properties in CTL

CTL formulas are sometime problematical to interpret. For this, a designer may fail to understand what property has been actually verified. Here we want to add some common constructs of CTL formula used in hardware verification.

1. *AG (Request → AF Acknowledgement)*: For all reachable states (*AG*), if *Request* is asserted in the state, then always at some later point (*AF*), we must reach a state where *Acknowledgement* is asserted. *AG* is interpreted relative to the initial states of the system whereas *AF* is interpreted relative to the state where *Request* is asserted. A common mistake would be to write *Request → AF Acknowledgement* in place of *AG (Request → AF Acknowledgement)*. The meaning of the former is that if *Request* is asserted in the initial state, then it is always the case that eventually we reach a state where *Acknowledgement* is asserted, while the latter requires that the condition is true for any reachable state where *Request* holds. If *Request* is identically true, *AG (Request → AF Acknowledgement)* reduces to *AG AF Acknowledgement*.
2. *AG (AF DeviceEnabled)*: The proposition *DeviceEnabled* holds infinitely often on every computational path.
3. *~AG(busy)*: The device should not be always busy.
4. *AG (EF start)*: From any reachable state, there must exist a path starting at that state that reaches a state where *start* is asserted. In other words, it must always be possible to reach the restart state.
5. *EF (x ∧ EX (x∧ EX x)) → EF (y ∧ EX EX z)*: If it is possible for *x* to be asserted in three consecutive states, then it is also possible to reach a state where *y* is asserted and from there to reach in two more steps a state where *z* is asserted.
6. *EF (~Ready ∧ Started)*: It is possible to get to a state where *holds started*, but *ready* does not hold.
7. *AG (Send → A (Send U Receive))*: It is always the case that if *Send* occurs, then eventually Receive is true, and until that time, *Send* must continue to be true.
8. *AG (in → AX AX AX out)*: Whenever *in* goes high, *out* will go high within three clock cycles.
9. *AG(~storage_coke→ AX storage_coke)*: if the coke storage of a vending machine becomes empty, it gets recharged immediately.
10. *AG AF ((~storage_coke ∨ ~storage_coffee) ∧ (storage_coke ∧ storage_coffee))*: the recharge transaction of a vending machine (of coke and coffee) takes place infinitely often.

VII. Fairness Properties in CTL

In verifying concurrent systems, we are occasionally interested only in correctness along *fair* execution [5]. It is often necessary to introduce some notion of *fairness*. For example, if there are two processes trying to use a shared resource using an arbiter, we may wish to consider only those executions in which the arbiter does not ignore one of its request inputs from either of the processors forever. Alternatively, we may want to consider communication protocols that operate over reliable channels which have the property that no message is ever continuously transmitted but never received. A *fairness constraint* can be an arbitrary set of states, usually described by the formula of the logic. If *fairness constraints* are interpreted as a set of states, then a fair path must contain an element of each constraint infinitely often. If *fairness constraints* are interpreted as CTL formulas, then a path is *fair* if each constraint is true *infinitely often* along the path. The path quantifiers in the logic are then restricted to fair path [6]. An example of a *fairness* condition is *P* that restricts the system to only those paths where *P* is asserted infinitely often. Basically we use *fairness constraints* to rule out undesired executions. Let us discuss this with an example.

In Figure 3 (a), the two processes (*PR1* and *PR2*) want to use the shared resource using the arbiter. Figure 3 (b) shows the corresponding STG. For this example, the atomic propositions are, $AP = \{idle_1, waiting_1, using_1, idle_2, waiting_2, using_2\}$ where, $idle_i$, $waiting_i$ and $using_i$ mean that process *i* is idle, waiting for and using the resource respectively. Here, the state *0* is the initial state. The *AP*s that are "True" in a specific state are expressed by a labeling function *L*. So, from the Figure 3 (b), we can find that $L(0) = \{ idle_1, idle_2\}$; $L(1) = \{ waiting_1, idle_2,\}$; $L(2) = \{ using_1, idle_2 \}$; $L(3) = \{ idle_1, waiting_2\}$; $L(4) = \{ idle_1, using_2\}$; $L(5) = \{ waiting_1, waiting_2 \}$; $L(6) = \{ using_2, waiting_1\}$; *and* $L(7) = \{ using_1, waiting_2 \}$. From this, we can make some assertions about a computation of the above graph. These are a) If at some stage process 1 is waiting then at some later stage it is using the resource (the path (1, 2) or (3, 4) or (5, 6, 7)); b) at no stage both processes are using the resource (all the states); c) If a process is waiting then it does so until it starts to use the resource (as in a)) and d) There is a stage at which both processes are waiting (5).

A computation in which 3, 5 and 7 are visited infinitely often but 4 and 6 are visited only finitely often is really unfair. So, it may be the case that the computation in the sequence 3, 5, 7, 3, 5, 7 … goes on infinitely. In this case, process2 never gets the access to the shared resource and as a result the formula $AG (waiting_2 \rightarrow AF (using_2))$ is "False". But we, of course want to see this formula "True" for the correctness of the design. To avoid such unwilling thing, we can put the constraints that any fair path must visit the any of the states got applying by the rule ($\sim waiting_2$ V $using_2$). This rule gives us all the states except (3, 5 and 7). Note that, it is clear from the graph that from the states 3, 5 and 7, if we want to hit any others states that must be visited; we have only to options either 4 or 6. In these two states, the process 2 gets the resource to use. So, it satisfies $AG (waiting_2 \rightarrow AF (using_2))$. For any design, we may need to add more than one *fairness constraints.* Here, we see the same problem if a computation goes infinitely often over the

path 0, 3, 4, 0, 3, 4 …or 0, 1, 2, 0, 1, 2…or 1, 5, 6, 1, 5, 6… . Here, we have just tried to narrate the necessity of *fairness* with example.

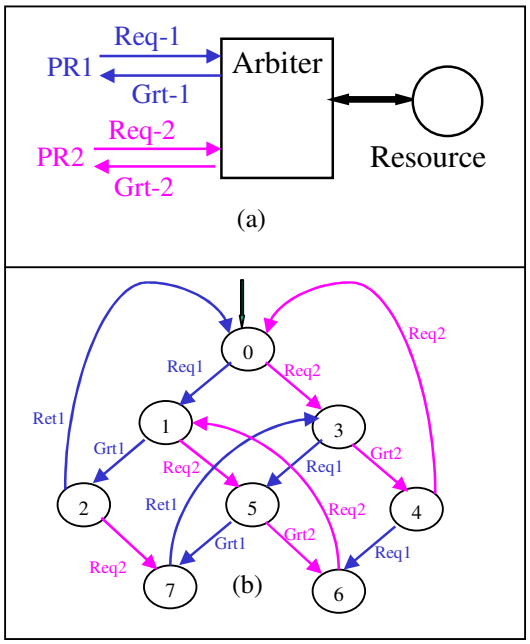


Figure 3 (a): Two processes use the shared resource using the arbiter; (b) the state transition graph

VIII. CASE STUDY

In this section we use the controller part of a simple processor, *SAYEH* and we verify this controller by standard *CTL*. The architecture of this processor is simple, but it has enough hardware for our work in formal verification and test and testability research. The processor has a 16-bit data bus and a 16-bit address bus. The processor has 8 and 16-bit instructions. Short instructions may contain shadow instructions, which effectively pack two such instructions into a 16-bit word.

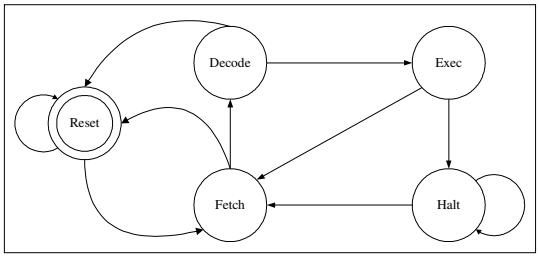

Figure 5: State machine of *SAYEH* Controller

The controller of *SAYEH* has five states*: reset, halt, fetch, decode,* and *exec*. External signals *ExternalReset* and *instruction* control transitions between states of this state machine. The state machine of *SAYEH* controller is shown in Fig. 5.

With *CTL*, all properties of this state machine are written. These properties are in three classes. With these three classes that are explained below, each state machine will be completely verified. The three classes are as follows:

The first class of properties should be checked for all states. This class is divided into three sets of properties: "There is no deadlock in any state". This property is expressed in ECTL as Equation 1.

$$AG((Pstate = S) \rightarrow EX(Pstate != S)) \quad \forall S \in \{reset, fetch, decode, exec\} \qquad (1)$$

"States are reachable from the initial state (reset)". This property is presented in ECTL as Equation 2.

$$AF(Pstate = S) \quad \forall S \in \{reset, fetch, decode, exec\} \qquad (2)$$

"Each state is reachable from any state". This property is shown in ECTL as Equation 3.

$$AG((Pstate = exec) \rightarrow EX(Pstate != reset)) \qquad (3)$$

The second class of properties is different from one state to another. In this class of properties *"immediate states after each states"* are checked. For example:

$$AG((Pstate = exec) \rightarrow EX(Pstate != reset)) \qquad (4)$$

The third class of properties is to check transitions between states with respect to the input signals and instructions. For example:

$$AG((Pstate = exec \ \& \ External\,\mathrm{Re}\,set = 1) \rightarrow AX(Pstate != reset)) \qquad (5)$$

IX. CONCLUSIONS

Formal verification replaces simulation in certain applications. For testing the correctness of a digital system that consists of FSMs verification is efficient and easy to use. This is an exact method and does not require test data. Model checking has many important advantages over the mechanical theorem provers or proof checkers for verification of the different hardware and protocols. In the cases like protocol design, network design and many others where it is more complex and expensive to check/test after the implementation, model checking can be brilliantly used in those cases to find the bug before the implementation. In model checking, CTL, an important family of *temporal logic* is effectively and increasing used to specify the properties of the model to be verified.

Undeniable Fair Electronic Auction

Yongyuth Permpoontanalarp and Montri Apiromvorakarn
Department of Computer Engineering, Faculty of Engineering
King Monkut's University of Technology Thonburi
126 Pracha-Utid Road, BangMod, Tung-Kru, Bangkok 10140, Thailand

***Abstract*- Fair e-auction is an e-auction which employs the fair exchange protocol. All existing approaches to fair e-auction achieve the fair exchange property between a single bidder and an auctioneer. But they do not offer the fair exchange between all bidders and an auctioneer. So, a malicious auctioneer can deny receiving bids from some legitimate bidders but do receive bids from conspired bidders. We propose a new fair e-auction protocol which provides the fair exchange for all bidders, called the undeniable fairness.**

I. INTRODUCTION

Many internet-based applications involve electronic exchange of information between senders and receivers, for example, e-mail, e-payment and e-auctions. E-auction involves the exchange of information between bidders and auctioneers. For example, after a bidder submits a bid to an auctioneer, the auctioneer will send back a bid receipt to the bidder. But, if one party behaves dishonestly, then the exchange becomes unfair to the other party. In particular, a malicious auctioneer may deny bids based on the bidders and amount, but receive bids from conspired bidders only. Thus, the conspired bidder can be the bid winner easily.

Fair e-auction is an e-auction which uses the fair exchange protocol. The fair exchange protocol (eg.[1,2,3,4,5,6,7]) allows both sender and receiver to exchange information such that either all of parties have the exchanged information or none of them do. There are three main approaches to fair exchange, depending on the use of a trusted third party (TTP). TTP is an additional infrastructure to mediate the exchange between a sender and a receiver. The first approach (eg. [1]) does not use TTP at all. The second approach (eg. [2,3]) uses online TTP to mediate the exchange. This approach is suitable for commercially practical use, but it has an additional cost on TTP. The third approach (eg. [4,5,6,7]) uses offline TTP, and is also called optimistic fair exchange. TTP is involved only when there is a dispute between sender and receiver.

All existing approaches to the fair exchange and fair e-auction achieve the fair exchange property between a single bidder (sender) and an auctioneer (receiver). But they do not offer the fair exchange between all bidders and an auctioneer. Thus, a malicious auctioneer can deny receiving bids from some bidders but do receive bids from conspired bidders. Note that the conspired bidders can intentionally reveal their identities to the auctioneer in some way when their bids are submitted. So, denied bidders will have much less chance to compete and are likely to be bid losers.

In this paper, we propose a new fair exchange protocol for e-auction which offers the undeniable fairness. The undeniable fairness means in addition to the usual fair exchange that an auctioneer cannot refuse to receive bids sent by any bidder. Moreover, we analyze the practicality of our new protocol for e-auction. Also, we consider open-bid e-auction only in this paper. A preliminary result of our work here is reported in [8].

II. RELATED WORKS

In the following, we discuss an online TTP approach. We use the following notations throughout the paper. Let *S, R*, *m* mean sender, receiver and message that *S* wants to exchange with *R*, respectively. $S \rightarrow R : M$ means that *S* sends *M* to *R*. $A_X(m)$ means public key encryption on message *m* by *X*'s public key, and $S_X(m)$ means *X*'s signature on message *m*. Also, *k(m)* stands for symmetric encryption of *m* by key *k*, and *h(m)* means hash of message *m*. $Mac_k(m)$ means message authentication code of message *m* by key *k*.

A. Abadi et. al.'s Approach [3]

Abadi et. al. presents an interesting fair exchange which uses online TTP in a minimal way. In particular, TTP does not store state information during the exchange. The following presents their simplified version.

1. $S \rightarrow R$: $k(m), A_{TTP}(k, S, R, h(k(m)))$
2. $R \rightarrow TTP$: $A_{TTP}(k, S, R, h(k(m))), h(k(m))$
3. $TTP \rightarrow R$: $h(k(m)), k$
4. $TTP \rightarrow S$: $S_{TTP}(A_{TTP}(k, S, R, h(k(m))))$

In step (2), *R* sends *h(k(m))* computed from *k(m)* in step (1). After step (2), TTP compares *h(k(m))* with *h(k(m))* in $A_{TTP}(k, S, R, h(k(m)))$ to verify that *R* gets the correct *k(m)* before issuing decryption key *k* in step (3). In step (4), TTP sends a receipt to *S* on behalf of *R*.

Again, malicious *R* can deny receiving message from legitimate *S* by not performing step 2. As a result, no exchange can be taken place.

III. UNDENIABLE FAIRNESS

Definition 1 Undeniable Fair e-auction
The undeniable fair e-auction means that

1. Either both a bidder and an auctioneer have exchanged information or none of them do, and
2. An auctioneer cannot deny receiving bids sent by any bidder by ignoring to participate into an agreed message-exchange protocol with the bidder. □

While (1) means the fair exchange between one bidder and one auctioneer, (2) deals with the fair exchange between all

bidders and one auctioneer. The undeniable fairness is also called the fairness for all bidders.

Our system provides the undeniable fairness in a loose sense in that if an auctioneer has denied receiving bids from some bidders, then soon the auctioneer will not be able to receive any further bids from any bidders. Thus, to always offer the bidding service to all bidders the auctioneer will have to receive all submitted bids. The strict undeniable fairness would require a sequential bid receiving because an undeniable fair auctioneer must read bid as soon as the bid arrives. In other words, the sequential bid receiving for all bids ensures the undeniable fairness. But our undeniable fair exchange system offers a more flexible bid reading in that an auctioneer can read bids in a non-sequential order.

Our system uses TTP to mediate the exchange between a bidder and an auctioneer. Before an auctioneer can read a bid message sent to her, the auctioneer has to obtain a key and an approval from TTP. TTP provides a reading queue of sent but unread bid messages for an auctioneer. To constrain bid receiving by auctioneer, TTP specifies a window of receivable bids in the reading queue. Only messages in the window can be read by the auctioneer and they can be read in any order. The window can be slid in forward direction across only messages that have been already read. If message at the leftmost of the window is not read, then the window cannot be slid. So, no additional messages can be read.

The size of windows is important since it indicates the trade-off between the flexibility for bid reading and the undeniable fairness. If the window is wide, then the auctioneer has a great flexibility to read any bid messages in the window. But the undeniable fairness is weak since the auctioneer can still read many other bids while denying reading some bid in the wide window. However, if the window is small, then the flexibility is decreased but the undeniable fairness is strong.

The size of the window should be adjustable dynamically as the bidding proceeds. If the system is highly fair for all bidders, then the window should be wide to allow for flexible reading. But if the system is not undeniably fair, then the window should be small to regain the fairness.

IV. UNDENIABLE FAIR E-AUCTION PROTOCOL

Our protocol is based on Abadi et. al.'s approach [3]. The protocol consists of two parts, namely basic protocol and dispute resolution protocol. Basic protocol describes steps used for exchanging messages between sender and receiver. However, dispute resolution protocol is used when there is a dispute occurring between bidder and auctioneer.

A. Basic Notations

1) $Q(R)$ = a unique running sequence number (called the bid number) generated by TTP for each bid that any bidder requests to send to auctioneer R
2) $Min_Q(R)$ = the smallest bid number of unread bid in R's reading queue (ie. the earliest unread bid in the queue)
3) $W(R)$ = receiver R's window
4) TS = the total number of sent bids by a bidder to an auctioneer
5) TR = the total number of received bids by an auctioneer
6) $Ratio_{fair}$ (a system parameter) = TR/TS where $TR \leq TS$
7) S_{all} = the set of all bidders' identities

B. Basic Assumptions

We assume that only TTP has a pair of private and public keys. All bidders and auctioneers have TTP's public key. Also, each bidder and each auctioneer have share keys with TTP, namely k_s and k_r, respectively. Moreover, TTP is trusted on all aspects, but both bidders and auctioneers are not trusted.

C. Basic Protocol

Before a bidder can send a bid to an auctioneer, the bidder must submit a request to TTP for a sending ticket. The ticket contains necessary information for the auctioneer to read the bid. Then, the bidder sends both ticket and encrypted bid to the auctioneer. To read the encrypted bid, the auctioneer requests the key from TTP. After TTP issues the key to the auctioneer, TTP sends out the receipt of the bid to the bidder.

TTP provides for each auctioneer R a reading queue of bids sent to R by any bidder. Bids in the reading queue are ordered according to their sending requests to TTP. When R requests to read a bid in the queue, TTP computes a range of receivable bids in the queue that are allowed to read by R.

Initially, $W(R)$=1

1) Bidder S sends an authenticated request for ticket to TTP.
$S \rightarrow TTP : S, R, h(k(m)), Mac_{ks}(S, R, h(k(m)))$
2) TTP issues a signed ticket to bidder.
$TTP \rightarrow S : S_{TTP}(Q(R), h(k(m)))$

$Q(R)$ is the bid number for m that S wants to send to R. The ticket consists of $Q(R)$ and $h(k(m))$.

3) The bidder sends the signed ticket, encrypted message and encrypted key to the auctioneer R.
$S \rightarrow R : S_{TTP}(Q(R), h(k(m))), k(m), A_{TTP}(k, S, R, h(k(m)))$

R can verify the validity of TTP's signature in the ticket, and verify that the ticket is for the encrypted bid $k(m)$.

4) The auctioneer requests from TTP the decryption key k to read bid m.
$R \rightarrow TTP : S_{TTP}(Q(R), h(k(m))), A_{TTP}(k, S, R, h(k(m))), h(k(m)), Mac_{kr}(h(k(m)))$

Then, TTP verifies its own signature in the ticket and verifies that the ticket corresponds with the encrypted key. Also, TTP verifies that the request is actually from R and that R received the correct $k(m)$.

5) TTP checks if R is currently allowed to read m.
If $Min_Q(R) \leq Q(R) \leq Min_Q(R)+W(R)$, then
$TTP \rightarrow R : h(k(m)), k_r(k)$
Else
$TTP \rightarrow R : S_{TTP}(\text{"Request is refused"})$
Go to step 4)

TTP allows R to read m if m is in R's window on bids in the reading queue.

6) TTP sends an evidential receipt of bid m by R to the bidder S.
$TTP \rightarrow S : S_{TTP}(A_{TTP}(k, S, R, h(k(m))))$

TTP certifies that TTP has released the decryption key for $A_{TTP}(k, S, R, h(k(m)))$. S can use this receipt with $k(m)$ to prove to a third party with the help of TTP that R has received m.

V. CALCULATION OF WINDOW SIZE

Definition 2 The system is fair for all bidders and auctioneer R if and only if $\frac{\sum_{S1 \in S_{all}} TR(S1, R)}{\sum_{S2 \in S_{all}} TS(S2, R)} \geq Ratio_{fair}$ where $TS(S,R)$ and $TR(S,R)$ mean the total number of sent and received bids, respectively, between S and R. □

Suppose that there are bidder S and auctioneer R such that $TR(S,R)_{period(S,R)}/TS(S,R)_{iperiod(S,R)} < Ratio_{fair}$. We call R as an unfair auctioneer and S as an unfairly treated bidder.

Indeed, $Ratio_{fair}$ defines an acceptable degree of the fairness for all bidders. If $Ratio_{fair}$ is large (ie. TR is closed to TS), then it results in a strict kind of bid receiving in that many submitted bids must be received by auctioneers soon after the bids are sent. However, with a large $Ratio_{fair}$, the system provides a stronger level of fairness due to the large TR. If more number of bid messages is received, then less number of bid messages can be denied.

The following algorithm generates a new window size $W(R)$ from an input window size $W'(R)$. The algorithm is involved in step (5) of the basic protocol.

Algorithm 1 Window Computation for auctioneer R
Input: $W'(R)$, $TR(S,R)$ and $TS(S,R)$ for all bidders S
Output: $W(R)$: positive integer
If the system is fair for all bidders and auctioneer R, then

$$W(R) = \lceil Ratio_{fair} \times TS_C(R) \rceil$$

where $TS_C(R)$ is the number of currently unread bids in R's reading queue
Else /* unfair for all senders */
If $UF\%(R) < T(UF\%)$ and $0 < W'(R)$ then

$$W(R) = \left\lceil W'(R) - (W'(R) \times \frac{UF\%(R)}{T(UF\%)}) \right\rceil$$

Else $W(R) = 1$
where $W'(R)$ is the last $W(R)$ when the system is fair at the last time but if the system has never been fair, then $W'(R)=1$, $S_{UF}(R)$ is the set of all unfairly treated bidders by auctioneer R, $T(UF\%)$ is the threshold of the highest acceptable degree of the unfairness in percentage and $UF\%(R)$ is the current degree of the unfairness by R in percentage which is defined by the following:

$$n = \frac{\sum_{j1 \in S_{UF}(R)} TR(j1, R)}{\sum_{j2 \in S_{UF}(R)} TS(j2, R)}, \quad UF\%(R) = 100 - (\frac{n}{Ratio_{fair}} \times 100\%)$$ □

Our method for window reduction is to reduce the window size according to the degree of the unfairness occurred. The higher the degree of the unfairness occurs, the more reduction the window size is. $UF\%(R)$ is compared with $T(UF\%)$ to reduce the window. A larger $Ratio_{fair}$ produces faster window reduction. As a result of the fast window reduction, the severity of the unfairness is low since the amount of bids that can be read by an unfair auctioneer during the unfairness is small.

VI. DISPUTE RESOLUTION PROTOCOL

Dispute resolution protocol is used when there is a dispute between bidder and auctioneer. For example, R may claim that she does not receive an encrypted bid in step (3) of the basic protocol for a bid message number $Q(R)$. As a result, R's window cannot be slid over $Q(R)$. In such case, R may engage in a dispute resolution protocol to provide a pre-committed receipt of bid message number $Q(R)$.

7) $R \rightarrow TTP : S_R(R, Q(R))$
8) $TTP \rightarrow R$: ok
9) $TTP \rightarrow S$: "Q(R) is pre-committed"

After (7), TTP will treat message number $Q(R)$ as if it has been read by R. And S can resolve the dispute by contacting TTP. In such case, TTP may act as a mediator for the actual message exchange. Note that here we show the use of auctioneer's private key, but other message authentication methods, for example MAC or passwords are allowed.

VII. ANALYSIS

We apply our protocol to a case study in e-auction. In our case study, bidders submit their bids on round basis. In each round, all losing bidders from the previous round submit their bids. After that, the auctioneer will read all those submitted bids and announce the round winner. Assume that there is only one round winner. There are two consecutive phases for the bidding where the second phase stands for a final period of bidding times (eg. last 30 minutes). The second phase requires stronger undeniable fairness than the first phase since the unfairness in the second has a direct effect on a bid winner.

In the first phase, there are 10 rounds. Let i be the number of bidders taking part in the second phase. Assume that there are $2i$ rounds in the second phase. Assume that there are 30 bidders in the first phase and 15 bidders in the second phase. In the first phase, $Ratio_{fair}$ is set to 50% and it is increased at the beginning of the second phase and becomes 100% at the middle of the second phase. The increment of $Ratio_{fair}$ prevents the auctioneer to behave unfairly to all bidders in the second phase. Also, $T(UF\%)$ is set to 50%.

First, we shall discuss the first phase. Figure 1 shows the change of $W(R)$ in the first round when all bids are submitted and the auctioneer starts to read (TS=30 and TR=1…30). Initially, the system is not fair, so $W(R)$ is 1. When TR=15, the system becomes fair (so $W(R)$ = 8) and then the auctioneer gets the flexibility for bid reading. After that, $W(R)$ is decreased toward 0 because $TS_C(R)$ is reducing. Figure 2 shows $W(R)$ in the second round. Initially, the system is fair and then the auctioneer gets the flexibility. Later, as $TS_C(R)$ is reducing, $W(R)$ is decreasing. All other rounds are similar to the second round.

Figure 3 shows the 1st round of the second phase. The size of $W(R)$ here is smaller than that in the first phase since only 15 bidders take part. $Ratio_{fair}$ is increasing towards 100%. At the 16th round of the 2nd phase, $Ratio_{fair}$ becomes 100%. So, from the 16th round onwards, $W(R)$ is mostly 1.

Now, we discuss the unfairness case. Suppose that in the first round of the first phase, bidders submit their bids more than expected. Thus, the system will be unfair and the window

should be reduced. Figure 4 shows the window reduction in the second round (*TR*=30) when *TS* is increasing towards 150 and *T(UF%)=50%. W(R)* is started to reduce from 15 at *TS*=61 and becomes 1 at *TS*=113. Thus, even though the number of submitted bids is more than the expected number (ie. 30) for a round, the auctioneer cannot process those excessive bids due to the reduction of *W(R)*. In other words, *W(R)* must not be more than 30. Otherwise, the auctioneer can read submitted bids on the next round while denying reading some bids on a current round.

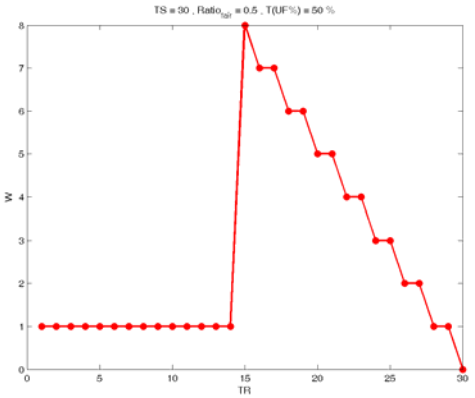

Figure 1. Window size in the 1st round of phase 1

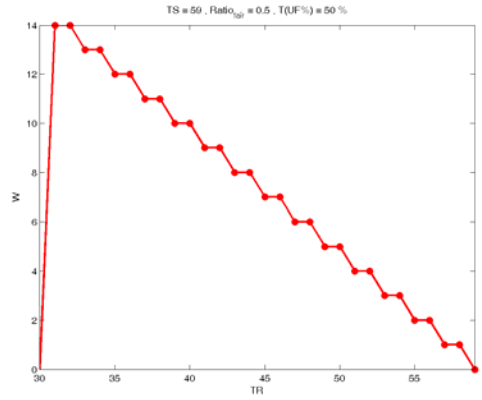

Figure 2. Window size in the 2nd round of phase 1

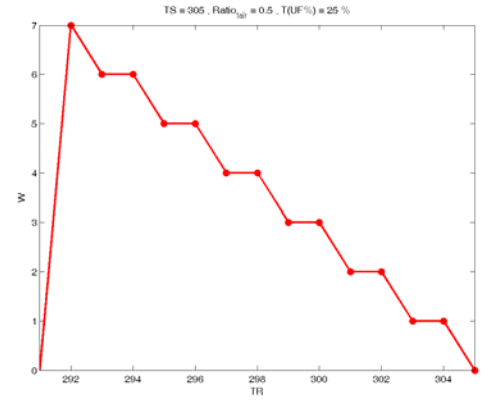

Figure 3. Window size in the 1st round of phase 2

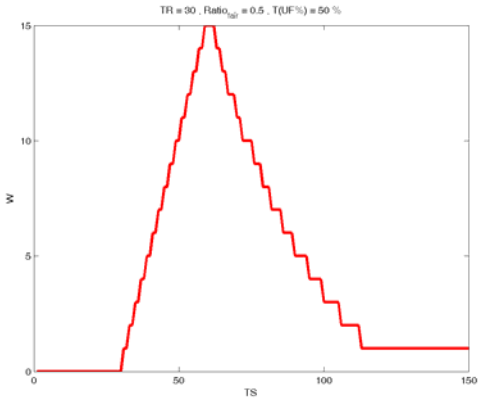

Figure 4. Window reduction during the unfairness

Our window reduction works fine if the amount of *TS* can be restricted. Without the restriction, when *TS* and *TR* are very large, *W(R)* can be much greater than the expected number of bids in a round. Due to space limit, our protocol presented here does not restrict *TS*. But our extended protocol to restrict *TS* is presented in [9] where it can also prevent the denial of service attack on the number of submitted bids in each round.

VIII. CONCLUSION

In this paper, we present a new fair e-auction which offers the undeniable fairness. The undeniable fairness is achieved by using $Ratio_{fair}$ and the window mechanism to constraint message receiving. Also, we have applied our protocol to a case study. The result looks promising. As a future work, we aim to apply our undeniable fair protocol to other applications.

A Cost Model for Bitmap Index Partition Techniques

Manlika Honghirun, Songrit Maneewongvatana
Department of Computer Engineering
King Mongkut's University of Technology Thonburi

***Abstract*- Bitmap indexes are efficient for online analytical processing (OLAP) applications and decision support systems that involve complex queries. They use a single bit in each key value instead of a list of row identifiers to indicate the specific value of data. The vital benefit of bitmap index is that Boolean operations can be easily manipulated on the bitmap strings. However, many scientific applications usually operate on floating point numbers and simple bitmap index scheme would generate too many bitmaps. The issue of using bitmap indexes in high cardinality attributes can be solved by assigning a bitmap to cover an interval of attribute values. This method requires partitioning of the attribute domain. We present the cost model for predicting the performance of two bitmap indexes partition techniques. The first technique called equal density of bitmap index partition technique and the second is equal interval of bitmap index partition technique. We verify our analytical results by a detailed experimental study and imply the suitable bitmap index partition technique for certain data and query distributions.**

I. INTRODUCTION

An index is a feature in a database allowing rapid access to some associated data in a table. It can improve performance of queries but it may decrease the performance on updates. In traditional indexing techniques, most DBMSes use B-tree or its variants as an index structure [5]. However, B-tree is not suitable for some systems such as online analytical processing (OLAP) or decision support system (DSS) due to the nature of operations on database which consists of a lot of complex queries and very few updates.

Bitmap index is another type of index that is particularly useful in the above applications. It uses only single bit for each key value instead of a list of row identifiers. The associated bit is set if and only if the record's value fulfils the property in focus. Since, the values are now bit, Boolean operations can be easily manipulated on the bitmap string. Moreover, Building and maintaining bitmap indexes usually costs less time and space for attributes with limited number of values (low cardinality). One major problem of simple bitmap indexes is that it cannot handle high cardinality domains effectively. This problem can be solved by assigning a bitmap to cover an interval of attribute values [3]. Bitmap partition techniques would determine proper intervals that each bitmap covers.

In this paper, we focus on the equal density and equal interval partitioning techniques for bitmap indexes when the attributes have high cardinality. We propose a simple yet accurate cost model for predicting the performance of two bitmap indexes partition techniques.

II. RELATED WORKS

Several database vendors including Oracle, Red Brick Systems, and Sybase have the introduced bitmap indexing to support complex query applications and application that support multidimensional analysis [1, 3, 5, 6, 7].

A detailed discussion on designing bitmap indices based on different encoding schemes is presented in [6]. In particular, space and time complexities are evaluated for multi-component indexed and each of these encoding schemes is suitable for different types of queries. In [1], an encoded bitmap indexing for data warehouses is presented. The domain of the indexed attribute is encoded by the mapping. It solves the problems of sparsity, at the same time, improves the space utilization and shortens the maintenance and processing range searches. In scientific data communities, the common attributes are non-discrete [7]. Wu and Buchmann presented an algorithm for processing one-sided range queries called GenericRangeEval and studied analytically and experimentally the performance behavior of multi-dimensional queries. A related task of finding an optimal partition with respect to data and query distribution is proposed in [3]. Typically, Bitmap is used for low cardinality attributes since the overall space requirement depends on the cardinality attributes. For high cardinality attributes, partitioning technique of associating a range of continuous values to a single bitmap is generally applied to reduce the space requirement [4]. Existing partition techniques include equal interval and equal density partition. In [2], the authors presented the techniques on partitioning the attributed domain into intervals for a bitmap that minimize candidate check cost, which is the cost of verifying whether candidate records satisfy the condition in the query or not.

III. BITMAP INDEXES PARTITION TECHNIQUES

The goal of partitioning is to dividing the attribute domain into k disjoint intervals. Each interval corresponds to a bitmap.

Let $\{L_i, U_i\}$ denote an interval I_i of data set, where $1 \le i \le k$, L_i is the lower boundary and U_i is the upper boundary interval i. The length of interval in interval i equal to U_i - L_i

$$I_i = U_i - L_i \quad (1)$$

A. *Equal Interval Partition Technique (E.I.)*

This technique partitions attribute domain so that each interval has the same length. If the data set is random, the numbers of data records in all intervals are roughly the same. In the other hand, if the data are clustered, the numbers of data records in all intervals can be very different and depend on the data distribution.

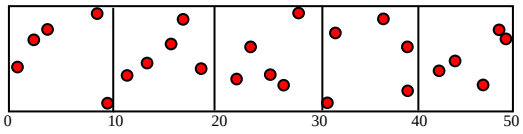

Figure 1. An example of equal interval partition technique
(Assume the data distribution is uniform)

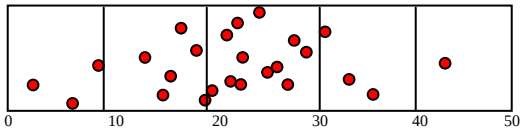

Figure 2. An example of equal interval partition technique
(Assume the data distribution is not uniform)

B. *Equal Density Partition Technique (E.D.)*

For non-uniform data distributions, equal interval partitioning is not suitable because the density of data records will be different (shown in Fig. 2). Some intervals may have a lot of data records while some have much fewer. If the high density interval is used during candidate check process, the cost would be rather high. This problem can be solved by the equal density partition technique which tries to partition each interval to the roughly same number of data records.

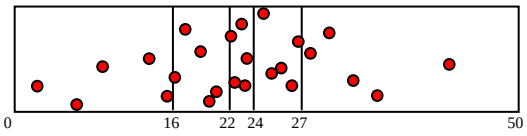

Figure 3. An example of equal density partition technique
(Assume the data distribution is not uniform)

IV. THE COST MODEL

A. *Candidate Check Cost*

To answer the query, the records that fall into specific intervals must be checked to make sure that they really satisfy the query condition. The candidate check cost (C_c) which dominates the query time [6] consists of the *candidate interval cost* and *candidate record cost*. The candidate interval cost is required to locate the desired intervals. The candidate record cost is proportional to the number of records falling into the interval.

Fig. 4 explains the candidate check cost (C_c) by means of an example. An attribute domain X with eight records is partitioned into five intervals. The first column lists the X value of each record. Assume the query X= 13, the answer would be in interval I_2 which has the range [10,20) and it has two candidate records 18 and 13 which the bit equal to 1. However, only the last record is a true match. All candidates must be checked during candidate record check.

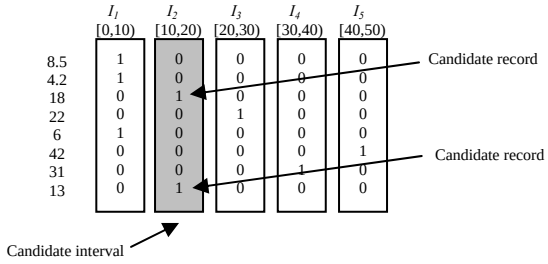

Figure 4. The candidate record cost and candidate interval cost of equal interval partition technique

In this paper, we verify our analytical results by a detailed experimental study and consider only normal and uniform distribution. The probability density functions are as the follow,

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2} \quad \text{For} \quad -\infty < x < \infty \qquad (2)$$

$$f(x) = \begin{cases} \dfrac{1}{b-a} & \text{For } a < x < b, \\ 0 & \text{For } x < a \text{ or } x > b, \\ \dfrac{1}{2(b-a)} & \text{For } x = a \text{ or } x = b \end{cases} \qquad (3)$$

Equations in (2) and (3) are the probability density function of normal distribution and uniform distribution respectively.

The distribution function is denoted by

$$\int_{-\infty}^{\infty} f(x)dx = 1 \qquad (4)$$

The following is the probability of data records to appear in interval i:

$$p_i = \int_{L_i}^{U_i} f(x)dx \qquad (5)$$

Assume the number of data records equals to n. For equal density partition technique, the number of data records in each interval equals to n/k, the probability of data that fall in each interval equals to $1/k$.

For equal interval partition technique, each interval has the same length of interval. Therefore, we know the certain L_i and U_i and can calculate the number of data records that appear in each interval (r_i).

$$r_i = p_i * n \qquad (6)$$

The followings are the candidate record cost and the candidate interval cost

$$\text{Candidate record cost} = \sum(r_r p_r) \qquad (7)$$

$$\text{Candidate interval cost} = \sum(I_r p_r) \qquad (8)$$

Therefore, the candidate check cost is

$$\text{Candidate check cost } (C_c) = \sum(r_r p_r) + \sum(I_r p_r) \quad (9)$$

Where r_r = number of data records in range r of query
p_r = probability of data retrieval in range r of query
I_r = number of intervals scans in range r of query

B. Disk Access Cost

The candidate check cost can partially predict the performance of two bitmap index partition techniques. In typically situations, the data set is too large to fit in memory and it requires massive amount of storage. Therefore, the cost model needs to add the cost of storage or disk access cost. We can hypothetically divided data records and bitmap indexes into two classes: active and inactive. Active records and corresponding indexes are placed in buffer space in RAM. Inactive portions are stored in hard disk and need to be fetched if once required. Disk access cost would be added to our cost model when bitmap indexes of data retrieval are not in buffer and we need to access bitmap indexes in the disk storage. We define the disk access cost (C_d) of bitmap index partition technique as the follow,

$$\text{Disk access cost } (C_d) = \sum_{i=1}^{n} \left((1 - p_{q_i}) \times n_{q_i} \right) \quad (10)$$

Where p_{q_i} is the probability of queries fall in interval i of data record or the probability of bitmap indexes are in memory and n_{q_i} = Number of queries that fall in interval i of data record.

C. Cost Model for Predicting the Performance of Bitmap Indexes Partition Techniques

From above, we can define the overall cost model for predicting the performance of bitmap indexes partition techniques:

$$\text{Total Cost } (C_t) = P_d C_c + P_b C_d \quad (11)$$

Where P_d = The percentage of data records which could be contained in disk
P_b = The percentage of bitmap indexes which could be contained in disk
C_c = Candidate check cost
C_d = Disk access cost

V. PERFORMANCE OF BITMAP INDEX PARTITION TECHNIQUES

We perform detailed experiments, to predict and compare the performance of two bitmap index partition techniques. We consider only normal and uniform distributes for data and query distributions. The main assumptions are as follow,

1) *Data and Query Distribution are normal.*
2) *Data Distribution is normal and Query Distribution is Uniform.*

We ignore the case when the data distribution is uniform because the records that fall into specific intervals are roughly the same. Even queries fall into different intervals, the number of data records to be scanned is roughly the same.

The experiments are parameterized with the cover conditions between data set and queries. When data and query distributions are normal, it covers 6 possible conditions.

TABLE I
THE CONDITIONS FOR DATA AND QUERY DISTRIBUTION ARE NORMAL

Conditions					
No.	Means	S.D.	No.	Means	S.D.
1	$\mu_q = \mu_d$	$\sigma_q = \sigma_d$	4	$\mu_q < \mu_d$	$\sigma_q = \sigma_d$
2	$\mu_q = \mu_d$	$\sigma_q < \sigma_d$	5	$\mu_q < \mu_d$	$\sigma_q < \sigma_d$
3	$\mu_q = \mu_d$	$\sigma_q > \sigma_d$	6	$\mu_q < \mu_d$	$\sigma_q > \sigma_d$

From Table I μ_d and μ_q are the means of data set and queries respectively. σ_d and σ_q are the standard deviation of data set and queries respectively.

If data distribution is normal and query distribution is uniform, we consider only the means of data set and queries. It covers 3 conditions: condition 1 is $\mu_q = \mu_d$, condition 2 is $\mu_q < \mu_d$, condition 3 is $\mu_q > \mu_d$.

A. Compare the Candidate Check Cost

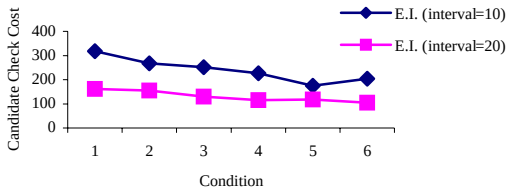

Figure 5. The candidate check cost of equal interval partition technique

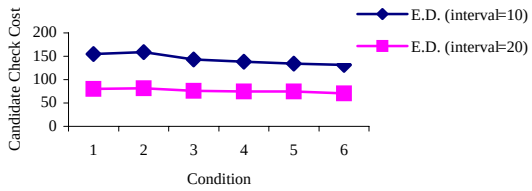

Figure 6. The candidate check cost of equal density partition technique

Fig. 5 and Fig. 6 show the comparison of the candidate check cost when the number of intervals equal to 10 and 20. The number of intervals of data record affects to the candidate check cost. Intuitively, larger number of intervals gives smaller candidate check cost. Similarly, when data distribution is normal and query distribution is uniform, the same behavior applies. Then, considering the candidate check cost between E.I. and E.D. At the same number of intervals E.D. give the less candidate check cost. However, this candidate cost is not the whole cost. It excludes the disk access cost which would be added to our total cost when the number of intervals increases. Therefore, we need to trade off between candidate check cost and disk access cost.

B. *Compare the Disk Access Cost*

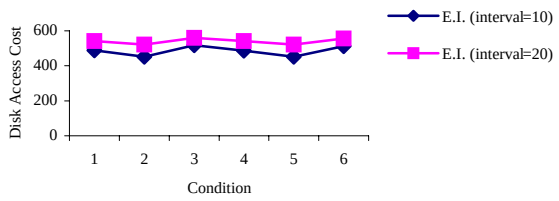

Figure 7. The disk access cost of equal interval partition technique

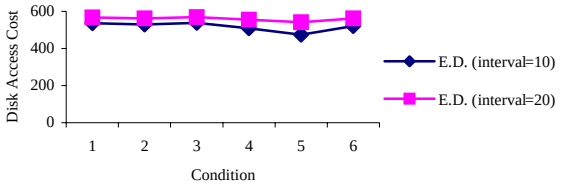

Figure 8. The disk access cost of equal density partition technique

Fig. 7 and Fig. 8 are the comparison of the disk access cost when the number of intervals equal to 10 and 20. The disk access costs increase when the number of intervals increases because the increasing of number of intervals requires massive amount of storage. If data distribution is normal and query distribution is uniform, the disk access costs are similarly to data and query distributions are normal. At the same number of intervals E.I. gives the less disk access cost. However, the feature of today's common memory technology is rapid developed and tends to be low-cost of high performance storage such as RAM. If high performance storage is cheap, increasing memory can decrease the disk access cost.

C. *Compare the Total Cost*

TABLE II
THE TOTAL COST OF EQUAL INTERVAL PARTITION TECHNIQUE

Condition	P_b =10%	P_b =20%	P_b =50%	P_b =80%
1	335.1076	383.9751	530.5778	677.1805
2	285.8723	331.1226	466.8735	602.6244
3	278.0062	329.7893	485.1388	640.4882
4	252.2186	300.958	447.1761	593.3943
5	202.2957	247.4028	382.724	518.0453
6	235.3191	286.5013	440.0478	593.5944

TABLE III
THE TOTAL COST OF EQUAL DENSITY PARTITION TECHNIQUE

Condition	P_b =10%	P_b =20%	P_b =50%	P_b =80%
1	193.0005	246.6622	407.6472	568.6323
2	195.9168	248.8335	407.5839	566.3342
3	182.5854	236.375	397.7437	559.1124
4	175.1335	225.9802	378.5205	531.0607
5	168.4384	215.8452	358.0658	500.2864
6	170.4524	222.5958	379.0262	535.4565

Tables II and III show the total cost of E.I. and E.D. with the different percentage of bitmap indexes which contained in disk (P_b) and the percentage of data record which contained in disk (P_d) equal to 90%. The total costs of E.D. less than the total costs of E.I. for all conditions and its increase when P_b increases. For data distribution is normal and query distribution is uniform, the total costs are similarly to data and query distributions are normal. Thus, the performance or the capacity of memory affects to the performance of two bitmap index partition techniques.

VI. CONCLUSION AND FUTURE WORK

We proposed a simple cost model for predicting the performance of two bitmap index partition techniques (equal density and equal interval partition technique). The candidate check cost and disk access cost are added in our cost model.

If data and query distributions are normal or data distribution is normal and query distribution is uniform, equal density partition technique is more efficient than equal interval partition technique. In a very high performance or capacity of storage (memory and disk) situation, the disk access cost literal affects to the performance of bitmap indexes partition techniques and may be equal to 0. Thus, our cost has only the candidate check cost and we can partition bitmap indexes in a highly number of intervals to reduce the candidate check cost. However, in general situation the partitioning bitmap index is important. We need to trade off between the candidate check cost and disk access cost. If the number of intervals increases, the candidate check cost will be decreased, but the disk access cost also increased, too.

For future work, we aim to improve the cost model for two bitmap index partition techniques by adding other dynamic factors in multi-database system environment such as CPU load, local CPU speed, etc. which affect the performance of retrieval data record. Then, our experiments will work with the real data set and queries.

Towards Evolvable Safety Arguments

Paul Mason & Chadchai Mattayom
Shinawatra University, Shinawatra Tower III, Viphavadi Road, Bangkok, Thailand

***Abstract*-Most safety critical systems must be certified before entering service. This normally involves submission to the industry regulator of a safety case (a reasoned argument and supporting evidence) that the system is acceptably safe to operate.**

The 'traditional' safety case is presented as a linear document. However, the level of detail often obscures the arguments presented so graphical notations have been developed to improve scrutability. Effective as these are, they lack means of representing evolution (i.e., changes) to an argument. This paper therefore extends one such notation to better manage safety case evolution.

I. INTRODUCTION

Safety critical systems must normally be certified before entering service. Typically, this involves submission to the appropriate regulatory body (e.g., the Civil Aviation Authority) of a safety case, a reasoned argument with supporting evidence that the system is acceptably safe to operate.

'Traditional' safety cases are presented as a linear document. They can run to several volumes (with hundreds of cross-references) so making sense of a body of arguments and evidence on this scale can be extremely difficult. Graphical notations have therefore been developed to improve their structure and scrutability. Examples include ASCAD (Adelard Safety Case Development) [1], and GSN (Goal Structuring Notation) [2].

While popular, such techniques lack means of representing changes to an argument. For example, an in-service 'safety incident' may invalidate the evidence on which an argument was originally based. Moreover, commercial forces dictate that the systems themselves must evolve. Put simply, the cost of incorporating multiple redundancies and in-built diagnostics that help critical systems meet stringent safety and reliability requirements mean developers strive to extend their 'shelf-life' through periodic revisions incorporating appropriate technological advances. Hence, just as the systems themselves change, so must their safety cases.

This paper introduces an approach (with tool support) which extends GSN (arguably the best known graphical safety argument notation) to better manage revisions to safety cases.

The rest of the paper is organized as follows. Section two provides an overview of Goal Structure Notation, as well as configuration management models with potential for managing their evolution. Section three introduces modifications to GSN based on these models to enable versioning of safety cases which is illustrated in Section four. Section five offers some conclusions.

II. FOUNDATIONS

This section introduces the foundations for our work, and sets out the contribution of the paper. Two aspects are considered, means of structuring safety cases, and means of managing their evolution.

A. Structuring Safety Cases Using GSN

The 'spine' of a goal structure has three core elements: i) *goals* (denoted as rectangles), constraints on the target system or its development process (note goals can be decomposed into sub-goals); ii) *strategies* (denoted as parallelograms) - courses of action for achieving a goal; and iii) *solutions* (denoted as circles) - pieces of analysis or evidence.

Additional elements can be added to provide *context*, e.g., operational conditions (denoted as rounded corner rectangles); and strategies often need some *justification* or are based on some *assumption* (denoted as ellipses) – see Figure 1.

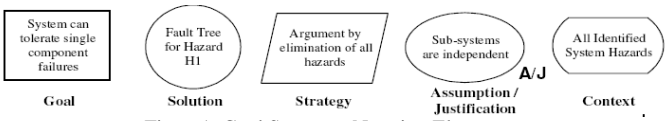

Figure1. Goal Structure Notation Elements

B. Managing Safety Case Evolution

This aspect of our work draws on software configuration management (SCM) theory, the discipline of managing the evolution of complex software systems. SCM helps developers perform coordinated changes to software by accurately recording the composition of versioned software products, thus enabling their evolution as revisions and variants, while maintaining consistency between interdependent components [3].

We can adapt this perspective to the safety case domain as performing coordinated changes to safety cases (reflecting changes to the systems they describe), by accurately recording the composition of versioned safety cases, thus enabling their evolution as *revisions* (intended to supersede their predecessor and the focus of this paper) and *variants* (intended to coexist), while maintaining consistency between interdependent components.

SCM theory distinguishes between *product* space and *version* space. These represent descriptions of a system (or in our case GSN elements of a safety argument) and the organisation of versions of these descriptions respectively.

Different revisions/variants of a safety case can be produced by combining different elements (either individual entities or larger fragments of a goal structure) and different versions of these elements into what is termed a *configuration*. The degree

of flexibility permitted in producing such combinations depends on the version model being used. Conradi & Westfechtel [4] distinguish three such models:

- ***Product First*** - the product structure is selected first, followed by the versions of each module (such that each configuration has the same structure);
- ***Version First*** - the product version is selected first which uniquely determines module versions (allowing different versions to be structured differently, though in the event of change, new versions are created for all 'parents' of the affected module - this is known as version proliferation); and
- ***Intertwined model*** - components and versions are selected in alternating order, preventing version proliferation (Figure 2).

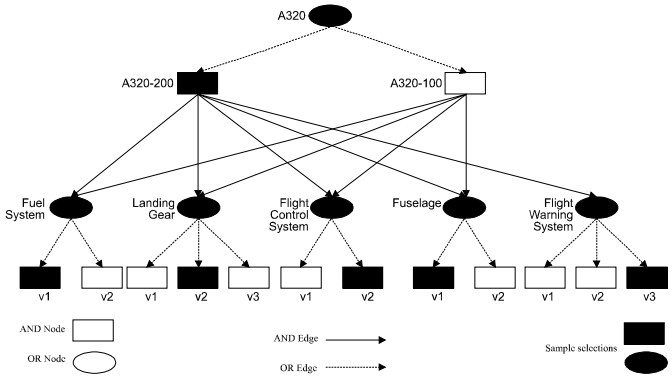

Figure 2. Intertwined Configuration Model

Note [5] address change management in the context of GSN. However, while presenting a systematic process for examining the impact of change (termed *challenges*) to the validity of a safety argument (termed the *damage phase*), they do not discuss means of structuring revisions (or variants) that may occur as a result (termed the *recovery phase*). The contribution of this paper is therefore to provide version management of safety arguments represented in GSN using an Intertwined model.

III. VERSIONING SAFETY CASES IN GSN

This section addresses structuring of versions using *AND/OR* graphs, together with use of GSN to express, analyse and manage change in safety cases.

A. AND/OR Graphs

Figure 2 showed how AND/OR graphs using an *Intertwined* model can capture the interplay between product and version space without the structural restriction and version proliferation problem of the *Product First* and *Version First* models respectively.

Recall AND/OR graphs contain two types of nodes and two types of edges. OR nodes (represented as ellipses) depict version clusters, while AND nodes (represented as rectangles) correspond to actual versions (in this case goals, strategies, solutions and other GSN elements); shading denotes selection. AND edges meanwhile show composition, whereas OR edges describe either a *revision* (successor relationship) or *variant* (coexistence relationship) between two goal structure fragments.

Finally, because Goal Structure Notation itself uses rectangles (denoting goals) ellipses (denoting assumptions/justifications), some 'syntactic sugar' is necessary when integrating the two conventions. GSN symbols are therefore depicted 'inside' AND nodes as illustrated for the core elements in Figure 3.

Figure 3. Intertwined GSN: Core Elements

B. Managing Change Using Intertwined GSN

Challenges to a safety case may come from various sources. For example, operational use may challenge *evidence* (e.g., hazard analysis) on which the original safety argument was based. Additional certification *requirements* must also be considered. For example, a safety case argued partly on the basis of having satisfied the evaluation criteria of an international standard such as IEC615803 [6] would be challenged if these criteria were changed in any way. Moreover, any changes in *context* need to be addressed, such as the emergence of new hazards.

Kelly & McDermid [5] use a cross (x) to indicate a challenge to a GSN element; we preserve this formalism. However, as the purpose of this work is to maintain different versions of a safety argument, semantics of the cross here are that the affected elements are pending investigation. Thus, when the argument is recovered – either by introducing new elements, or where no action is deemed necessary as the argument still holds – then the cross is removed. Note the rationale underlying both actions is captured using the UML Note symbol (a 'dog-eared' rectangle). Again, this enhances the audit-trail for engineers revisiting the safety case in future.

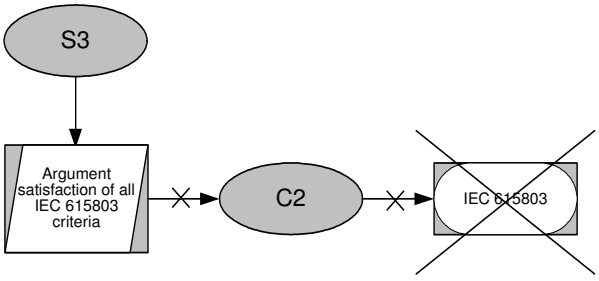

Figure 4. Requirements Challenge Example

Figure 4 illustrates a context challenge where safety is being argued on the basis that all criteria for systems developed according to the afore-mentioned IEC 615803 standard have been addressed. Hence, the set of criteria defined by this standard provide context to a strategy. If however the requirements change, the current argument may be invalidated.

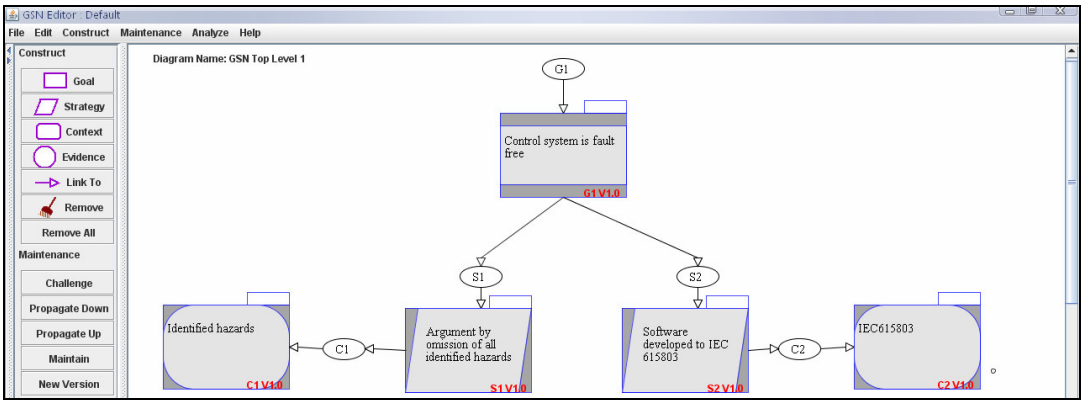

Figure 5. Top Level Goal Structure for Control System (developed using iGSN Tool)

Having identified an immediate challenge to a safety argument, engineers can use the goal structure to determine the extent of the 'damage', i.e. which other elements are affected. As a rule, [5] note that changing a core item (goal, strategy or solution) challenges items higher up (parents) and items lower down children) the goal structure, as well as context items (to the left and right). However, changes in context, justifications and assumptions challenge not only the core items that introduce them, but all child goals strategies and solutions.

After establishing the full extent of damage, engineers can determine what action is necessary to recover the safety argument. This is where an intertwined goal structure can be used to manage their evolution, providing full audit trail history. We demonstrate this in the following section.

IV. INTERTWINED GSN WORKED EXAMPLE

We now consider a simplified safety argument for a control system (C/S) where the top level goal is to show the system is fault free (Figure 5).

Strategies demonstrating that the top level goal has been met are to argue that all identified hazards have been addressed (in the context of all known hazards) and that the system has been developed to meet all IEC 615803 evaluation criteria (the standard itself providing context)[1].

The strategy of addressing all known hazards is realized by demonstrating that unintended opening of the press after Point of No Return, and unintended closing of the press can only occur due to component failure. These goals are satisfied by appeal to fault tree analysis and results of hazard directed testing.

The strategy of demonstrating IEC 615803 compliance is realized by demonstrating that the formal specification has been validated and that all software safety functions perform correctly. These goals are again satisfied by direct evidence (the VDM and architecture specification and dynamic analysis results respectively).

Given this initial safety case, we now consider a brace of challenges to its arguments and the process of recovering them, i.e. versioning of the safety case. The first challenge is to a solution to the goal that unintended closing of the press can only occur as a result of component failure, which may be invalidated by operational use. Recall challenges to core GSN elements propagate up the goal structure, here invalidating the top level claim (Figure 6).

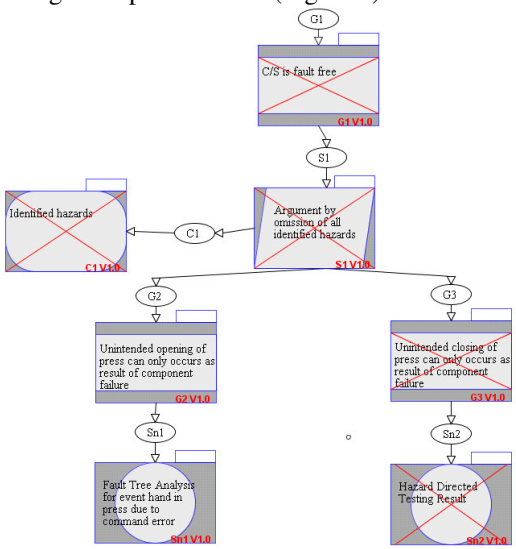

Figure 6. Hazards Challenge (Damaged Argument)

In this case, recovery of the damaged argument is relatively straightforward, requiring only that further hazard directed testing is undertaken and the results included as a solution (Figure 7).

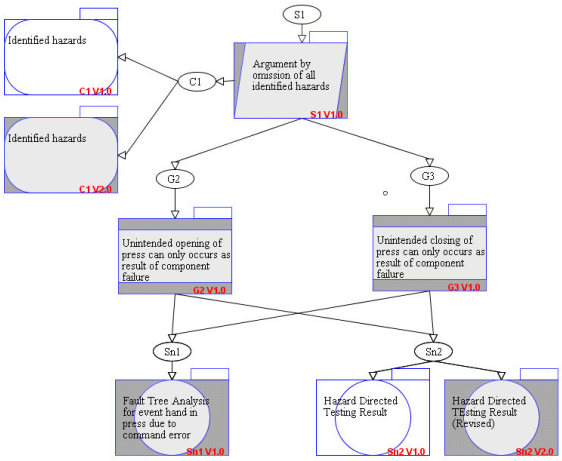

Figure 7. Hazards (Recovered Argument)

[1] Decomposition of the two strategies our safety argument is based on shows their damaged and recovered forms only (Figures 6-9).

In the second challenge we assume the context to our strategy of demonstrating IEC 615803 compliance is challenged by revisions to the standard itself. Recall that challenges to context propagate to all children of the core goal structure element to which the context is attached (see Figure 8).

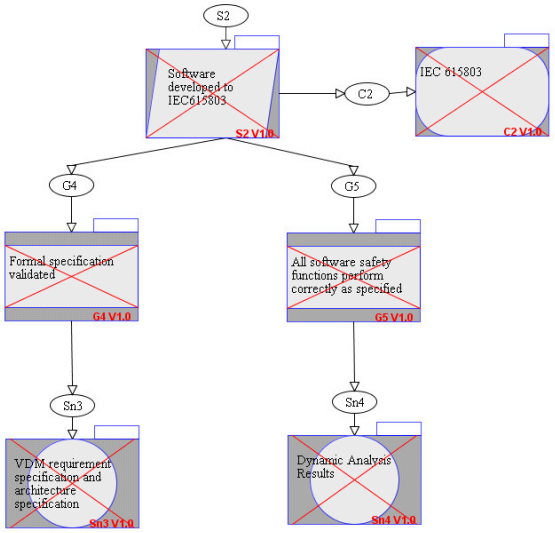

Figure 8. IEC 615803 Challenge (Damaged Argument)

Having assessed the challenge and identified the damage to the existing argument, engineers can begin steps towards its recovery. That may involve inserting new evaluation criteria (as additional goals), and evidence of their satisfaction (solutions), as well as revisions to existing criteria. See Figure 9.

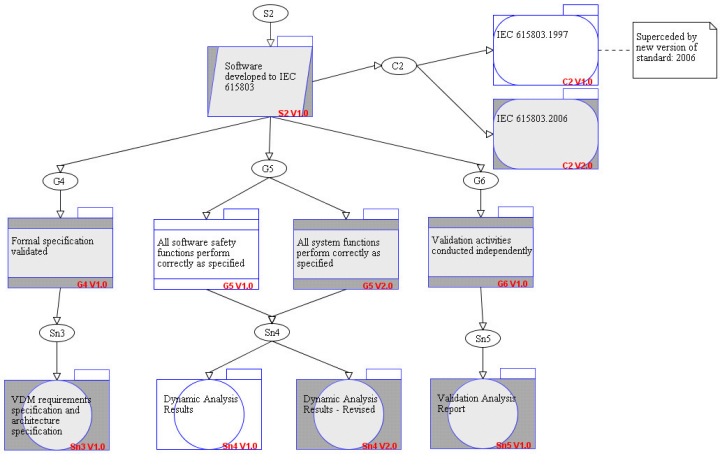

Figure 9. IEC 615803 (Recovered Argument)

Notice the UML Note convention on the original context element recording the reason IEC 615803 is no longer valid. In practice rationale would be attached to all obsolete goal structure items.

Of course arguments in this form don't show the constituent items making up each safety case version. This is accomplished by projecting the relevant nodes (N) and edges (E)[2] from the goal structure. For example, for the (partial) safety arguments in Figures 6 and 7, we can determine the following (partial) safety case revisions:

SC.$_{v1}$ = N1 + E1 where:
N1 = {G1.$_{v1}$, S1.$_{v1}$, C1.$_{v1}$, G2.$_{v1}$, G3.$_{v1}$, Sn1.$_{v1}$, Sn2.$_{v1}$} and
E1 = {<G1.$_{v1}$, S1.$_{v1}$>, <S1.$_{v1}$, C1.$_{v1}$>, <S1.$_{v1}$, G2.$_{v1}$>, <S1.$_{v1}$, G3.$_{v1}$>, <G2.$_{v1}$, Sn1.$_{v1}$>, <G3.$_{v1}$, Sn2.$_{v1}$>, <G2.$_{v1}$, Sn2.$_{v1}$>, <G3.$_{v1}$, Sn1.$_{v1}$>}

SC.$_{v2}$ = N2 + E2 where:
N2 = {G1.$_{v1}$, S1.$_{v1}$, C1.$_{v2}$, G2.$_{v1}$, G3.$_{v1}$, Sn1.$_{v1}$, Sn2.$_{v2}$} and
E2 = {<G1.$_{v1}$, S1.$_{v1}$>, <S1.$_{v1}$, C1.$_{v2}$>, <S1.$_{v1}$, G2.$_{v1}$>, <S1.$_{v1}$, G3.$_{v1}$>, <G2.$_{v1}$, Sn1.$_{v1}$>, <G3.$_{v1}$, Sn2.$_{v2}$>, <G2.$_{v1}$, Sn2.$_{v}2$>, <G3.$_{v1}$, Sn1.$_{v1}$>}

We could then find the symmetric difference (properties specific to SC.$_{V1}$ and SC.$_{V2}$) between the two arguments to determine how they have changed.

V. INTERTWINED GSN WORKED EXAMPLE

Traditional' means of presenting safety cases as a linear document are inadequate as the level of detail often obscures the arguments presented. Graphical techniques such as Goal Structure Notation have therefore been developed to improve their structure and scrutability. However, GSN currently lacks the ability to record versions of safety arguments. This is especially important as industries like aerospace and defence offset huge development costs through revisions and variants of their systems.

What safety practitioners require therefore is an effective and efficient means for configuration management of safety cases; the actual level of effectiveness and efficiency depends on the underlying configuration model. An Intertwined approach has been shown to combine both qualities and was therefore the model adopted here.

This combination of GSN and Intertwined configuration model was shown to have great potential for configuration management of safety cases, especially when supported by a CASE tool. Further testing on larger case studies is currently being undertaken to determine scalability.

Extending Cross-Tool Traceability to Source Code

P. A. J. Mason
Shinawatra University, Shinawatra Tower III, Viphavadi Road, Bangkok, Thailand

***Abstract*- Traceability is the term describing means to record and navigate relationships between system development artifacts. While simple in theory, in practice the range of separate CASE tools engineers use to express these artifacts, and a lack of well defined approaches to their integration, mean traceability is difficult to achieve across the complete lifecycle, especially to source code documents. This paper describes a framework known as MAST (Meta-modeling Approach to System Traceability) which offers one possible solution to that problem.**

I. INTRODUCTION

Traceability is the term software engineers use to describe mechanisms for recording and navigating relationships between development artifacts, including requirements, design and source code. While establishing and maintaining these relationships imposes a sizable administrative overhead, the many benefits include helping verify a system meets its requirements, tracking the effects of changes and determining the rationale underpinning a design or implementation [1]. Moreover, traceability is recognized as essential for efficient project and quality management, as its significance to process improvement frameworks such as CMMI bears testament.

In theory, the ability to link artifacts (and parts of artifacts for finer grained traceability) is simple. What complicates matters is the fact that engineers use a range of (often poorly integrated) CASE tools to express and store these artifacts. This normally causes 'breaks' in the traceability chain, especially traceability to and from source code.

To counter the tool integration problem, some vendors have taken to producing integrated suites of tools, normally supporting a particular software development process. Examples include IBM's Rational software suite (tailored to the Rational Unified Process) which, while offering lifecycle traceability across artifacts expressed in UML, linking and navigating to notations expressed in other tools – including compilers - is far from straightforward. This is particularly significant for developers of dependable systems who must model properties such as real-time and failure behavior of a system, aspects not easily represented or beyond the scope of the UML. For example, engineers may wish to link results of a vulnerability analysis to all source code arrays in support of security claims that all potential sources of buffer overflow have been checked.

This paper describes the MAST framework (Model-based Approach to System Traceability) which provides 'seamless' traceability between heterogeneous CASE tools (potentially, any commercial or bespoke tools). We concentrate here on traceability of Java source code for reasons outlined above.

The rest of the paper is organized as follows. Section Two provides an overview of MAST, while Section Three introduces means of structuring Java source code (or more generally any language with a formal foundation) to enable traceability. This is demonstrated by example in Section Four. Section Five has some conclusions and pointers to future work.

II. MODEL-BASED APPROACH TO SYSTEM TRACEABILITY

The premise of this work is that poor integration prevents practitioners from tracing across disparate tools (Figure 1), with lack of traceability to source code a particular concern.

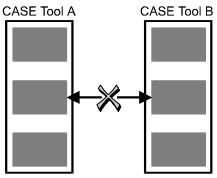

Figure1. Inter-Tool Traceability Problem

Our solution to this problem is a framework known as MAST which is realised by exporting information from the internal data structures of tools to a Workspace of notation dependent '*traceability structures*' (meta-models), represented here in UML (with constraints expressed in the Object-Constraint Language, OCL [2]). How information is structured has long been recognised as a core traceability issue [3]. By expressing the traceability structures in a common language, links (expressed in the same language as the structures) can be inserted that capture dependencies among data in CASE tools, within the Workspace.

To maintain consistency, the structures are verified against a system model – the Product Data Synthesis (PDS). PDS is similar to a data dictionary, capturing architectural and behavioral elements of the emerging system (and their inter-relationships), e.g., Module *hasInterface* Interface, Module *hasFunction*, etc. Where a 'clean' mapping of elements to the Workspace is not achieved, *tool2mast* creates an error-log. The likely cause is 'bad data' detected by PDS cross-checks. For more information on the PDS, readers are referred to [4].

The mechanics of mappings across the CASE tool/mast interface are described here by a function, *tool2mast* that takes as its input parameters, a populated CASE tool (internal) data structure (pCDS), with a corresponding un-populated notation dependent structure (uNDS) and the PDS, and returns a populated notation dependent structure (pNDS). This is expressed as follows:-

pNDS *tool2mast* (pCDS, uNDS, PDS)

The resulting Workspace provides an integrated environment

(Figure 2) allowing traceability between otherwise disjoint data, e.g. from a requirement in DOORS or low-level specification stated in RTN-SL (see Section 4), to a Java class declaration.

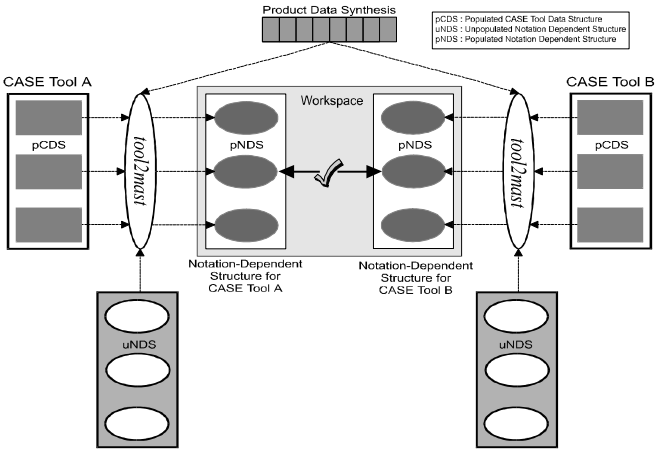

Figure2. Realising Inter-Tool Traceability

III. STRUCTURING JAVA CODE FOR TRACEABILITY

This section introduces a structure - capturing a subset of the concrete syntax for the Java programming language – based on a modeling philosophy developed previously in parallel with a SPARK Ada meta-model [5]. The philosophy (discussed in section 3*A*) provides a set of guidelines by which the structure may be extended to include the complete Java syntax, or indeed used to structure *any* other language with a formal foundation. Here we concentrate on representation of a single Java construct - the class_declaration.

Java class declarations include the following (in order):

- Modifiers such as public, private, protected, etc.
- The class name, with the initial letter capitalized.
- The name of the class's parent (superclass), if any, preceded by the keyword extends.
- A comma-separated list of interfaces implemented by the class, preceded by the keyword implements.
- The class body, surrounded by braces, {}.

The following illustrates use of class_declaration statements:-

```
public class MyClass extends MyPackage.MySuperClass
implements YourInterface {//field, constructor, and
    method declarations}
```

A. A Modeling Philosophy for Structuring String Grammars

Representation of the nominated construct takes as its starting point the concrete Java grammar stated in Backus Naur Form (BNF). In BNF, categories (i.e., entities) are defined in terms of other categories using productions consisting of the name being defined, followed by the ::= symbol and a defining sequence (which may include punctuation and reserved word 'tokens'); categories that cannot be further decomposed are known as terminals. Other symbols of note are **[ ]** square brackets enclosing optional items, **{ }** braces enclosing optional items that may appear zero to *n* times and the **|** vertical bar separating alternatives.

Our philosophy provides a series of principles allowing object-based representation of language constructs stated as BNF categories, and to do so at a level of abstraction which is sufficient to identify traceability primitives. The guidelines are deliberately general allowing their application to any language with a concrete BNF syntax (see section 5).

Further MAST modeling concepts referenced are StructureElement and SystemsEngineeringEntity [4]. The former ensures a common basis for all notation dependent structures, while the latter is a generalisation of all elements of notation dependent structures that simplifies definition. A further concept is ArtifactProperty which subsumes all built-in and abstract data types. With these considerations in minds, the guidelines are as follows:-

1. Each BNF category is represented as a class (both an instance of the StructureElement meta-class and a specialisation of SystemsEngineeringEntity).
2. Categories forming the defining sequence of a category are themselves represented as classes (related to the subject class through aggregation), except where rule 3 applies.
3. Where nothing is gained traceability-wise by mirroring definition of a category in terms of other categories (and hence the corresponding class in terms of other classes) - that is, no constituent categories can be represented by classes that map to PDS elements (nor trace to elements of other notations) - it is treated as atomic and represented through specialisation of the String type (as well as an instance of StructureElement and a specialisation of SystemsEngineeringEntity).
4. All tokens (i.e., reserved words - such as class, extends, final, etc. - together with punctuation marks - such as commas, semicolons, parentheses and ampersands) are represented as specialisations of the standard String class (and also as instances of ArtifactProperty).
5. Categories of a defining sequence that exist exactly once are modeled with a multiplicity of one (1) for aggregate component classes; attributes representing tokens have an implicit multiplicity of one.
6. Optional items from a defining sequence (expressed in BNF using square brackets) are modeled as follows:-

a) Categories are represented by applying a zero-or-one multiplicity constraint (0..1) on the component side of associations between the class representing the category being described (aggregate) and each class representing an optional defining category (component).

b) Tokens are promoted from attributes to classes (linked to their host using composition) to allow for expression of optionality.

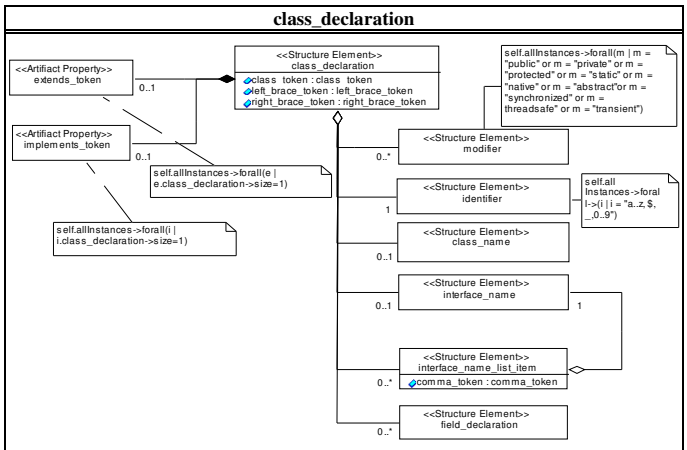
7. Categories of a defining sequence that may be omitted, appear once, or be repeated several times (expressed in BNF using the braces formalism) are modeled using a zero-to-many multiplicity constraint (0..*) on the component side of associations between the class representing the category being described (aggregate) and each class representing an optional, singular or repeated defining category (component).
8. Categories decomposed into alternatives (expressed in BNF using the vertical bar separator) are modeled differently depending on what form their defining sequence takes. See [5] for more information.
9. The modeling of a defining sequence in which an item type appears at least once, but which may be repeated (as a comma or semicolon delimited list) - i.e., category ::= item {, item} - features a subtle variation from the BNF syntax; we represent the mandatory single item as a class (corresponding to a 'list head')

and the optional repeated part (enclosed between braces in BNF) as a separate 'list-item' class containing an appropriate delimiter attribute, together with an aggregation association (multiplicity of one) to the afore-mentioned item class.

B. Java Class_Declaration: Meta-model Definitions

We now present a brace of schemas for a partial Java structure capturing the above class declaration statement. Each constituent element is systematically expressed in terms of its BNF syntax and corresponding UML representation. To give a flavor of tool support, the UML classes are implemented in O-Telos using ConceptBase [6]. We further highlight the influence of our modeling philosophy in deriving these structures. We begin by describing the class_declaration syntax which marks the origin for our modeling.

- **class_declaration** : consists of an optional modifier, followed by the class_token reserved word, then the class identifier; this can be followed by an optional parent class (identified by its class_name and preceded by the extends_token reserved word); an optional comma-separated list of interfaces implemented by the class may follow (each identified by their interface_name, and preceded by the implements_token reserved word). Note, the UML and O-Telos representations introduce an additional class (in accordance with rule 9) - interface_name_list_item - to represent optional interface_name elements following the single mandatory instance. Finally, the class declaration includes zero or more instances of a field_declaration enclosed within braces (see Figure 3).



BNF Syntax

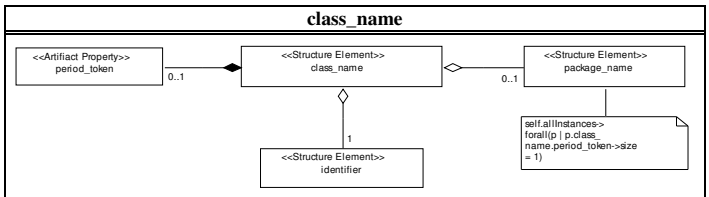
```
class_declaration ::=
    { modifier } "class" identifier
    [ "extends" class_name ]
    [ "implements" interface_name {
    "," interface_name } ]
    "{" { field_declaration } "}"
```

O-Telos

```
class_declaration in StructureElement,
SimpleClass isA
SystemsEngineeringEntity with
has_property
     class_token : class_token;
     left_brace_token :
left_brace_token; right_brace_token :
right_brace_token end
has_part
     modifier : modifier; identifier :
     identifier; class_name class_name;
     interface_name : interface_name;
interface_name_list_item :
interface_name_list_item;
field_declaration : field_declaration
end
```

Figure3. class_declaration schema

- **class_name** : comprises either an identifier, or package_name and identifier separated by a period_token (see Figure 4). Note interface_name is similarly defined.



BNF Syntax

```
class_name ::=
    identifier | package_name "." identifier
```

O-Telos

```
class_name in StructureElement,
SimpleClass isA
SystemsEngineeringEntity with
has_property
     period_token : period_token
has_part
identifier : identifier;
     package_name : package_name end

period_token in ArtifactProperty,
SimpleClass isA String with constraint
period_Is_period: $ forall p/
period token p = "." $ end
```

Figure 4. class_declaration schema

- **field_declaration** is defined in BNF in terms of a method_declaration, constructor_declaration or variable_ declaration; space limitations prevent inclusion of this schema.

C. Java Meta-model: Class Declaration Worked Example

The code fragment for **MyClass** introduced in section 3 will be used as the subject of this example.

Instantiation of class_declaration schema (Figure 3)

```
myClassDeclaration in class_declaration, Token with
modifier _modifier : "public"
class_token classToken : "class"
identifier _identifier : "MyClass"
extends_token extendsToken : "extends"
class_name className : mySuperClass
implements_token implementsToken : "implements"
interface_name interfaceName : yourInterface
left_brace_token leftBraceToken : "{"
field_declaration fieldDeclaration : myClassFieldDeclaration
right_brace_token rightBraceToken : "}"end
```

Instantiation of class_name/interface_name schema (Figure 4)

```
mySuperClass in class_name, Token with
package_name packageName : "MyPackage"
period_token periodToken : "."
identifier _identifier : "MySuperClass" end

yourInterface in interface_name, Token with
identifier _identifier : "YourInterface" end
```

This example, combined with the Java meta-model and modeling philosophy illustrates our approach to representing (in this case formal textual) notations as meta-models capable of receiving data from CASE tools via *tool2mast*.

IV. REALISING TRACEABILITY FROM REQUIREMENTS TO CODE

In MAST, traceability associations are modeled as classes (Figure 5). TraceabilityAssociation is an abstract class whose subtypes – such as ImplementedBy featured in this example - realize traceability between two SystemsEngineeringEntity subtypes (as described in section 3*A*).

ImplementedBy relations link specifications to their implementation. We now demonstrate this using the Java code fragment from section 3 and a partial specification expressed in the Real-Time Network Specification Language (RTN-SL) [7].

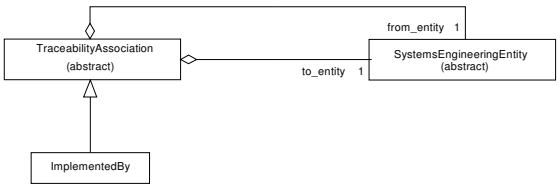


Figure 5. Traceability Association

RTN-SL is a language for defining both the functions - termed *activities* - and behavior of Real-Time systems. Activities are concurrent processes that exchange information and synchronize through shared data in their connections; they are represented in RTN-SL as circles, with behavior depicted as an abstract state machine inside each activity. Abstract data types (ADTs) - denoted as diamonds (with extension shown by dotted lines) - may be defined to support definition of a Real-Time Network. Figure 6 illustrates RTN-SL's graphical syntax, as well as traceability between the MyClass ADT and the Java code fragment (from section 3) that implements it.

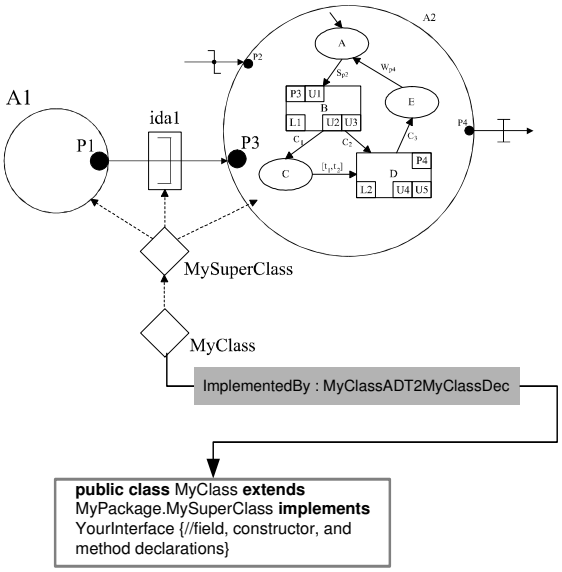

Figure 6. RTN-SL Fragment

Of course, to realize traceability between the two representations in the figure we require an RTN-SL meta-model instantiated with the network fragment shown (see Figure 7).

Finally, we populate an O-Telos instance of ImplementedBy (from Figure 5) to achieve traceability between the RTN-SL and Java fragments featured in this paper. Its source is the MyClass ADT (from Figure 6), and its target, the myClassDeclaration object from section 3*C*.

```
MyClassAdt2MyClassDec in ImplementedBy, Token with
from_entity fromEntity : MyClass
to_entity toEntity : myClassDeclaration end
```

V. CONCLUSIONS & FUTURE WORK

This paper proposed a framework called MAST to enable

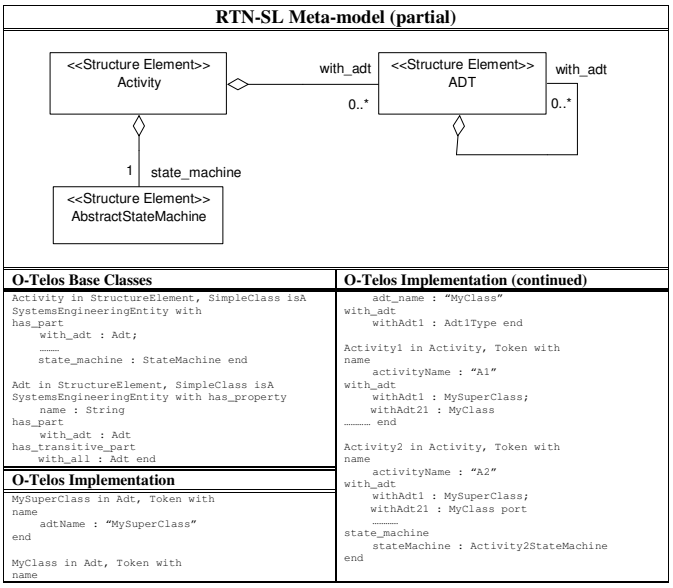

Figure 7. RTN-SL Fragment

traceability across disjoint CASE tools. MAST is achieved by exporting data from the internal models of these tools to structures (meta-models) expressed in a common modeling language. Traceability associations (expressed in the same language as the structures) may then be established between the models and their elements.

The paper concentrated on a meta-model for representing Java source code (based on the concrete BNF syntax). The structure was developed using guidelines for developing meta-models for BNF supported languages generally.

The novelty of work presented here lies in the following:-

- A framework (based on meta-modeling) enabling traceability between tools, across artifacts represented using different notations.
- A (partial) meta-model for the Java language, together with a generic modeling philosophy applicable to any BNF supported language.
- Means of creating associations among the meta-models, in this case demonstrated using the RTN-SL.

We are currently experimenting with applying the concepts discussed here to other languages with a formal grammar, including VDM and C++, which in turn will test the robustness of the modeling philosophy.

***Abstract*– This paper presents a cellular wireless backhaul network design using a genetic algorithm to minimize the cost of the design process including the cost of network equipment and their installation. The problem is to find a minimum-cost network topology which includes selecting the location and type of base station controllers and mobile switching controllers as well as their link types. In this research, a genetic algorithm (GA) is used as a meta-heuristic technique for obtaining good solution for the design problem. Various sizes of network design problem are considered and discussed. The GA results are evaluated with those from a brute force search algorithm, showing that our approach gives optimal or near optimal solutions for small-size problems and can solve large-size problems within a reasonable computational time.**

***Keywords:* Cellular Network Design, Optimization Technique, Genetic Algorithm**

I. INTRODUCTION

Cellular wireless networks have become essential to mobile users that need communication services regardless of time, location, and mobility pattern. A typical architecture of a cellular wireless network is illustrated in Figure 1. A base transceiver station (BTS) serves as a fixed access point for all mobile terminals within its coverage area. The network includes base station controllers (BSC), which manage a group of base stations and perform radio level channel management and call handoff. The BTS and BSC are connected to backbone networks via mobile switching centers (MSC). The MSC is then connected to the public switched telephone network (PSTN) or other transmission networks. The network is generally organized into a tree-like structure. Each BTS is connected to a BSC and the BSC is then connected to a MSC.

The network service providers have to dedicate a substantial amount of their resources to do the network planning, install, and maintain the network equipments, such as BTS, BSC and MSC, network link and link interface. Thus cost effective network design becomes a necessity.

In this paper, we propose a design of cellular wireless network with a heuristic approach called Genetic Algorithm. We consider a proposed network design model [1] which finds the network topology, the location of the BSCs and MSCs, the type of BSCs and MSCs, and the type of links. We consider tree network topology. The design objective is to minimize the cost of the design, network equipments and their installation.

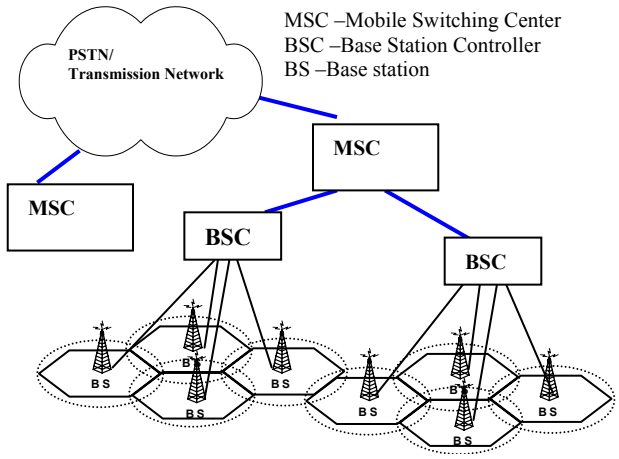

Figure 1. Typical wireless network architecture.

Previously, the model was proposed as a constraint programming model for cellular network design and solved with a local search heuristic called Constraint Programming Local Search (CPLS) [1]. Many research papers presented network design models and techniques to solve the network design problem. In 1993, an early research group [2] proposed an enumerative and branch&bound algorithm for reliable network design considering tree, ring, and chordal ring topologies. Later, Kumar et al [3, 4] proposed a genetic algorithm to solve distributed system topology design problems and optimize reliability for computer network expansion. We also use a genetic algorithm to optimize communication network design by finding network component allocation and network topology with cost constraint in our previous work [5]. Genetic Algorithm (GA) is usually used to solve many difficult engineering problems, and it is particularly effective for the combinatorial optimization problems. GA can also be used to solve optimization problems when the problem space is huge and trying all possibilities is not an option. An example of problem solving with GA is the component redundancy allocation in series- parallel systems [6].

The remainder of this paper is organized as follows. In the next section, we describe the cellular wireless network design problem and the network design model based on the constraint

programming model proposed in [1]. Section III gives a genetic algorithm concept and presents our parameter settings used for obtaining good solutions in the cellular wireless network design problem. Section IV presents our numerical results and analysis. Lastly, section V concludes our research work and contribution.

II. NETWORK DESIGN PROBLEM AND MODEL

We consider a cellular wireless backhaul network design problem to determine the network topology including the location of the BSCs and MSCs, the type of BSCs and MSCs, and the type of links. The network design problem can be formulated as an optimization-based model. In this paper, we adopt the constraint programming model from Reference [1]. The network design objective is to minimize the total network cost as shown in Equation 1 consisting of the cost of the links and interface cards and the cost of the BSCs and MSCs which include the installation cost.

Objective:

$$\min_{v,w,x,y,z} C_L(v,w,z)+C_N(x,y) \tag{1}$$

where C_L is the cost of the link and interface cards, and C_N is the cost of the allocated BSCs and MSCs. Their descriptions are represented as following

$$C_L(v,w,z)=\sum_{i\in I} a_{iv_i}+\sum_{j\in J}\sum_{i\in L} b^l_{jw_j} z^l_j \tag{2}$$

$$C_N(x,y)=\sum_{j\in J} c^{x_j}_j+\sum_{k\in K} d^{y_k}_k \tag{3}$$

where I is the set of BTSs, J is the set of BSCs, and K is the set of MSCs. The cost parameters consist of a_{ij}, b^l_{jk}, c^s_j and d^t_k where a_{ij} is the link and interface card costs including the installation cost for connecting BTS $i\in I$ to a BSC at site $j\in J$, b^l_{jk} is the link and interface card costs including installation cost for connecting a BSC at site $j\in J$ to an MSC at site $k\in K$ through a link and interface type $l\in L$, c^s_j is the cost of a BSC of type $s\in S$ and installed at site $j\in J$ and lastly is the cost of an MSC of type $t\in T$ and installed at site $k\in K$.

The decisions variables v, w, x, y and z are defined as the following. v_i is the value of the BSC site assigned to the BTS $i\in I$. w_j is the value of the MSC site assigned to site $j\in J$. x_j is the value of the BSC type installed at site $j\in J$. y_k is the value of the MSC type installed at site $k\in K$. z^l_j is the number of links of type $l\in L$ installed from the BSC site $j\in J$ to a MSC.

This network design problem has the following constraints.

*1) **BSC Capacity Constraints***: the number of BTS interfaces that can be installed at a BSC of type x can not exceed the maximum number of interfaces that the BSC can obtain. In addition, the capacity (in circuit) of all BTSs connecting to the BSC must not exceed the capacity that the BSC can obtain.

*2) **MSC Capacity Constraints***: the number of BSC interfaces that can be installed at a MSC of type x can not exceed the maximum interface cards that the MSC can obtain. In addition, the capacity (in circuit) of all BSCs connecting to the MSC must not exceed the capacity that the MSC can obtain.

*3) **Link Capacity Constraints***: the type of each BTS-BSC interface must support the capacity requirement from the connecting BTS, and the type of each BSC-MSC interface must support the capacity requirement from the connecting BSC.

*4) **BTS Type***: the type of each BTS is chosen so that the BTS can support all the traffic (in erlang) from the BTS to a BSC. The traffic (in erlang) from BTS_i to a selected BSC is

$$t_i=\sum_{i'\in I}\left(g_{ii'}+g_{i'i}\right)+\left(g_{ip}+g_{pi}\right) \quad ,i\in I \tag{4}$$

where $g_{ii'}$ is the average number of communications per hour from BTS_i to $BTS_{i'}$, g_{ip} is the average number of communications per hour from BTS_i to the public network, and g_{pi} is the average number of communications per hour from the public network to the BTS_i.

*5) **BSC Type***: the type of each selected BSC is chosen so that the BSC can support all the traffic (in erlang) from all BTS pairs (i and i') that communicate via the BSC and another BSC, and the traffic from its own BTSs and the public network (via a MSC) defined as follows.

$$t_j=\sum_{i\in I}\left[\left(v_i=j\right)\sum_{i'\in I}\left(v_{i'}\neq j\right)\left(g_{ii'}+g_{i'i}\right)\right]+\sum_{i\in I}\left(v_i=j\right)\left(g_{ip}+g_{pi}\right) \quad ;(j\in J) \tag{5}$$

where v_i is a decision variable, which is equal to 1 if BTS_i is connecting to the BSC (i.e. $(v_i=j)=1$). Otherwise it is zero. $v_{i'}$ is equal to 1 if the $BTS_{i'}$ is connecting to a different BSC (i.e. $(v_{i'}\neq j)=1$).

*6) **MSC Type***: the type of each selected MSC is chosen so that the MSC can support all the capacity (in circuit) from all the connecting BSCs and can handle all the interfaces (not exceeding the limit) as discussed in constraint (2).

III. GENETIC ALGORITHM APPROACH

Genetic Algorithm (GA) is a stochastic optimization technique that uses the biological paradigm of evolution. It has a concept where good chromosome has a better potential of being carried to the next generation than the bad chromosome.

It uses mathematical principle to indicate which chromosome is better or worse than the others.

Firstly, to use GA we must encode the solution of problem into string called "chromosome" and each string has its unique characteristic inherited by "gene". Each chromosome is evaluated by a fitness function to indicate its potentiality toward the final solutions. The desirable fitness function value is depended on the problem (maximization/minimization).

After that we must generate an initial population (a set of chromosomes), and use the three main operators to find the best solution, as described next.

Step 1: Selection operator: The process of selecting potentially good chromosomes from the current population generation to the next generation.

Step 2: Crossover operator: The process of shuffling any two randomly selected chromosomes to generate the new offspring (like breeding).

Step 3: Mutation operator: The process that randomly selects one chromosome to change one or more genes into random value for generating the new offspring.

Step 4: Repeat these 3 steps until the goal is reached.

A. Encoding

The string encoding is a set of integers that indicates the relation of the BTS, BSC, and MSC. Suppose in the network design problem, we have 8 BTSs, 4 possible BSCs, and 2 possible MSCs. The corresponding string encoding is displayed in Figure 2. The first 8 integer positions, each with position i ($i \in I$) having the value a_i represents the connection from BTS_i to BSC_{ai}. The next 4 integer positions each represents the MSC identifier number, b_j, which the BSC is connected to. The value $b_j = -1$ if the BSC is not selected for the network design problem.

Let x be the number of BTS, y be the number of BSC, z be the number of MSC. We can encode the string as shown in equation (6).

$$a_0 a_1 \cdots a_{I-1}\ b_0 b_1 \cdots b_{J-1} \tag{6}$$

where
$I = \{0, 1, 2, \ldots, I\text{-}1\}$
$J = \{0, 1, 2, \ldots., J\text{-}1\}$
$K = \{0, 1, 2, \ldots., K\text{-}1\}$
$i \in I, \quad j \in J;$
$a_i \in J;$
$b_j \in K$ or $\{-1\};$

1	1	1	1	3	3	3	4	1	-1	1	1

Figure 2. An example of string encoding.

B. Initial Population

We set the initial population by randomly generating a set of chromosomes consisting of genes with uniform random number, and calculate their fitness value according to the fitness function presented in section 3A.

C. Selection

The chromosomes or population are sorted by their fitness values. The top 10 % of population with best fitness values (low total cost) are preserved to the next generation, 80 % of population are selected for the crossover process, and the remaining 10 % of population are new chromosomes which are randomly generated.

D. Crossover

We select a pair of chromosomes from the current population for a crossover, to produce two new offspring chromosomes. One parent chromosome comes from the top 10% and another parent chromosome can be any chromosome. In each crossover, 10% of the genes are exchanged between the two parent chromosomes. The exchanged genes are randomly selected.

Example : 1 1 1 1 3 3 3 4 | 1 -1 1 1 Parents1
2 2 3 1 2 2 1 3 | 1 0 0 1 Parents2

10 % of the genes in each chromosome are 1.2. We ceil to 2.

Randomly finding 2 genes to exchange between the parents, we obtain a pair of offsprings.

For example, suppose the crossover point is at gene positions 3 and 5, the results are

1 1 **3** 1 **2** 3 3 4 | 1 -1 1 1 Offspring1
2 2 **1** 1 **3** 2 1 3 | 1 0 0 1 Offspring2

The next population generation consists of the best 10 % of the current population generation with the minimum cost values, 80 % from the crossover process, and the rest 10 % comes from randomly generated population (alien).

E. Mutation

The offsprings from the crossover process are mutated with 25% rate. Only 1-2 genes in a chromosome are mutated at a time. The resulted chromosomes are combined and considered as the chromosomes in the current population generation.

IV. COMPUTATION RESULTS

In our experiments, we consider the network design with 3 BTS types, 3 BSC types and 3 MSC types which are similar to the previous research paper [1]. Their descriptions are presented in Tables 1-3. Also we consider DS-1 links for the connection from the BTS layer to the BSC layer. DS-1 and DS-3 link types are considered for the connection from the BSC layer to the MSC layer. The interface costs and link costs are presented in Tables 4-6.

We generate various test problems with a number of BTS, BSC and MSC. Their locations are randomly generated with a uniform distribution in a square region of 100 kilometers. The type of each BTS is randomly selected. The demand between each pair of BTSs and between the BTSs and the public network was generated randomly in the interval [0,0.2] erlang with a uniform distribution. The call blocking rate is 2%.

Our GA approach is implemented in JAVA and runs on a Pentium 4 PC (1.73 GHz and 512MB of RAM). For each

problem size, three random network sites and communication demands (between 0-0.2 Erlang) are investigated. Each result is an average from the 3 networks, each with 10 simulation runs.

Table 1. Feature of the BTS types

	Type A	Type B	Type C
Capacity (circuits)	96	288	576
Number of BTS DS-1 interfaces	1	3	6

Table 2. Costs of the BSC types (including the installation costs)

	Type A	Type B	Type C
Switch fabric capacity (circuits)	5,000	10,000	15,000
Maximum number of BTS interfaces	15	30	60
Maximum number of MSC interfaces	15	30	60
Cost ($)	50,000	90,000	120,000

Table 3 Costs of the BSC types (including the installation costs)

	Type A	Type B	Type C
Switch fabric capacity (circuits)	100,000	200,000	300,000
Maximum number of BSC interfaces	50	100	150
Cost ($)	200,000	350,000	500,000

Table 4. Costs of the interface types (including the installation costs)

Interface type	Capacity (circuits)	Cost ($)
DS-1	96	500
DS-3	2,688	2,500

Table 5. Costs of the BTS-BSC links (including the installation costs)

BTS type	Number of the DS-1	Capacity (circuits)	Cost ($/km)
A	1	96	2,000
B	3	288	3,000
C	6	576	4,000

Table 6. Costs of the BSC-MSC links (including the installation costs)

Link type	Capacity (circuits)	Cost ($/km)
DS-1	96	2,000
DS-3	2,688	4,000

At first, we attempt in solving 5 small to moderate network problems with the GA and a Brute Force Search approach where the results are compared as presented in Table 7. The results show that the GA can give the optimal network costs as guarantee by the Brute Force Search approach. Moreover, the GA requires significantly less CPU time than the traditional approach.

Table 7 The result comparisons between Brute Force approach and Genetic Algorithm

Problem Size	Brute Force Search		Genetic Algorithm	
(bts_bsc_msc)	Cost	CPU Time (sec)	Cost	CPU Time (sec)
5_3_2	683,206.4	1.0	683,206.4	1.0
8_4_2	989,271.5	9.0	989,271.5	3.5
10_4_2	1,066,101.6	206.2	1,066,101.6	3.0
12_4_2	1,211,395.8	5,016.2	1,211,395.8	4.2
22_9_5	1,664,949.6	84,387.0	1,664,949.6	63.0

For larger network problem, we apply the GA and compare its results to those from the Constraint Programming Local Search (CPLS), proposed by Pomerleau et al. [1]. Since the network input data set is randomly generated, we cannot precisely compare the network costs but the simulation time. We use a comparable Pentium4 PC. In addition, the CPLS is a heuristic approach so that it cannot guarantee the optimal solutions. Therefore, we use a Brute Force Search approach to verify our GA results for small-size problems. From Table 8, we present average and best network costs and CPU time obtained from the GA. The results show that the GA approach outperforms the previous CPLS with a marginal simulation time difference.

Table 8 Number of generations, simulation time, and total network cost obtained from the Genetic Algorithm

Problem Size	Best Cost	Average Cost	GA CPU Time (sec)	CPLS CPU Time (sec)
50-20-10	2,730,402.9	2,904,218.7	207.1	1,794.0
100-20-10	5,164,524.4	5,619,468.7	1,766.0	3,875.0
100-20-20	5,111,400.3	5,464,075.7	2,116.4	4,050.0

V. CONCLUSION

From our experiments, Genetic Algorithm is effective in solving cellular wireless network design problem, as verified by a brute force search approach where all possible solutions are considered. The CPU time consumed by the GA is significantly less than those consumed by traditional searching algorithms or previous heuristic approaches such as a brute force search technique or a constraint programming approach.

Performance Analysis of IEEE 802.11g Access Point under Heavy-Loaded Condition

Roungsan Chaisricharoen and Thitiporn Pramoun
School of Information Technology, Mae Fah Luang University
333 Moo 1, Thasud
Muang, Chiang Rai 57100 Thailand

***Abstract*-The famous IEEE 802.11g wireless LAN (WLAN) provides services in contention manner utilizing the access point (AP). As the amount of clients increases, the performance of AP may be dropped due to collision avoiding. The vendor-specific maximum clients of an AP, based on an AP's capacity to keep record of the MAC address, are the upmost limit that should not blindly follow because there is no guarantee that an AP is able to service at the required quality. Therefore, full-factorial experiment is conducted under heavy-loaded conditions to examine and model the goodput of an AP based on the number of concurrent TCP streamed sessions and maximum transmission rate. The obtained regression model presents the high correlation with the experimental results based on the adjusted R^2 of 92.2%. Carefully utilizes this model, the practical limit of maximum clients that an AP can support can be systematically predicted.**

I. INTRODUCTION

Since its introduction, the IEEE 802.11g wireless LAN (WLAN) has grown rapidly to hold its place as fundamental infrastructures that organizations of any size should have. As an extension to IEEE 802.11b, IEEE 802.11g standard can support transmission rate in data link layer up to 54Mbps. This quite-high data rate attracts the consumers who prefer flexibility/mobility over transmission ability. In providing the WLAN access to clients, no matter what entire network configurations are; the access point (AP) must be utilized to serve clients as a wireless hub in the service area. It can be said that the AP is one of the most importance parts in providing WLAN because the WLAN services cannot be supplied without an AP.

Due to its roles, the quality of WLAN in a particular service area has significantly depended on the performance of the operated AP, which has been studied in many perspectives. Most of the literature concerns MAC throughput [1 – 5] and area coverage [2 – 4]. MAC throughput analyses are conducted in saturated [1, 5] and non-saturated conditions [2 – 4]. The saturation analyses are conducted in ideal operating conditions at maximum or specified signal strength while the non-saturation analyses count the quality of signal that is related to the service area as part of the throughput estimation. Though these analyses can provide framed design issues for WLAN installer, the analyzed data is based on one or few clients. As IEEE 802.11g provides contention service based on CSMA/CA, the performance of an AP may be reduced as the amount of clients increases. Usually, the number of supported clients identified by an AP is based on its capacity to keep record of the MAC address. Therefore, this specification only states the upmost limit of client's quantity without any transmissible guarantee. To install a useable WLAN practically, the amount of clients that is the practical limit, which reflects the actual ability in data transmission of an AP should be able to estimate based on the required minimum throughput. In addition, any install networks are suppose to carry the user data such as message, voice, video, etc., which resides in application layer and usually measured in byte. If the minimum required AP's throughput could be specified in byte/sec at the portal of application layer, it may be more preferable especially to non-specialist installers that are increasing rapidly as the price of WLAN products are reduced daily. In this literature, the model for predicting the goodput (the application level throughput) of an AP is presented based on the full-factorial experiment that simulates the heavy-loaded condition, which is the worst situation of an AP that all clients are connected at full possible data link capacity and simultaneously transfer TCP stream. The factors are the number of concurrent TCP sessions and the provided data link capacity of an AP. Because there is no such operating condition worse than this, an obtained model can be utilized to estimate the practical limit of the amount of clients related to the required goodput.

II. EXPERIMENTAL ENVIRONMENT

A. Network Configuration

All clients are paired while connecting to the only serviced AP at maximum transmission rate and signal strength. Each pair is composed of one server and client to establish one TCP session as illustrated in fig.1.

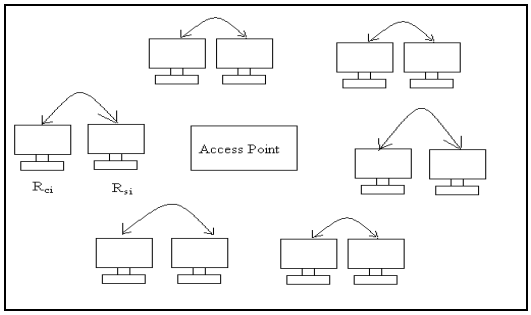

Figure 1. WLAN configuration of the experiment

The dedication of each pair to only one session is for avoiding the bottleneck situation that might happen if there is only one server. The server and client are both running the data-rate measurement program summarized in fig. 2.

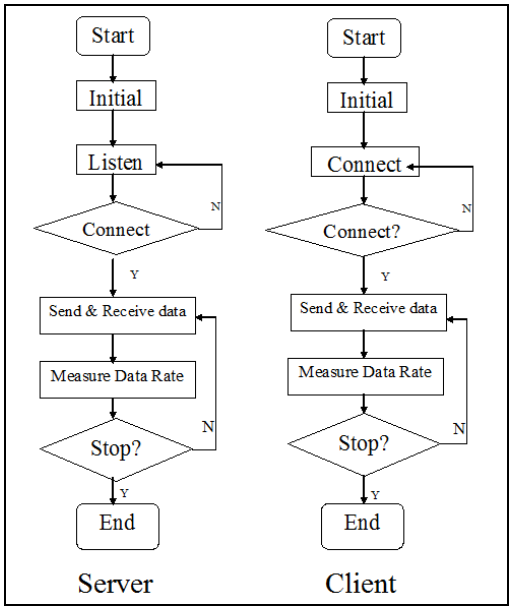

Figure 2. Flowchart of measured program

To simulate heavy-loaded condition, each side continuously transmits block of data immediately after received from a partner. In this fashion, only one pair of measured program can utilize 100% of AP's capacity. As both sides exchange data in half-duplex style and the measured data-rate on each side is the amount of receiving data divided by specified interval, the total data-rate of each pair is the summing of data-rate measured in server and client.

B. *The Access Point*

The AP in this experiment is the LINKSYS Wireless-G Access Point model WAP54G, which is configured with default value for MAC properties as illustrated in fig. 3 [6].

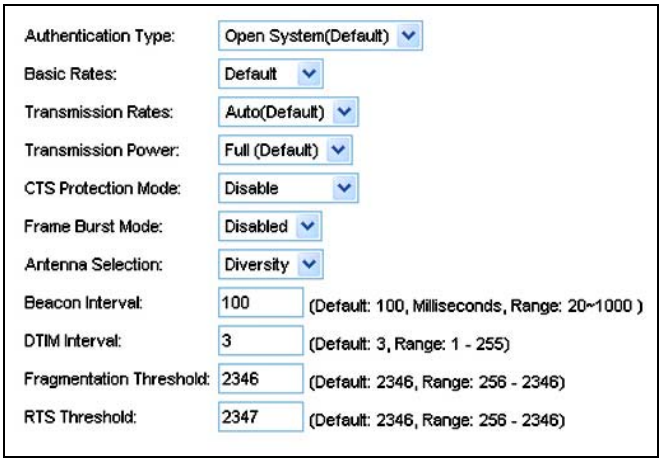

Figure 3. Advance wireless settings screen [6]

C. *The Clients*

All clients are PCs of similar configuration (P4 630, 256MB RAM, WinXP) equipped with LINKSYS Wireless-G PCI Adapter model WMP54G.

III. DESIGN OF EXPERIMENT

A. *The Factors*

The factors which we are interested in are the amount of concurrent TCP streams and the maximum transmission rate in M bit/sec at data link layer limited by the AP. To aid in presentation, the amount of streams will be designated by "S" symbol, and the transmission rate will be designated by "R" symbol.

B. *The Response*

To provide an exploitable model that can be easily interpreted by non-specialists, the response is the goodput of an AP in K byte/sec. Based on the experiment the response can be formulated as (1).

$$T_{S,R} = \sum_{i=1}^{S} (DRs_{i,R} + DRc_{i,R}) \qquad (1)$$

$T_{S,R}$ is the AP's goodput employing S stream sessions and R Mbps, $DRs_{i,R}$ and $DRc_{i,R}$ are the data rate measured at server and client of the i^{th} pair based on R Mbps.

C. *The Design*

To study the main effects and interaction between factors, the experiment is designed to be 2-factor full factorial experiment. The test is run on each combination of factors three times (three replicates).

S factor is designed to have six levels; R factor is designed to have three levels. This yields a 6×3 factorial design with the factor description in table I. With three replicates, there are 54 runs, which are assigned at random.

TABLE I
FACTORS DESCRIPTION

Factor	Level value
S	1 2 3 4 5 6
R (Mbps)	24 36 48

Though the maximum value of stream session is only six, it requires twelve PCs to produce. Incidentally, the transmission rates are specified in three values with the equal space of 12Mbps.

IV. RESULTS AND ANALYSIS

The raw results of the experiment are displayed in table II, which are checked for model adequacy at first sight for the normality and constant variance assumption.

TABLE II
EXPERIMENTAL RESULTS

TCP streamed sessions	Transmission Rate (Mbps)		
	24	36	48
1	1044	1206	1280
	1040	1204	1290
	1044	1205	1292

TCP streamed sessions	Transmission Rate (Mbps)		
	24	36	48
2	1073	1250	1310
	1085	1262	1247
	1078	1228	1288
3	1027	1258	1242
	1000	1216	1277
	1015	1183	1205
4	1006	1299	1231
	991	1132	1211
	985	1129	1246
5	1008	1218	1258
	972	1171	1268
	970	1171	1259
6	950	1111	1184
	984	1107	1220
	949	1121	1206

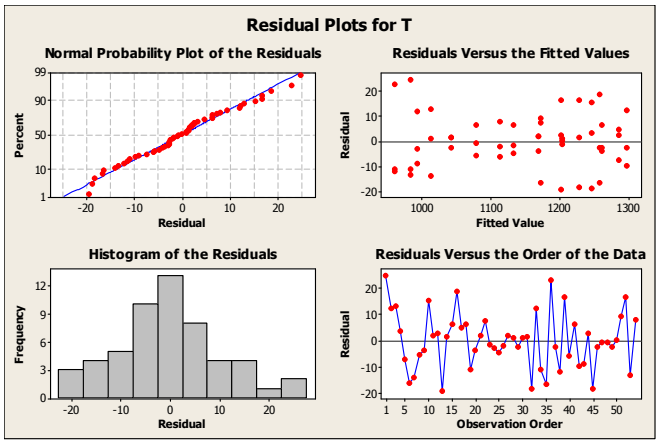

Figure 4. Residual Plots for normality checking

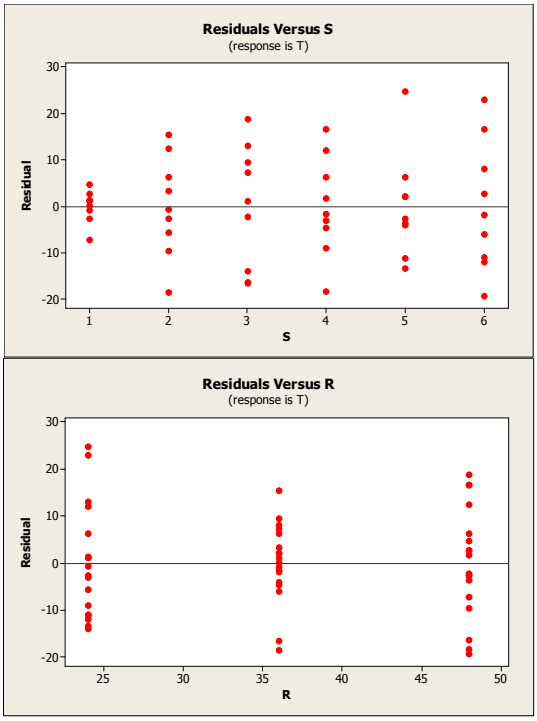

Figure 5. Residuals plot for constant variance checking

From these graphs, there is no severe indication of any problems with the validity of normality and constant-variance assumption.

To determine whether the factors affect the response or not, we use ANOVA tables with $\alpha = 0.05$.

TABLE III
ANOVA FOR THROUGHPUT, USING ADJUSTED SS FOR TESTS

Source	DF	Seq SS	Adj SS	Adj MS	F	P
R	2	554285	554285	277142	1693.33	0.000
S	5	76550	76550	15310	93.54	0.000
R*S	10	4414	4414	441	2.70	0.014
Error	36	5892	5892	164		
Total	53	641140				

From ANOVA, there are strong indications of significant effects of S and R on AP's goodput. In addition, the interaction between S and R is also significance. To intensely analyze these effects and interaction, main effects and interactions of the response are separately plotted.

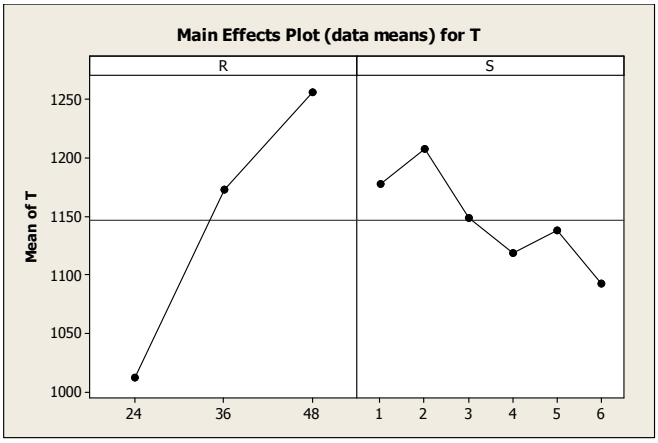

Figure 6. Main effects Plot

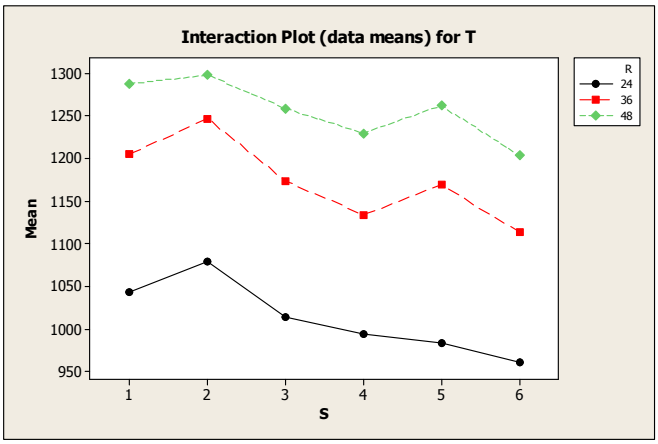

Figure 7. Interaction Plot

The main effect plots in fig.6 show the effect of each factor on the AP goodput. The interesting point is the effect of concurrent TCP stream sessions that significantly reduce the goodput of an AP. Based on fig. 7, the interaction of the transmission rate and sessions are not of serious concern because the goodput obtained at a higher transmission rate is

more than a lower one no matter how much concurrent TCP streamed sessions.

To obtain a model for predicting the goodput of an AP, the regression analysis is carried out and results in (2) with adjusted R^2 of 92.2%.

$$T(S,R) = 872 - 25.8S + 9.51R + 0.187SR \quad (2)$$

Substitute R of a configured AP in (2), results in one variable formula *T(S)*. To predict the number of clients based on the required AP's goodput, set an equation as in (3) and solve it to estimate the practical limit of maximum clients connected to particular APs.

$$T(S) = K \quad (3)$$

K denotes the minimum required goodput of an AP when carrying user data. For example; if the installer wants to guarantee that the installed AP can transfer user data at least 800k byte/sec based on the maximum data-link transmission rate of 54Mbps, (2) incorporated with (3) becomes:

$$800 = 1385.54 - 15.702s \quad (4)$$

As s = 37.2908, the amount of clients should not exceed 37 in order to guarantee the service of an AP under any situations.

However, being strict to the practical limit can cause an un-optimized installation because the worst situation as in an experiment is hardly to occur. Therefore, the maximum amount of supported clients can be dwelled reasonably between the practical limit and halfway to the upmost limit if the traffic is generally not too dense.

V. CONCLUSION

The conducted experiment shows strong evidences of the AP's goodput deterioration as the concurrent sessions are increasing. Based on the amount of clients and maximum transmission rate, the model is drafted for predicting the goodput of an AP. This model can be utilized to estimate the practical limit of maximum supported clients while vendors specify the upmost limit based on the AP's ability to keep track of MAC addresses. As the model is crafted based on worst-case simulation, any operating condition are guaranteed to function validly if the practical limit is not exceeded.

ACKNOWLEDGMENT

The authors would like to convey special thanks to Mr. Charles Lichtenberger JR. whom kindly reviewed this manuscript and provided precious comments on grammatical issues. We also like to express gratitude to the staffs of MFU's IT service center whom kindly provides technical information of AP's configurations and operations.

***Abstract*-A completely overlapping network (CON) is an extension of LANs with several overlapping communication lines. Given a graph $G = (V, E)$ where V is a set of vertices and E is a set of edges, and a set of vertices $V' \subseteq V$, we show that finding adjacent and non-adjacent nodes in V' on CON can be done optimally and has a significant speedup over the sequential machine.**

I. Introduction

Graph problems have many interesting applications. Applications vary, depending upon how one defines the relationship between nodes and edges of a particular graph. In this paper we discuss non-optimized and relaxed versions of two classical graph problems called *maximum clique* and *maximum independent set* problems [1]. Given a graph $G = (V, E)$ where V is a set of vertices and E is a set of edges, and a set of vertices $V' \subseteq V$, we want to find all adjacent nodes in V' and all non-adjacent nodes in V'. Sequential algorithms for these two graph problems have the running times of $O(|V'|^2)$ and this bound appears to be the lower bound for these problems. If the size $|V'|$ is proportional to $|V|$, the running times become $O(|V|^2)$. When the problem size is large, these algorithms will become impractical due to their high time complexities. Parallel computation will be useful in this case.

The concept of parallel computation has been around for decades. However, parallel architectures such as hypercube and mesh are generally expensive [2] and, hence, their use is limited to only those who can afford them. In this paper we use one alternative to these expensive parallel machines called a *completely overlapping network* or CON for short [3] to compute the solutions to our graph problems.

In the following sections we first give a review of CON. Secondly, the algorithm for finding adjacent nodes and its properties are given. Thirdly, the non-adjacent nodes finding algorithm and its properties are shown. Finally, we conclude with some comments and practical use of our algorithms on CON.

II. Completely Overlapping Network

A completely overlapping network is a generalized version of an overlapping network [4-6] and is composed of several overlapped communication lines that connect among several nodes (or processors) to provide parallelism. There are vertical communication lines and horizontal communication lines. These lines constitute a grid-like network for parallel communication as shown in Fig. 1 below.

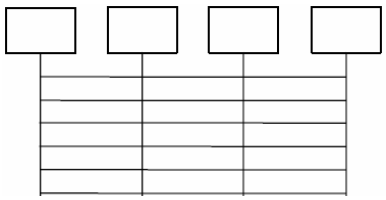

Figure 1. Four-node completely overlapping network

The number of vertical lines is equal to the number of nodes N and the number of horizontal lines is equal to $N(N-1)/2$. One straight line *segment* equates one step horizontally and vertically. (Note that a line in CON comprises several line segments.) For instance, Fig. 2 shows a communication of 9 steps between the leftmost node and the rightmost node.

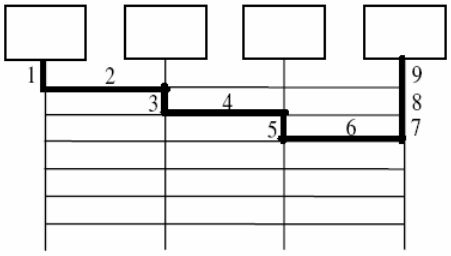

Figure 2. Nine-step communication between nodes

Like any other networks, there are rules of operations. These rules are reasonable and can certainly be implemented. The rules are as follows.

- Horizontal and vertical line segments cannot be shared. That is, any line segment can be used only one at a time.
- Each line segment is bidirectional.
- A same message can be concurrently sent from one node to several destination nodes as long as there is no collision of messages.
- If contention exists in a communication line segment, some kind of priority can be applied.

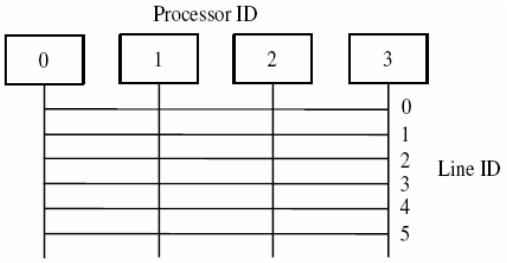

Figure 3. Numbering scheme for a four-node CON

In order to enable readers to understand our communication method, a numbering of both nodes and communication lines is necessary. Our numbering scheme is illustrated in Fig. 3. This figure shows a four-node CON with node and line identification numbers. It is easy to generalize this numbering scheme for a *N*-node CON. Hereafter, we will refer to this numbering scheme when explaining our algorithms.

III. ADJACENT NODES FINDING ALGORITHM ON CON

Given a graph $G = (V, E)$ where V is a set of vertices and E is a set of edges, and a set of vertices $V' \subseteq V$, we want to find all adjacent nodes in V' using CON. The algorithmic definition for such work is given below. Variables *dataset* and *knownPts* are V' and the set of all nodes adjacent to node *k* respectively.

It is assumed that $N > 2$ and each processor (or node) in the CON has its identification number stored in it initially. We also assume one process per processor and constant *myID* is its own process identification number. The subroutine **length**(*A*) returns the number of elements in the array *A*. There are two communication subroutines in the algorithm: **send**(*data*, *destination process*, *communication line number*) and **recv**(*data*, *source process*). These subroutines require identification numbers for both lines and nodes. Also note that **append**(*A*, *n*, *x*) is a subroutine that appends *n x*'s to the array *A*. The subroutine **pack**(*item1*, *item2*, …, *itemN*) is a subroutine that packs all stated items together as one larger item and the subroutine **unpack**(*packed items*, *item1*, *item2*, …, *itemN*) does just the opposite. It is also assumed that an amount of time spends on pack and unpack items is the same for any number of items. Subroutine **matching**(*senderID*, *adjacent nodes*) organizes the process identification number and their adjacent nodes into the form {{*senderID*, *Pts1*}, {*SenderID*, *Pts2*}, …, {*senderID*, *Ptsj*}}, where *Ptsi* is in the set of adjacent nodes and the size of this set is *j*.

INPUT: *dataset* and *knownPts*
OUTPUT: a set of adjacent nodes in V'
Adjacent Nodes Finding Algorithm for Process P_*k*
1 *mySize* = **length**(*knownPts*)
2 *maxSize* = *mySize*
3 **for** $i = 0$ to N-1 and $i \neq myID$
4 **send**(*mySize*, *P_i*, *myID*)
5 **for** $i = 0$ to $N - 1$ and $i \neq myID$
6 **recv**(*size*, *P_any*)
7 **if** *maxSize* < *size*
8 *maxSize* = *size*
9 *extralength* = *maxSize* – *mySize*
10 *newPts* = **append**(*knownPts*, *extraLength*, -1)
11 **if** *myID* ∈ *dataset*
12 *matchPts* = *newPts* ∩ *dataset*
13 *IDandPts* = **pack**(*myID*, *matchPts*)
14 **send**(*IDandPts*, *P_0*, *myID*)
15 *result* = ∅
16 **if** *myID* = 0
17 **while recv**(*IDandPts*, *P_any*) ≠ NULL
18 **unpack**(*IDandPts*, *senderID*, *Pts*)
19 *result* = *result* ∪ **matching**(*senderID*, *Pts*)
20 return *result*

One of the arguments in subroutine **send**() indicates the communication line to use. (There is no such argument in **recv**().) Fig. 4 shows how the lines are used in this algorithm in lines 3 and 5. Four different sources of communication are denoted by four different arrow patterns. There are a total of 11 communication steps. This communication scheme can be easily generalized for a *N*-node CON.

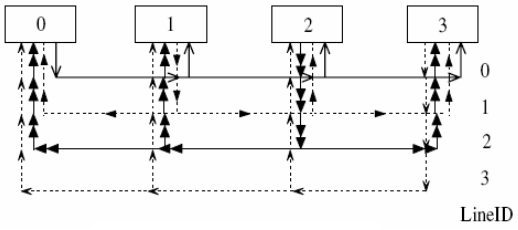

Figure 4. Overall steps

Like any communication scheme, it is vital that there be no collision of messages on any of these communication lines (or any line segment) at any point in the algorithm. Kantabutra et al [3] showed that this communication scheme produces no collision and takes O(*N*) time steps.

Theorem 3.1 (Time Complexity) *The Adjacent Nodes Finding Algorithm on CON has O(N) time complexity, where N = |V|.*

Proof: Assume one communication step is equal to one computation step. Without loss of generality, we only consider communication time. Lines 4 and 6, and lines 14 and 17 dominate the running time. Hence, the time complexity is O(*N*). The theorem holds. ■

Theorem 3.2 (Lower Bound) *The adjacent nodes finding problem on CON has Ω(N) time complexity, where N = |V|.*

Proof: In order to solve *any* instance of the adjacent nodes finding problem on CON, some *global* information is needed since each node only knows its adjacent nodes (i.e., *knownPts*) and does not have complete knowledge of graph G (i.e., does not know E). Therefore, in order to produce a solution, at least one of the nodes must gather necessary information from the other nodes either *directly* or *through some other nodes*. In either case, the distance between such pair of nodes is *at least* $\lfloor N/2 \rfloor + 2$ steps (i.e., one node in the middle and the other nodes in either leftmost or rightmost positions where N is odd). Thus, this establishes the lower bound. The theorem holds. ■

Theorem 3.3 (Optimality) *The Adjacent Nodes Finding Algorithm is time-optimal on CON.*

Proof: Theorems 3.1 and 3.2 directly imply the optimality of the algorithm. Hence, the theorem holds. ■

IV. NON-ADJACENT NODES FINDING ALGORITHM ON CON

Given a graph $G = (V, E)$ where V is a set of vertices and E is a set of edges, and a set of vertices $V' \subseteq V$, we have shown the algorithm to optimally find all adjacent nodes in V' using CON. Given the same inputs, we now want to find all non-adjacent nodes in V' using CON. The algorithmic definition for finding non-adjacent nodes in V' is almost the same as the one for finding adjacent nodes in V'. All assumptions and subroutines in the previous section still apply to this algorithm. Following are the code and some important theorems.

INPUT: *dataset* and *knownPts*

OUTPUT: a set of non-adjacent nodes in V'

Non-Adjacent Nodes Finding Algorithm for Process P_*k*

```
1  mySize = length(knownPts)
2  maxSize = mySize
3  for i = 0 to N-1 and i ≠ myID
4      send(mySize, P_i, myID)
5  for i = 0 to N – 1 and i ≠ myID
6      recv(size, P_any)
7      if maxSize < size
8          maxSize = size
9  extralength = maxSize – mySize
10 newPts = append(knownPts, extraLength, -1)
11 if myID ∈ dataset
12     matchPts = newPts ∩ dataset
13     noCon = dataset - matchPts
14     IDandPts = pack(myID, noCon)
15     send(IDandPts, P_0, myID)
16 result = ∅
17 if myID = 0
18     while recv(IDandPts, P_any) ≠ NULL
19             unpack(IDandPts, senderID, Pts)
20             result = result ∪ matching(senderID, Pts)
21     return result
```

Theorem 4.1 (Time Complexity) *The Non-Adjacent Nodes Finding Algorithm on CON has O(N) time complexity, where N = |V|.*

Proof: Because this code differs from the code in theorem 3.1 only in line 13, the time complexity is still dominated by the communication time. Hence, the time complexity is O(N). The theorem holds. ■

Theorem 4.2 (Lower Bound) *The non-adjacent nodes finding problem on CON has Ω(N) time complexity, where N = |V|.*

Proof: This problem is a complement of the Adjacent Nodes Finding problem on CON. That is, using $G = (V, \bar{E})$ as the input graph instead of G. Thus, the lower bound is the same as the one in theorem 3.2. ■

Theorem 4.3 (Optimality) *The Non-Adjacent Nodes Finding Algorithm is time-optimal on CON.*

Proof: Theorem 4.1 and 4.2 directly imply the optimality of the algorithm. Hence, the theorem holds. ■

V. CONCLUSIONS AND OPEN PROBLEM

Graphs have many applications in the real world and, as a consequence, so do our algorithms on CON. For instance, if an edge between any pair of two nodes (i.e., persons) represents a genetic relationship (i.e., great grandmother) between them. Given a subset of nodes, we may want to know who is related to whom genetically. In this paper we have shown that, given a graph $G = (V, E)$ and $V' \subseteq V$, our algorithms find adjacent and non-adjacent nodes in V' on CON in *asymptotically minimum* time and both have a speedup factor of N over their respective sequential algorithms. However, we have so far considered the fine-grained model in which one vertex in V gets mapped to one node in CON. Taking advantage of the gap between communication and computation speeds, we may want to map more than one vertex in V onto one node in the coarse-grained model in which processors are more powerful. The interesting problem in this model is how to map these vertices optimally. This remains a challenge for us to conquer.

ACKNOWLEDGMENT

***Abstract*-This paper presents a study on the effects of using virtual local area network (VLAN) on top of wireless local area networks (WLAN) that is used for indoor positioning systems based on location fingerprinting technique. This study investigates how VLAN on WLAN can improve the positioning performance of indoor positioning systems. The approach taken by this research is based on performing measurement experiments on positions within a building. We compare the results between a system with VLAN and without VLAN. Our results indicate that the system with VLAN can determine positions with higher precision than that without VLAN. The measurement results show that precision is improved by 5% - 10% on the average within the error distance (or accuracy) of 1 - 3 meters in the hallway area. The results of the experiment in this research suggest that VLAN can help increase positioning performance without having to add or install any real access points (APs) to the WLAN-based positioning system.**

Keywords: WLAN, Geolocation, Positioning System, Location Fingerprint, VLAN

I. INTRODUCTION

Nowadays, the most popular solution for positioning system is the Global Positioning System (GPS). The GPS system can find object's position by using at least three signals from at least three different satellites around the earth's orbits. However, GPS has limitation when using for indoor positioning due to the limitation in a line-of-sight between the object in indoor and the satellites. One of the solutions is to build repeaters for GPS signal in indoor as in [1]; however, the cost of the installation and additional devices becomes higher for the GPS-based indoor positioning system.

There are other alternative techniques used to create indoor positioning systems such as infrared, ultrasound and radio frequency (RF). Thus far, one of the radio frequency techniques which use only radio frequency patterns to determine locations in [2] has gained a lot of attention. This is due to a better signal penetration of RF in indoor than the other types of signals. The basic idea of this radio frequency based positioning system is to exploit the relationship between patterns of received signal strength (RSS) from access points (APs) in wireless local area network (WLAN) and locations of objects. Without determining the angle of arrival (AOA) and the time of arrival (TOA), the system uses only the pattern of RSS to determine a location of an object, and this technique is called the *location fingerprinting technique* [2]. This technique has the advantage over the other technologies in its implementation since the system can reuse the pervasive and existing installation based of WLANs in most buildings to implement indoor positioning systems. Currently, wireless local area networks have been deployed extensively in both government sector and private companies. Moreover, there is no need in adding any special devices to enable the indoor positioning system.

The idea of using WLAN for location fingerprinting has been around for some time. The direction of most researchers in this area has been focusing on improving the performance of indoor positioning system with novel algorithms [3][4][5][6]. However, recent advances in WLAN technology itself might have impact on the performance of indoor positioning systems. The IEEE standards have created 802.11b, 802.11a, 802.11g, and soon the 802.11n [7]. However, all of them can be applied to the location fingerprinting technique since the RSS is still available for measurement.

Another improvement on WLAN is to enable the use of VLAN on top of WLAN. The technique of VLAN allows only one AP to broadcast multiple service set identifiers (SSIDs) to mobile clients [8]. This creates multiple virtual networks per AP. From the client's perspective, it is as though the system has additional access points, depending on the number of VLAN created. To the best of the authors' knowledge, there is no study in the literature that has addressed the impact of VLAN on location fingerprinting technique.

Generally, the deployment of fingerprinting based positioning systems can be divided into two phases [2]. First, in the off-line phase, the location fingerprints are collected by performing a site-survey of RSSs from multiple APs at different positions. The distance between two closest physical positions during the survey period is called *grid spacing* which is usually reported in meters or feet. The RSSs from all APs that can be received on a position is measured with enough statistics to create a database of RSS patterns called a *radio map*. The vector of RSS values at a position on the grid is called the *location fingerprint*. This off-line phase can be very time-consuming if there is no survey plan with a clear performance objective, and the size of indoor area is very large.

Second, in the on-line phase, a mobile station (MS) reports a sample measured vector of RSSs from different APs to a position location server (or a group of APs collects the RSS

sample from a MS and sends it to the server). Then, the server uses a pattern classification technique to estimate the location of the MS and reports the estimate back to the MS (or an application requesting for position information). The most common algorithm used to estimate the location is to compute the Euclidean distance between the measured RSS vector and each fingerprint in the radio map.

The study in this manuscript shows the results of the experiment of the indoor positioning system based on both prototype and our own modified version of NIST (National Institute of Standards and Technology) Location Systems [11]. We compared the positioning performance of the system with and without VLAN. The organization of this paper is as follows. First, we begin our discussion of VLAN technique and fundamental of VLAN in Section II. Next, we describe our experiment environment and setup in Section III. The results of the experiments and the analysis are reported in Section IV. Finally, we conclude our finding and suggest our plan on the future work in Section V.

II. WLAN AND VLAN

Virtual Local Area Network (VLAN) is the technology that builds a model of Local Area Network (LAN) that does not depend on a physical connection [8]. Because VLAN is a LAN model, for example, one LAN switch can create a model of five networks, or three LAN switches can be combined into one network. To create one VLAN from multiple switches, a dedicated port, called a *trunk port*, is required to connect each switch together. VLAN can only be used with devices with routing or switching capability such as routers or switches.

VLAN protocol works on Layer 2 (data link layer) of a protocol stack, which is developed to control Layer 2 broadcasting. Most Layer 2 switches now support IEEE 802.1Q VLAN standard [9]. VLAN can be divided into five categories based on its membership construction. The first category creates a Layer 1 (physical layer) VLAN membership using physical ports. The second category creates a Layer 2 VLAN membership using MAC (Medium Access Control) address in which system diverts traffic according to the MAC address, and this is the case in our experiment with WLAN. The third category creates a Layer 2 VLAN membership using protocol types. The fourth category creates a Layer 3 (network layer) VLAN membership using IP subnet address. Finally, the fifth category creates higher layer VLAN. We commonly use VLAN to mitigate network congestion due to broadcast traffic, to simplify network administration, and to add security of access control to the network.

VLAN also works on WLAN, and it employs the same principle as that of wired LAN switches [8]. Most WLAN switches or access points create multiple VLANs based on MAC addresses since they do not have physical ports. In our experiment, we used Cisco 1100 AP which divided VLAN according to MAC address or Basic Service Set Identifier (BSSID)[10].Without VLAN, each AP periodically broadcasts beacon frame of 50 bytes over the air to advertise single network information such as Service Set Identifier (SSID), supported rates, capability information, parameter sets, and traffic indication map [7]. In indoor positioning system that collects RSSs from APs, the reception of beacon is a means to measure the RSS for creating location fingerprint. Note that an alternative is to send a probe request to an AP and waiting for a probe reply to determine the RSS. However, the RSS measurement is normally performed by the wireless card without user intervention. The user can obtain the RSS information through specialized API as in NIST's code [11].

In case of a system with VLAN, the AP broadcasts more beacon signals for multiple identities depending on the number of enabled VLANs. For example, if one AP is configured to have four VLANs or SSIDs, it will broadcast four beacons during a pre-determined beacon broadcasting period. Typically, the period between the burst of beacons is set to 100 ms [7]. Since the number of beacons increases with the number of VLANs, the number RSS samples is also increased. This study attempts to determine the gain from enable VLAN on APs in indoor positioning systems.

III. SYSTEM AND SETUP

A. Testbed Environments

In this research, we chose a location on the first floor of our engineering department building at King Mongkut's Institute of Technology North Bangkok as shown in Figure 1. The area of our interest is shown inside the dash-line box which is 48 by 16 meters. The building has six floors and has 11 APs which are all Cisco Aironet 1100 Series. Four out of 11 APs are installed on the first floor as denoted by the black circles in Figure 1. In our experiments, we collected RSSs from all APs to create radio map. However, the signals from all APs cannot be measured at all locations due to obstructions inside the building. Each AP is configured to have four VLANs. Thus, logically to a wireless client, it has 16 APs on the first floor!

In our experiment, we used a Compaq Presario V2427AU laptop computer with an Orinoco Classic Gold PCMCIA wireless interface card. The laptop runs a position location software prototype from NIST [11] which has graphic user interface as shown in Figure 2. The NIST's software allows us to create our own image of map layout and radio map. The deployment of the system follows the same off-line and on-line phases as described in Section I. The program starts by letting the user create an image map. Then, the user has to train the system or collecting the fingerprints in the map. After finishing the process, user can start the location mode or testing the location determination of the system.

We modified the NIST location system so that it can recognize distinct VLANs of the same physical AP. In case of a system with VLAN, the program simply considered each broadcast SSID as a real AP and recorded each RSS in different elements inside a location fingerprint pattern. Note that in one location fingerprint pattern it consists of an array of elements of pattern from multiple APs.

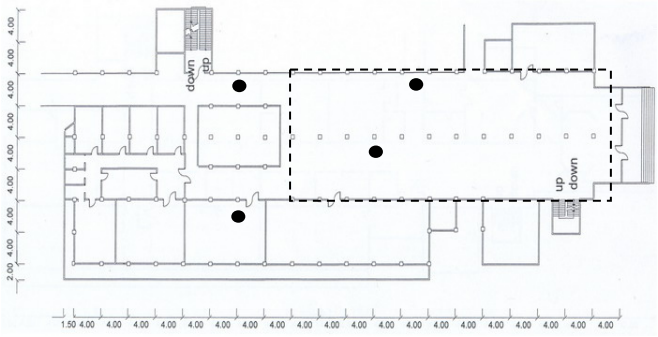

Figure 1.The first floor of our engineering building.

In case of a system without VLAN, the program combined all SSIDs of the same AP into a single element of fingerprint pattern of that AP. This in effect created a fair comparison of both systems because both use the same amount of data samples. The dimension of the radio map of the system with VLAN will be approximately four times larger than the system without VLAN. We used NetStumbler software [12] to detect beacons for the number of VLANs to verify our experiments and to identify the MAC addresses and the SSIDs of the same APs.

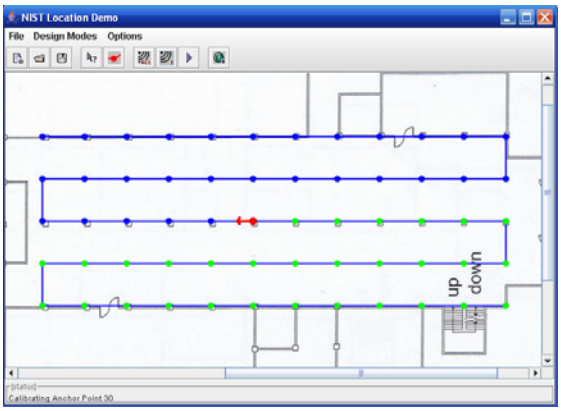

Figure 2.Example of NIST Location prototype program.

B. Experimental Setup

In our experiment, the goal is to compare the performance of the Location system with VLAN and without VLAN. We divided our setup into two phases. In the off-line phase or a training phase, we used the prototype Location System software and the modified Location System software to collect 200 samples of RSS from different APs at each grid location and to create a radio map with the grid spacing of 4 meters. Totally, we had 60 points of grid locations. The radio map is used for location finding in the localization phase. In the on-line phase, or the localization phase, we used the prototype NIST program and the modified NIST program to compare a vector of sampled RSS at a randomly selected location (100 samples from 60 points). Note that the NIST location system utilizes a Markov algorithm embedded in its program to find the most likely position according to the RSS vector [13].

We conducted two experiments of on-line phase, one with measured locations on the grid point and another with measured locations between grid points to compare the performance of the approximation algorithm. In each experiment, we sampled 100 locations and calculated the distance error between the estimated position returned by the program and the actual position. Note that the prototype NIST program and the modified NIST program do not calculated error distance for us. We performed calculation of the error distance by using Euclidean distance equation as in Equation 1. We denoted x_1 and y_1 as the coordinate of actual location while x_2 and y_2 are the coordinate of estimated location returned from the program. In each experiment, we used the same data set to calculate the performance of system with VLAN and without VLAN.

$$\text{Error distance} = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2} \quad (1)$$

IV. Results and Analysis

In the beginning of our investigation, we studied samples of RSSs from different VLANs that came from one of our APs. The results are shown in Figure 3. The graph indicates that the values of the RSS from different SSID are not equal. This led us to take the advantage of the variation in RSSs from different VLAN in location system.

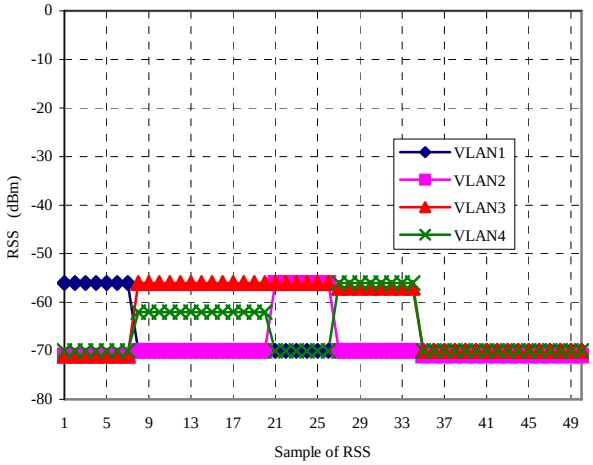

Figure 3.Comparison of the RSS of different SSID from the same AP.

The performance analysis of any positioning systems can be based on two major performance metrics: the accuracy and the precision. The location accuracy is usually reported as the error distance deviated from the actual position, while the location precision is reported in percentages of position information that are within the distance of accuracy [14]. These two performance metrics can be reported in a single plot between error distances or accuracy versus cumulative distribution function (CDF) or precision.

From the two experiments, we divide and discuss the results into two parts. Figure 4 shows the cumulative distribution function (CDF) of the error distance of the experiment that the tested locations are directly on the grid point of positions. The results compared between the system with and without VLAN.

Figure 4 shows that the system with VLAN can improve the precision by about 10% at the small distance error (accuracy)

up to 7 meters. Moreover, at the median (or CDF = 0.5), the system with VLAN can improve the accuracy by about 3 meters. However, the improvement is not significant at the large error distance.

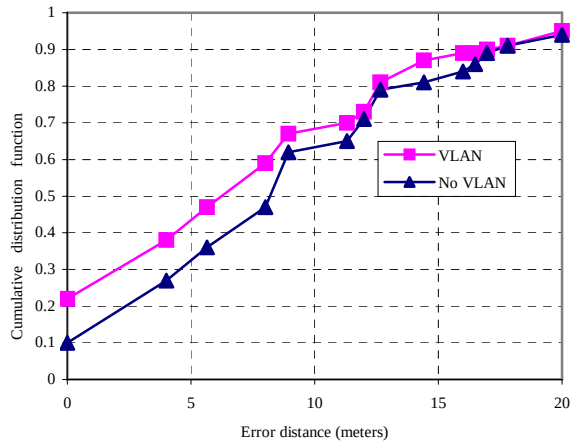

Figure 4. The error distance distribution of measurement at direct grid points.

Figure 5 shows the results of experiments that the tested locations were not directly on the grid points. This shows the similar result as the system with VLAN can improve the precision of the location system over the system without VLAN; however, the error distance is slightly more or the accuracy at the comparable precision is worst than the previous experiment with direct grid point measurement. The improvement of the precision is only about 5%. At the median, the accuracy is improved by about 1-2 meters. Note that the CDF at zero meter in this experiment is zero is because there are no measured locations that are actually in the radio map.

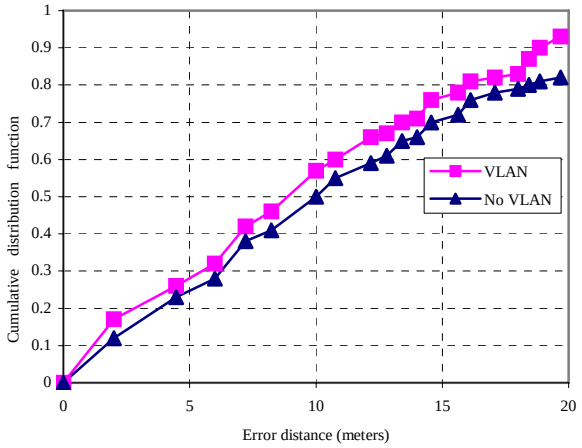

Figure 5. The error distance distribution of measurement at the location between grid points.

In [3], the authors analytically showed that the effect of increasing the number of APs in any location system could improve the overall performance of the system. The technique of using VLAN as showed above is one of efficient ways to increase number of APs to the system. The performance gain is due to a better separation of location fingerprints that have higher degree of freedom.

V. Conclusion and Future Work

Currently, most WLAN deployment employs IEEE 802.11b/g Access Points, and has been extensively used to provide indoor network access. Additionally, switches with VLAN capability become more available at the commodity price. Thus, it is easy to set up VLANs within WLANs as the testbed used in this study. We have shown that the VLAN on top of WLAN can improve the accuracy and precision of the positioning system based on the location fingerprinting technique. The accuracy can be improved by 5% to 10% on the average of 1 to 3 meters of improvement. Although, this is a small number, the improvement requires no additional hardware and can be easily set up from existing WLAN without any additional cost.

For the future work, we will take the advantage of using VLAN for indoor positioning system to track users or devices at same floor and different floors of building.

***Abstract*-Inter-vehicle communications is said to be part of the next generation Internet where vehicles can communicate to other vehicles or a roadside station in ad hoc manner to realize the Intelligent Transport System (ITS) which can increase road safety and provide traffic information etc. Several existing routing protocols are extensively studied for inter-vehicle communications. In this paper, we study the effect of installing fixed roadside stations on the performance of routing protocols such as DSR, AODV and GPSR. The study has shown that by adding more roadside stations, the successful rate of transmission is increased. However, the delay is almost constant in any case. For a small city section of 1.2x1.2 km, only about 7 stations per sq. km. is needed to provide the inter-vehicle communications with the successful rate of 96%.**

Keywords: Car-to-Car communication, Inter-vehicle communication, Vehicular Ad-Hoc Network, Routing Protocols, Roadside Station

I. INTRODUCTION

Transportation is part of our daily life or business transactions. Currently, the number of vehicles on roads has constantly increased, but the expansion of road quantity is slower. This causes the traffic jam and also the increasing of road accidents. In order to provide better transportation, Intelligent Transport System (ITS) has been proposed as a solution to ease transportation problems. ITS employs information technologies to mitigate the problems. One important requirement for ITS is vehicle-to-vehicle or vehicle-to-roadside communications to acquire information or to inform vehicles in real-time. For example, a road accident in front of us can be reported from the scene by the vehicles in the accident or nearby vehicles to vehicles in the same traveling route to warn drivers to reduce car speed in real-time. Additionally, the accident is immediately reported to roadside station to inform highway police and related officers to resolve the accident quickly. The car-to-car communication can also be used to prevent serious injury such as to activate the reversible seat belt pretensioners or preconditioning of airbags when an inevitable accident is detected by sensors to prevent severe head injury [1]. The car-to-roadside communication can be used to detect accidents or traffic jams and also used to broadcast information to road users [2].

Proving car-to-car communications have been interested by car manufacturers and communications standard organizations. In 2003, an IEEE standard for car-to-car communications, Dedicated Short Range Communication (DSRC) or IEEE 802.11p, has been published to support a high speed short range communication between vehicles [3]. For example, a vehicle on-board communications system uses DSRC to detect potential accidents to provide the vehicle safety services. Additionally, many research groups have proposed several solutions to realize the vision of car-to-car communications as one of the next-generation networks. One of the problems in the area of vehicle communications is the performance of routing protocols that is not efficient enough to support inter-vehicle communications due to the frequent change of vehicle location due to the high moving speed [4]. In this research, we study the performance of car-to-car communications by adding the roadside stations as fixed wireless nodes to help vehicle communicate with each other and to improve the overall system performance. In this study, we utilize the ns-2 simulator with Restricted Random Waypoint mobility model on the city sections to evaluate the performance of AODV [5], DSR [6], and GPSR [7] routing protocols.

This paper is organized as follow. First, we overview some mobility models and the routing protocols in Section II. In Section III, we explain our simulation experiment and discuss the simulation results in Section IV. Finally, we conclude our major research findings and future research directions in Section V.

II. RELATED WORKS

A. *Mobility Model for City Sections*

Random Waypoint is a common mobility model used in many simulation studies; however, it is not appropriated for studies of inter-vehicle communications where cars are limited on roads or sections. The Random Trip model is proposed as an extension to the Random Waypoint that it restricts cars to be on roads in a city section and always follows other cars without any collision [8]. With respect to Random Trip model, the city section is a particular instance of random waypoint model on a general connected area. The domain of the model is the union of line segments defined by the edges of a given space graph.

B. *Dynamic Source Routing (DSR)*

DSR is one of popular routing protocols for ad hoc networks [6]. It uses broadcast route discovery to build a route to a particular destination. The basic operation of DSR is the hop-by-hop forwarding procedure. When a route request (RREQ) is received, a node looks at the destination address

inside the RREQ. If the address is not already in the request, it puts the address in the request, and forwards the RREQ to neighbors. If the address is already in the RREQ, it means the RREQ has already been processed, and the RREQ is discarded. If the address is its address, it keeps the incoming route and sends back the route reply (RREP) with the list of nodes transversing the route indicating that the destination is found. Due to the hop-by-hop nature, DSR has a large header when a route is long and this normally causes high delay. However, it saves up memory since it only keeps the list of nodes inside the route request.

C. Ad-hoc On Demand Distance Vector Routing (AODV)

AODV is also another popular protocol that is extensively developed and applied for ad hoc routing [5]. Similar to DSR, it broadcasts a route request to its neighbor and the request is forwarded hop-by-bop. However, to reduce the route request overhead, each node maintains a routing table keeping a list of neighbor nodes, and a request is then forwarded according to the table. Therefore, it is important for AODV nodes to keep the table up-to-date. Each node maintains the table by periodically (or on request) checking its neighbors, and broadcasts to other nodes when there is a change. This reduces the route overhead in the request. However, AODV is vulnerable high mobility, which can cause high traffic due to the table updates. To reduce the traffic, the rate of update is reduced; however, it can increase the possibility of routing failure.

D. Greedy Perimeter Stateless Routing (GPSR)

GPSR is a responsive and efficient routing protocol for mobile, wireless networks. Unlike traditional routing algorithms, which use graph-theoretic notions of shortest paths and transitive reach ability to find routes, GPSR exploits the correspondence between geographic position and connectivity in a wireless network, by using the positions of nodes to make packet forwarding decisions [7]. GPSR uses greedy forwarding to forward packets to nodes that are always progressively closer to the destination. In regions of the network where such a greedy path does not exist such as the only path requires that one move temporarily farther away from the destination. GPSR recovers by forwarding in perimeter mode, in which a packet traverses successively closer *faces* of a planar subgraph of the full radio network connectivity graph, until reaching a node closer to the destination, where greedy forwarding resumes.

III. EXPERIMENTS

In this section, we analyze and compare the results of our experiments of routing protocols for inter-vehicle communications which uses random waypoint on a city section as a mobility model. We conducted experiments using the ns-2 network simulation [9].

Our experiments use a real world map of 1200x1200m of West University area, in Houston, TX, USA. The map is extracted using the information from TIGER database [10] as shown in Figure 1. All lines represent actual roads within the plotted area. The map includes about 383 intersections and 594 road segments.

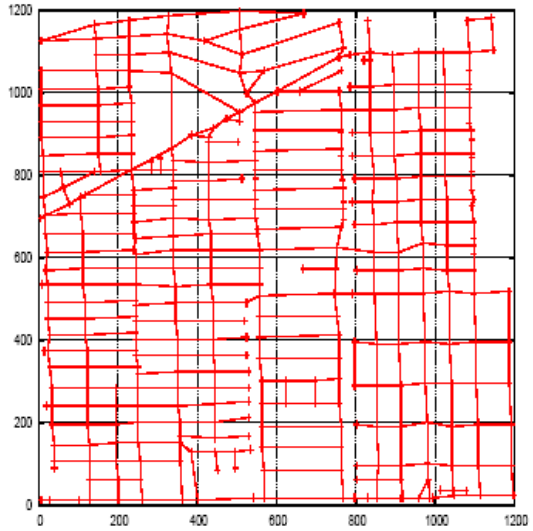

Figure 1. Realistic street scenario of size 1200m× 1200 m

To conduct a large number of experiments required in this study, each scenario was repeated with multiple mobility patterns to attain a 95% confidence interval. In this experiment we consider measuring a successful rate and end to end delay. The successful rate is a ratio of received packets at destinations divided by the number of sent packets from sources. The end to end delay is duration of a packet sent from sources and successfully received at destinations. In the experiments, we set other related routing parameters for simulation as shown in Table I.

TABLE I SIMULATION PARAMETERS

Parameter	**Value(s)**
Number of Nodes	30-300
Simulation Time	1000 sec
Routing Protocols	AODV, DSR, GPSR
NS2 Version	ns 2.29.2
Transmission Range	250m
CBR Sources	20 sources (interval 5-10 sec)
Mobility Models	Random Trip Model for a city section
Topologies	1200x1200m Grid , Real Map
Average Node Speed	5 meters/sec

IV. SIMULATION RESULTS

A. The Variation of Number of Nodes

In this section we compare the performance of different ad-hoc routing protocols as we vary the number of total nodes. The results of the successful rate and the end-to-end delay are shown in Figure 2 and Figure 3.

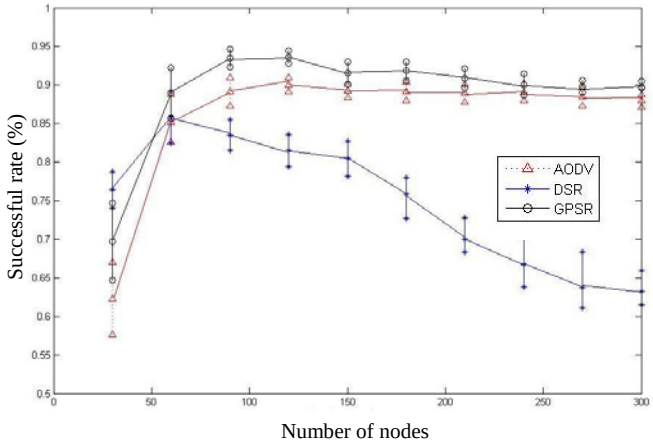

Figure 2. The successful rate with different node numbers

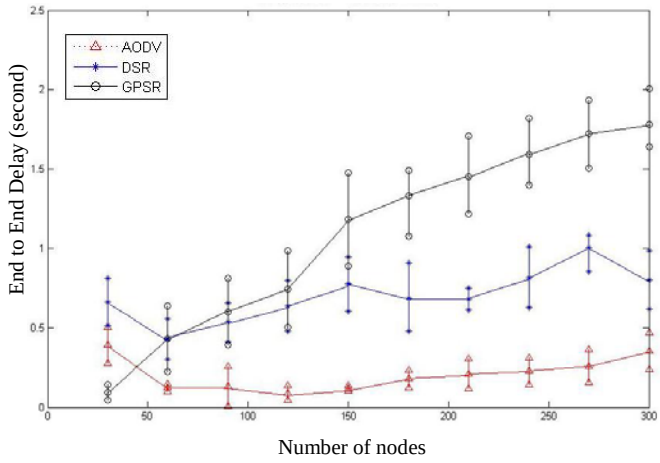

Figure 3. The end to end delay with different node numbers

In Figure 2, the results indicate that for the number of less than 50 nodes, DSR yields the highest successful rate. However, for 50 or more nodes, GPSR and AODV yield the higher successful rate. The reason is that DSR is only efficient when the network size is small, or the path length in hops is short. For GPSR, the greedy forwarding mode is activated to increase the range of packet forwarding to decrease the number of hops in a path. For AODV, each node maintains the route table locally; thus, it is more scalable than other protocols.

Figure 3 compares the end-to-end delay among all routing protocols. GPSR has increasing delay as the number of nodes increases because GPSR greedily uses perimeter forwarding to many neighbors when destination is out of range. In a large network with many neighbors, this causes the increasing delay. As AODV yields the lowest delay because each time a packet is sent, it selects the best route with the minimum number of hop. Thus, the delay tends to be stable as the number of nodes increases.

B. Roadside station into map

For this experiment, we randomly insert fixed wireless stations, called roadside stations, into the map of 1200x1200 meters to introduce vehicle-to-roadside communication to increase network connectivity. We simulate 50 vehicle nodes (the vehicle density is 34.72 nodes/km^2), with a nominal 250-meter transmission range and 10 traffic sources. The results are shown in Figures 4 and 5.

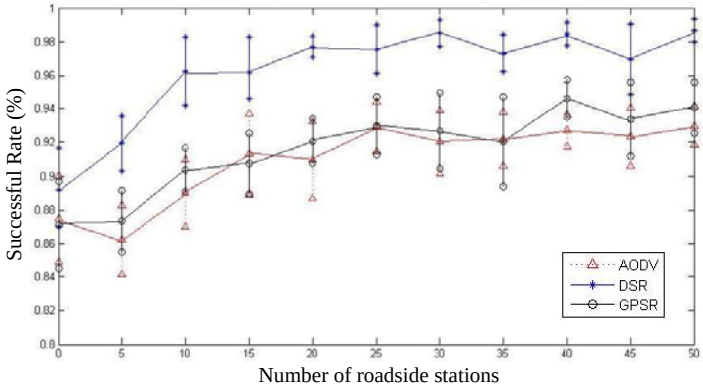

Figure4. The successful rate with different numbers of roadside stations

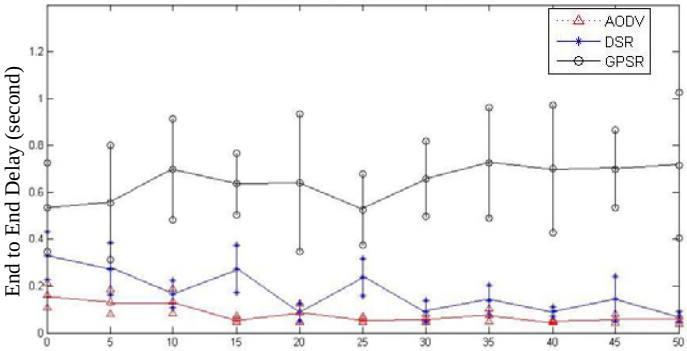

Figure 5. The end-to-end delay with different numbers of roadside stations

In Figure 4, the successful rate of all protocols increases compared to that in Figure 2 as the number of stations increases. However, DSR has the best performance as it benefits from stationary nodes or stations. We notice that the successful rate is slowly increased as the number of roadside stations is more than 10 nodes with 96% of successful transmission. Thus, this is probably the optimal number of roadside stations for this city, and the density of roadside stations for this city area is 7 nodes/km^2.

Figure 5 shows that the end-to-end delay of GPSR tends to be constant, and it is slightly longer than AODV and DSR. For GPSR, the delay depends on the number of hops in routes and the size of the network. As opposed to the delay shown in Figure 3 where adding more moving nodes increases the delay, the delay is rather constant as we add more stationary nodes. It is shown that GPSR gains benefits from having roadside stations for inter-vehicle communications.

C. The Effect of City Block Size

The city block size is also an important factor in determining the performance of the routing protocols for inter-vehicle communications. Given a larger block size, vehicles

spend a relatively longer time in traversing the distance between intersections. We perform experiments where we span the map size to be 2400x2400 meters and determine the performance as the density of vehicle nodes and roadside stations is similar as previously done. We experiment with 200 vehicle nodes ($34.72\ node/km^2$), and we vary the number of roadside stations.

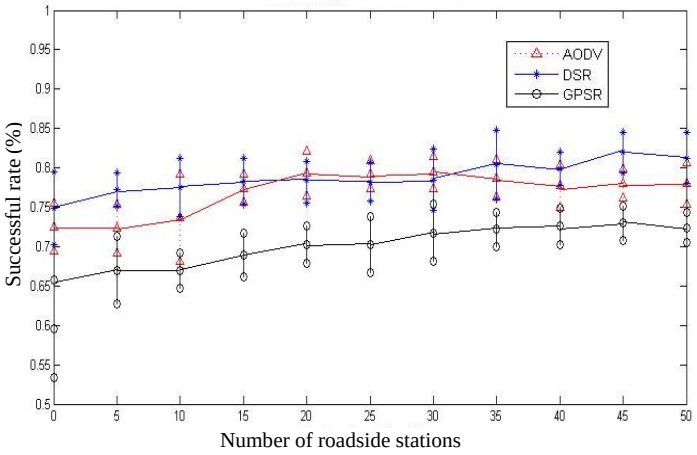

Figure6. The successful rate with different numbers of roadside stations on 2400m × 2400 m map

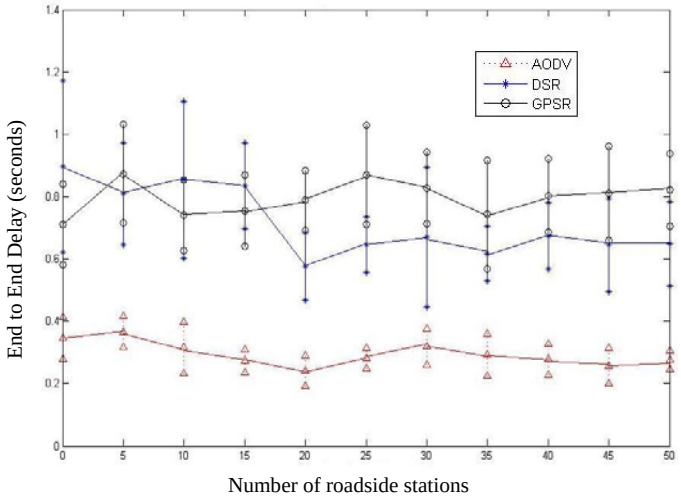

Figure 7. The delay with different numbers of roadside stations on 2400x2400m map

The results in Figure 6 indicate that for a larger map, all routing protocols tend to have constantly increasing successful rate as the number of stations increased while the vehicle density is fixed. In Figure 7, the end-to-end delay is rather stable as in previous experiments. Therefore, we can conclude that by increasing the number of roadside stations, we are able to make transmission with more successful rate in case of a larger city area network. To farther confirm our conclusion, we increase even more number of roadside stations to observe the trend. In Table II, it is shown that all routing protocols yield more successful rate when the number of roadside stations increased.

TABLE II COMPARISON OF ROUTING PROTOCOLS WITH 100 NODES

Number of roadside station	Average Successful Rate		
	AODV	DSR	GPSR
10	0.7367	0.775	0.6695
50	0.7803	0.8126	0.7238
100	0.8243	0.8699	0.7703

V. CONCLUSION

In this paper we present simulation experiments and results on the effect of the number of roadside stations for inter-vehicle communications with the use of three different routing protocols, DSR, AODV, and GPSR. First, we compare the performance of different ad hoc routing protocols as the number of vehicle nodes increase. GPSR yields the highest successful rate; however, it yields the longest delay. This is because GPSR utilizes positions of nodes to make packet forwarding decisions; thus, a packet is routed over more hops when network size is larger. Second, we evaluate the effect of the number of roadside stations, and from the experiment we conclude that the density of roadside stations for a small city section is about 7 nodes/km^2 with about 96% of successful transmission. With the larger network topology, we have the same result that the successful rate is increased if number of roadside stations increased.

The Improvement of TCP Performance in Heterogeneous Networks

K. Kuprasert and P. Oothongsap

King Mongkut's Institute of Technology North Bangkok,
Pibulsongkram Rd., Bangsue, Bangkok 10800, Thailand

***Abstract*- Currently various modified TCP congestion control algorithms have been proposed for specific network environments such as wireless or high-speed long-delay environments. However, there is no research study on a TCP congestion control algorithm in a mix environment such as high-speed long-delay and wireless environment. Thus, we study various TCP congestion control algorithms such as BIC-TCP, S-TCP, HS-TCP, TCP Westwood and TCP Hybla in the mix environment by using Network Simulator (NS-2) [1] and we propose a new TCP congestion control algorithm called NEO-TCP which can improve bandwidth utilization and fairness.**

I. INTRODUCTION

Future communication and computer networks will be characterized by requirements to carry wide varieties of network services and traffic types. Two growing technology trends, Internet and wireless technologies, are resulted in a combination network. Such environments are expected to become the norm in the future because there has been an increase in supporting data applications over networks with both wired and wireless link. Mixing wired and wireless network becomes very popular. This event creates new challenges for network designers and researchers.

This heterogeneous environment is expected to support wide ranges of applications such as high-speed data transfer, real time multimedia, multimedia web streaming, and computational grids [2]. These applications tend to use TCP [3] as a Transport control protocol because TCP supports a reliable transmission and be able to detect and resolve network congestion.

Several literatures have studied TCP performance only in a specific environment. For example, BIC-TCP [4], S-TCP [5], and HS-TCP [6] are proposed to solve the TCP performance degradation in a high-speed long-delay environment. TCP Westwood [7] and TCP Hybla [8] are proposed to solve the TCP performance degradation in a lossy environment and a satellite environment, respectively. Currently, there is no literature survey that studies and solves the problem of TCP performance in the heterogeneous environments.

As we noticed, each environment has a unique characteristic. For instance, in high-speed long-delay network, TCP congestion control algorithm prevents TCP source to fully utilize available bandwidth. Hence, the current TCP flow cannot maintain a high throughput, even though abundant network resources are available. Suppose a connection has a round-trip time (*RTT*) of 100ms, a packet size of 1500bytes and an available bandwidth of 10Gbps. With this environment, the TCP congestion window (*cwnd*) will be equal to 83333 packets. According to the AIMD in the TCP congestion control, after an immediate detection of a congestion event, the *cwnd* will be set to 41667 packets. The longest time interval that congestion avoidance phase would go through will be 4167 seconds, roughly 1.2 hours.

In the wireless environment, a wireless channel is characterized by high bit-error rates (*BER*) and random losses. Furthermore, a wireless channel may cause burst errors when the channel is in a deep fade for a significant amount of time. When random errors occur, a TCP source cannot differentiate congestion losses from random losses. A TCP source treats all packet losses as indicators of network congestion and slowdowns transmission rate unnecessarily.

In the satellite environment, TCP performance will be degraded by both long *RTT* and high bit-error rates as in [9].

To solve the above problems, this paper proposes a new congestion control mechanism called NEO-TCP. The NEO-TCP algorithm operates in two modes, each of which uses the different algorithm for changing the *cwnd* size. The first mode is for the normal network where *RTT* is equal to or less than 50ms, and the second mode is for the long-delay network where *RTT* is more than 50ms. Furthermore, it also has a special mechanism to counter with random losses in wireless environment. With these properties, the NEO-TCP algorithm promises excellent utilization, efficiency, fairness and friendliness.

The paper is organized as follows. In section II, we propose the concept and the congestion control mechanism of NEO-TCP. In section III, we present a series of NS-2 experiments. Finally, future work and conclusion can be found in section IV.

II. NEO-TCP CONGESTION CONTROL

The NEO-TCP algorithm is the modification of the congestion control algorithm of TCP Hybla. The NEO-TCP algorithm operates in two modes: a standard, and a long-delay mode. The standard mode is for the normal network where *RTT* is equal to or less than 50ms, and the long-delay mode is for the long-delay network where *RTT* is more than 50ms. To be able to acquire available bandwidth in the high-speed and long-delay environment, the congestion control algorithm of NEO-TCP is *RTT* dependent. If the *RTT* between a source and destination is large, the *cwnd* grows quickly. If the *RTT* between a source and destination is small, the *cwnd* grows

slowly. The *cwnd* increment depends on a normalized *RTT* (*k*) which is calculated as follows.

$$k = MAX\left(1\ ,\ \frac{RTT}{RTT_{ref.}}\right) \quad (1)$$

We separate the NEO-TCP operation mode by using the $RTT_{ref.}$ value which is equal to 50ms. This value is chosen because most long-delay networks have the *RTT* more than 50ms [10]. The congestion control mechanism of NEO-TCP is proposed as follows.

On the arrival of an acknowledge (*ACK*):

Slow Start Phase

Standard mode (k=1): $cwnd \leftarrow cwnd + 1$ (2)

Long-delay mode (k>1): $cwnd \leftarrow cwnd + (4^k - 1)$ (3)

Congestion Avoidance Phase

Standard mode (k=1): $cwnd \leftarrow cwnd + \frac{1}{cwnd}$ (4)

Long-delay mode (k>1): $cwnd \leftarrow cwnd + \frac{4k^2}{cwnd}$ (5)

On a packet loss :

3 DUPACKs

Standard mode (k=1): $cwnd \leftarrow \frac{cwnd}{2}$ (6)

Long-delay mode (k>1): $cwnd \leftarrow cwnd - \frac{1}{cwnd}$ (7)

Timeout

Standard mode (k=1): $cwnd = 1$ (8)

Long-delay mode (k>1): $cwnd = 2 \times k$ (9)

In the beginning of the connection, a NEO-TCP source measures the *RTT* between itself and a receiver and calculates the *k* value. Then, the NEO-TCP source will perform according to the operation mode, which concurrent with the *k* value.

If *k* is equal to 1, the NEO-TCP congestion control algorithm will operate in the standard mode, and it will perform like the standard TCP (TCP Reno).

If *k* is greater than 1, the NEO-TCP congestion control algorithm will operate in the long-delay mode. The NEO-TCP algorithm increases *cwnd* more aggressively than standard TCP does. The increased rate of *cwnd* depends on the *RTT* value in the network. If the *RTT* is so long, the *cwnd* will increase so fast. In the slow start phase, the NEO-TCP algorithm will increase the *cwnd* as in (3). In the congestion avoidance phase, it will increase the congestion window size as in (5). Equation (3) and (5) are derived from the TCP Hybla algorithm, because the congestion window update mechanism of TCP Hybla is satisfied conditions of high-speed long-delay network [8].

If the NEO-TCP sender receives triple duplicate acknowledgments, the NEO-TCP sender will not decrease the *cwnd* by half like the TCP Reno sender, but it will decrease *cwnd* as in (7). This is to prevent the NEO-TCP algorithm from decreasing *cwnd* drastically. In the high-speed long-delay and wireless environment, the loss rate is high, so the TCP sender decreases *cwnd* frequently. If the sender decreases *cwnd* by half frequently, the sender cannot send more data. This will lead to low bandwidth utilization. The NEO-TCP algorithm can improve bandwidth utilization by decrease the *cwnd* gradually as in (7).

In case of timeout, the NEO-TCP algorithm will decrease the *cwnd* as in (9).

The NEO-TCP algorithm also adopts the selective acknowledgement (*SACK*) option [8] because it allows the TCP sender to recover more than one packet per *RTT*. This option is currently widely spread and available in most TCP implementations and is also often turned on by default in most operating systems.

III. TCP PERFORMANCES

In this section, we will study the TCP performance in this heterogeneous network. All of the simulations are performed with network simulator (NS-2) and TCP performance metrics are throughput, intra-protocol fairness, TCP friendliness and round-trip time fairness (*RTT* fairness).

A. Throughput

In this section, we study the bandwidth utilization of NEO-TCP and other TCP variants in the heterogeneous network at 20ms, 100ms and 200ms *RTT*, respectively. The topology is shown in Fig. 1. S1 is the source node, R1 is the access point, and D1 is the destination node. The bandwidth between S1 and R1 is 1Gbps with the one way delay varied from 10ms, 50ms, and 100ms, respectively. The bottleneck link is the wireless link between R1 and D1. The bottleneck bandwidth is 11Mbps with 64 μs one way delay as the 802.11b standard. We choose 802.11b standard because it is popular in today wireless networks and public hotspots as well as business and home environments. The random loss rate in the wireless link is 0.001 [5]. Each TCP variant connection is established from a fix host sender (S1) to a mobile host receiver (D1). The data are transferred via FTP flow from the sender to the receiver. The FTP packet size is 1000 bytes. The queue size at the access point is 50 packets. The simulations are run for 500 seconds to eliminate transient behaviors.

The simulation results present that NEO-TCP can provide higher throughput than other TCP variants when it operates in long-delay network. Because it increases the *cwnd* aggressively depend on the *RTT* in the network. Moreover, when triple DUPACKs are received, NEO-TCP will decrease *cwnd* gradually and it uses *SACK* option for loss recovery mechanism.

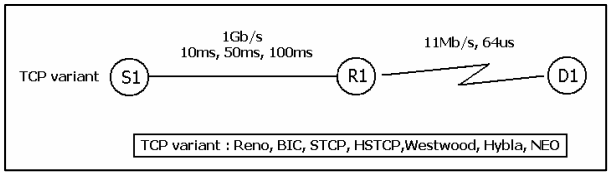

Figure 1. Topology of throughput simulation.

TABLE I
AVERAGE TCP THROUGHPUT VALUE

Protocol	Average throughput (Mbps)		
	RTT 20ms	RTT 100ms	RTT 200ms
HS-TCP	3.131	1.376	0.733
S-TCP	3.902	2.534	1.923
BIC-TCP	3.830	2.549	1.879
TCP Reno	3.256	1.604	0.789
TCP Westwood	4.048	1.444	0.669
TCP Hybla	3.490	2.904	2.689
NEO-TCP	**3.416**	**3.830**	**3.695**

B. *Intra-protocol Fairness*

Intra-protocol fairness is the fair share of bandwidth utilization when different flows use the same protocol. In this section, we study the fairness of NEO-TCP in the heterogeneous network at 100ms *RTT*. Six NEO-TCP flows are studied.

Fig. 2 shows the network topology for intra-protocol fairness simulation. The bandwidth between each source node and R1 is 150Mbps with the one way delay 10ms. The high-speed long-delay link between R1 and R2 has bandwidth 1Gbps with the one way delay 40ms. The wireless link between R2 and each destination node is bottleneck link, which has the specification follows the 802.11b standard.

The simulation result shows that NEO-TCP flows get a fair share of bandwidth, because every flow of NEO-TCP increases *cwnd* in equal rate. The reason of this result is every flow of NEO-TCP has the same *RTT*, so they operate in the same manner. If the network has so many competing flows, the throughput of each flow tends to be lower because the bandwidth in the network is saturated. Then the throughput is limited by the bottleneck link in the network.

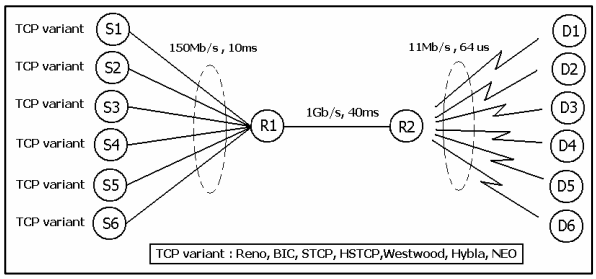

Figure 2. Topology of intra-protocol fairness simulation.

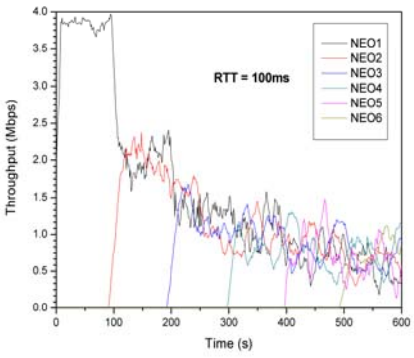

Figure 3. NEO-TCP fairness.

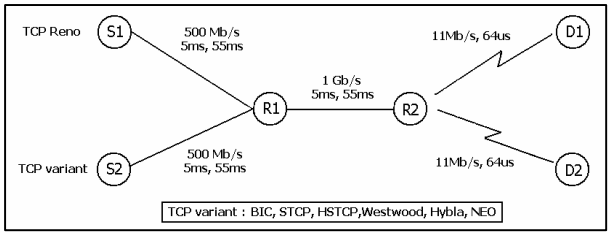

Figure 4. Topology of TCP friendliness simulation.

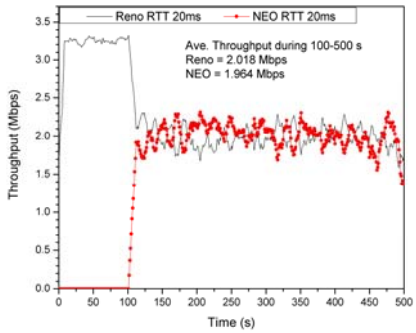

Figure 5. NEO-TCP friendliness.

C. *TCP Friendliness*

The friendliness means the connections with different TCP variants does not prevent unmodified TCP from consuming available bandwidth. In this section, we study the TCP friendliness of NEO-TCP in this environment. Two TCP flows are studied. One flow uses a TCP Reno algorithm and the other one uses a NEO-TCP algorithm.

Fig. 4 shows the network topology for TCP friendliness simulation. The bandwidth between each source nodes and R1 is 500Mbps with the one way delay varied 5ms and 55ms. The link between R1 and R2 has bandwidth 1Gbps with the one way delay varied 5ms and 55ms. The wireless link between R2 and each destination node is bottleneck link, which has the specification follows the 802.11b standard.

TCP Reno connection is established between the source node, S1 and the destination node, D1 and NEO-TCP is established on another connection from the source node, S2 to the destination node, D2. The data are transferred via two FTP flows from the senders to the receivers.

The simulation results in Fig. 5 show that NEO-TCP is friendly to standard TCP because NEO-TCP operates in a standard mode. In this mode, when the NEO-TCP sender receives the acknowledge signal from the receiver, it will increase and decrease the *cwnd* size as same as the standard TCP.

D. *RTT Fairness*

Round-trip time fairness is the fairness of two flows with different *RTT*. In this section, we study the *RTT* fairness of NEO-TCP in this environment.

Fig. 6 shows the network topology for *RTT* fairness simulation. The bandwidth between the source node, S1 and the access point, R1 is 500Mbps with the one way delay 15ms. The bandwidth between the source node, S2 and the access

point, R2 is 500Mbps with the one way delay varied from 15ms, 45ms and 105ms, respectively. The link between R1 and R2 has bandwidth 1Gbps with the one way delay 15ms. The wireless link between R2 and each destination node is a bottleneck link, which has the specification follows the 802.11b standard.

There are three cases for the simulation. For case A, the *RTT* of the first flow and the second flow is 60ms. For case B, the *RTT* of the first flow is 60ms and the *RTT* of the second flow is 120ms. For case C, the *RTT* of the first flow is 60ms and the *RTT* of the second flow is 240ms.

In case of *RTT* fairness, the simulation results show that if both flows of NEO-TCP operate in the same mode, it provides a bounded fair share, NEO-TCP with large *RTT* does not starve NEO-TCP with small *RTT*. When one flow suffers from random loss and cannot take up for more bandwidth, another flow will consume the unused bandwidth immediately.

The interested reader can find more result of NEO-TCP when compare with other TCP variants in [11].

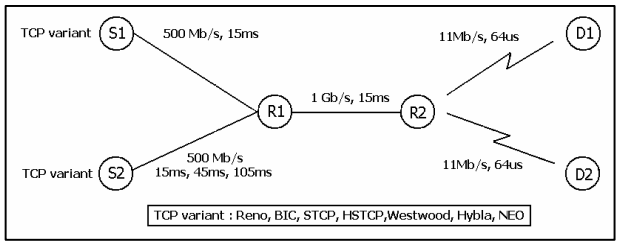

Figure 6. Topology of *RTT* fairness simulation.

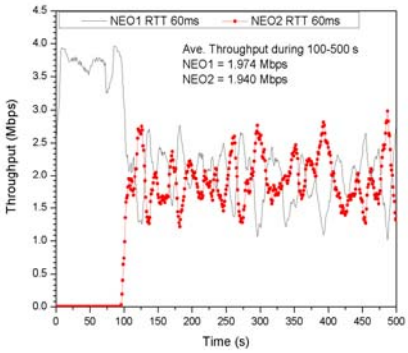

Figure 7. NEO-TCP *RTT* fairness case A.

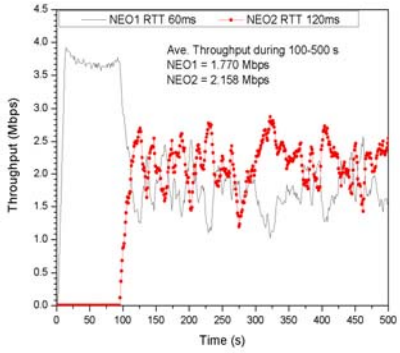

Figure 8. NEO-TCP *RTT* fairness case B.

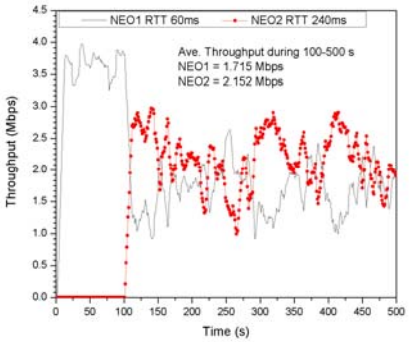

Figure 9. NEO-TCP *RTT* fairness case C.

IV. Conclusion and Future Work

In this paper, we present the simulation results evaluating the performance of TCP Reno, HS-TCP, S-TCP, BIC-TCP, TCP Westwood, TCP Hybla and NEO-TCP in the heterogeneous networks. The new congestion control algorithm, NEO-TCP can outperform the traditional in term of throughput and fairness. The major advantage of NEO-TCP is that it provides the high bandwidth utilization in the proposed environment.

Current NEO-TCP uses a constant *RTT*, which is measured only in the beginning of the connection. However, the *RTT* value should not be a constant since it reflects the network condition. Then for NEO-TCP to adopt to the current network condition, *RTT* must be measured more frequent. Thus, the normalized *RTT* parameter (k) should be changed dynamically. Moreover, the mathematical model of NEO-TCP should be researched, and it should be implemented and tested over real networks. This would reveal any implementation problems that are not foreseen during the initial design.

Early Warning of Internet Worms by ICMP Scan Data Visualization

Pitichai Pitimaneeyakul, Saroj K. Biswas
Department of Electrical and Computer Engineering
Temple University, Philadelphia, PA19122

***Abstract*—This paper investigates early detection of Internet worms using ICMP port scan data. The ICMP port scan data is plotted as a scatter plot in the plane of port scan vs. scan rate, which is referred to as 'port-scan plane'. It is observed that the normal port scan activity remains within a small boundary in the port-scan plane, and exits the normal activity boundary when a computer worm starts to infect the Internet. The normal port scan boundary is determined using historical port scan data at a monitoring station. A worm attack warning is issued when the port scan activity exceeds the threshold boundary of the port scan plane. Simulation results are presented using worm data generated by the well known epidemic model. Port scan data collected during Code Red attack was also used to validate the proposed method. Additional port scan data collected at Temple University firewall during a worm attack in the Spring of 2004 is also used to validate the results.**

I. INTRODUCTION

Security threat of the Internet dates back to 1988 when Morris worm [1] infected a large number of computers connected to the network. Since then computer viruses and worms continued their attack with the grim reminder that no computer is safe on the Internet. More recently, in 2001 a number of worms such as, Code-Red, Code Red V2, Code-Red II and Nimda, spread over the Internet, and infected hundreds of thousands of computers in a few hours. Two years later, January 25th 2003, SQL Slammer [2] appeared, and infected 90 percent of vulnerable computers in 10 minutes without any warning. Many networks around the world had to be shut down because of a lack of an appropriate defense against this worm. Moreover every new generation of worm seems to be faster and more intelligent than its predecessor, and infected more and more hosts on the Internet. Stanford et.al. [2, 3, 4] showed that, if a worm uses a better algorithm in scanning its target, then it can occupy all computers on the Internet in less than an hour.

Damage to hosts on the Internet due to a worm varies with its payload, which depends on the imagination of the worm author. Even without the payload a worm can generate a lot of traffic, which can lead to denial of service on the network. If worms can be detected early, one can develop strategies to slow down or halt attacks, and keep the system running as normal. Given the fast speed of infection, it is necessary to set up a nation-wide worm detection system for early warning.

An unknown (zero-day) worm is difficult to detect using worm signature since it is not available until the worm infects many computers. However, when the worm attacks, the network traffic is altered compared to the traffic in a normal state. Thus by monitoring the network traffic, one should be able to detect the changes in traffic, which can in turn be used to predict worm attacks.

This paper investigates detection of a worm by monitoring the network traffic. The ICMP port scan data is plotted on the *port-scan plane*, which is the plane of port scan per unit time versus scan rate. It is observed that for normal network traffic, the ICMP scanning activity remains within a small boundary in the port-scan plane, however, it grows very fast whenever a worm attacks the Internet. The normal port scan boundary may be determined using historical port scan data at a monitoring station. Simulation results are presented using worm data generated by the well known epidemic model. Port scan data collected during Code Red [5,6] attack was also used to validate the proposed method. Additional port scan data collected at Temple University firewall during a worm attack in the Spring of 2004 was also used to validate the results.

The paper is organized as follows: Section II introduces the basics of a computer worms and viruses. Section III discusses the methods that are commonly used to detect worms. Section IV presents the main result of this research, a phase-plane method for detection of appearance of a new computer worm, which is followed by concluding remarks in Section V.

II. WHAT IS A WORM

A worm is a computer program [4] that attempts to find the vulnerability on other computers, and gain access into those computers across the network. A worm typically copies itself to a target computer after it exploits the security hole of the target. When the target computer becomes infected, it starts the process to conquer new targets. Clearly, the worm's infection rate increases exponentially, and has the characteristics similar to that of human or animal diseases. Zou et.al. [6,7] modeled the Code Red worm by using a classical simple one-species epidemic model:

$$\frac{dx(t)}{dt} = \alpha x(t)[N - x(t)] \qquad (1)$$

where $x(t)$ is the number of infected hosts at time t, N is the total number of computers, and α is the infection rate. A more realistic model [9] of worm uses the classical general epidemic model, the Kermack-McKendrick Model that classifies hosts in three basic categories:

susceptible → infected → removed

A Virus is a computer program, containing malicious code that can replicate itself by human interactions, such as copying the program, running the program, sharing the diskette or open the document file. A *Worm* is a malicious computer program, which can replicate itself across network without human interaction. However, there are some worms that require user interaction, such as, opening of email or document. Thus, a worm can spread and infect vulnerable computers a lot faster than a virus.

III. Detection of Worm

Worm detection methods can be classified into two categories: 1) *detection of known worm*, 2) *detection of unknown worm.*

Known worms are detected using their signature or known pattern of network attack. The antivirus software is an example of signature-based detection, which detects worms only when its signature is available. Thus if there is a new virus/worm that spreads on the Internet, it is likely to spread quickly over the Internet because of lack of a signature. For example, if a worm uses ICMP sweep scan to the network, the anti-virus will detect the sweep scan, and will alert the network manager. Note that these signatures would not have been known when the worms first attacked the Internet.

There are a number of methods that have been proposed in recent years for detection of unknown worms. The following is a brief summary.

Monitoring Border Gateway Protocol (BGP):
When Code Red/Nimda attacked the Internet, the behavior of the BGP in the routing table of the gateway router had changed from the time before the worm attack [7]. The number of BGP update messages increased because the worm inside a local area network tried to propagate across to other networks (egress scan) so that the gateway router had to update information in the routing table to find destinations for the worm. Michael Liljenstam [10] has shown the correlation between CodeRed worm propagation and BGP instability by the SSFNET software simulation.

Monitoring ICMP:
Before breaking in, the worm sends ICMP packages to the target to check whether the target is still active and ready to receive a warhead. The destination IP addresses are often chosen randomly so that many ICMP packages are actually sent to non-existent IP addresses. Thus the ICMP "unreachable" will be returned to the source host. Gorge Bakos [11, 12] presented a method of detecting active worms by monitoring ICMP unreachable message, which can increase exponentially when the worm spreads. However, some worms use other types of the packages such as, SYN, HTTP, etc to probe the target, or do not probe the target at all. Thus monitoring of ICMP unreachable message is not suitable to detect many worms.

Kalman Filter:
Another method by Zou et.al. [7] shows how to use the Kalman filter to estimate a worm propagation on the network. Since a worm's propagation follows the epidemic model, the Kalman filter can be used to estimate the worm propagation growth rate. As the worm grows exponentially, the Kalman filter estimates the growth rate, and the worm attack is detected. Convergence of Kalman filter requires that the network traffic be monitored for many IP addresses over a long time, which might be too late for taking any actions to halt the attack.

The three methods discussed above require a considerable amount of time and a substantial amount of network traffic data before a worm is detected. Thus, although the system administrator will know that a new worm has attacked the network, it may be too late to make any defense plan.

IV. Detection Based on ICMP Traffic Visualization

In this study, we examine the relationship between the number of scans in the networks, called "scans", and difference between the number of the scans at a current time point, and the previous time point, called "delta scans". We assume that the worm uses ICMP as the scanning engine. The hypothesis is that there will be a difference between plots of scans versus delta scans under normal conditions, and those during the worm attacks. The concept is based on the phase-plane plot of a second order system, which shows a clear and significant difference between a stable and an unstable system. Our analysis is based on network ICMP scan data collected during a worm attack as well as simulated worm attack data.

1) Code RED Worm

The phase plane method of worm detection was tested using the network traffic data collected by Goldsmith [5] during the CodeRed worm attack on July 18 and 19, 2001. Figure 1A shows the normal Internet activity when there is no virus or worm attack, whereas Figure 1B representing worm attack clearly shows a significant increase in the scan activity. In fact the small dark region near the origin of Figure 1B represents data points of Figure 1A.

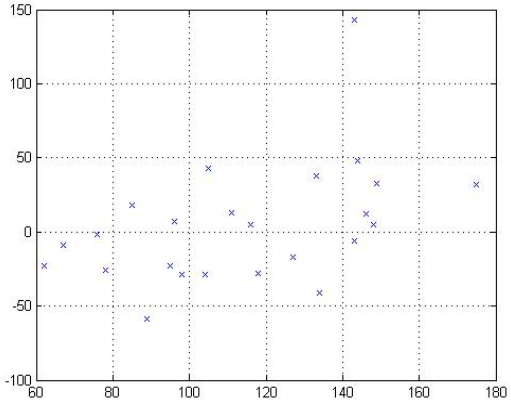

Figure 1A: Scan versus Delta Scan on 07-18-2001 before codeRed attacked the network.

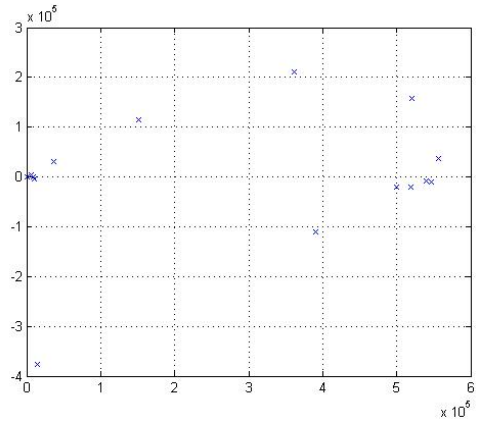

Figure 1B: Scan versus Delta Scan on 07-19-2001 when CodeRed peak attacked.

It is noticed that the network always has some ICMP activity even when there is no worm attack. Thus, the boundary of the scatter plot between scans/delta scan remains confined in a small region around the origin. However, when the worm attacks the network, the boundary of scatter plot of ICMP scan/delta scan grows substantially big.

2) Nimda worm simulation:

Propagation of Core Red worm was successfully analyzed using a simulated network [3] of 360,000 IP addresses. The simulation experiment was setup under two conditions: 1) the initial number of infected computer taken as 0 to simulate the normal condition without any worm attacks, and 2) the initial number of infected computers taken as 10 to simulate the worm attack condition. Figure 2 shows the normal ICMP activity, (i.e., no worm attack) represented as a scatter plot of scan vs. delta scan.

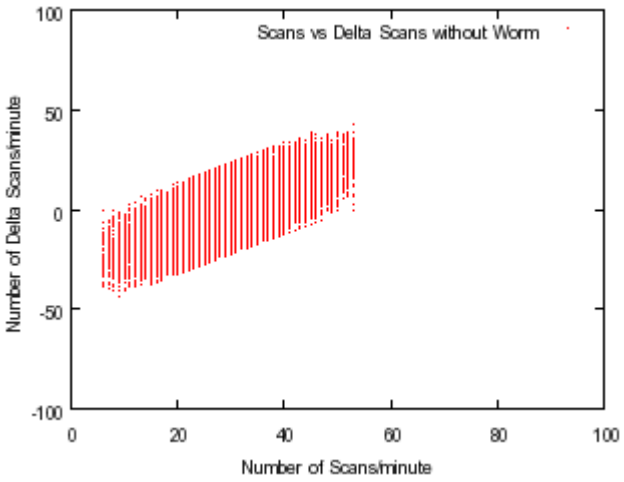

Figure 2. Scan versus Delta Scan without Worm

Figure 3 shows the simulated Code Red attack as a function of time. The figure shows that after a small incubation period, the number of infected computers increased exponentially.

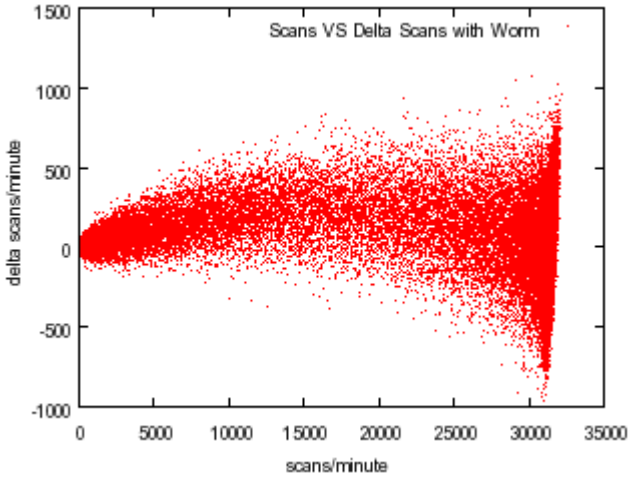

Figure 4. Scan versus Delta Scan with Worm Attacks.

Figure 4 shows the scatter plot of ICMP traffic following a simulated attack of Code Red worm. Clearly, compared to the normal network condition, the ICMP activity expressed as scan vs. delta scan grows by many orders of magnitude when there is a virus attack. In normal conditions, the boundary of the ICMP traffic scan plot would have been around the origin.

3) Data collected at Temple University Firewall

Network traffic data was collected using TCPDUMP at the Tempe University Firewall, which is the connection between the university Network and the Internet. Two sets of data were captured in the Spring of 2004: the first data set was captured inside the firewall to represent egress scan, and the second set at the external interface to represent ingress scan.

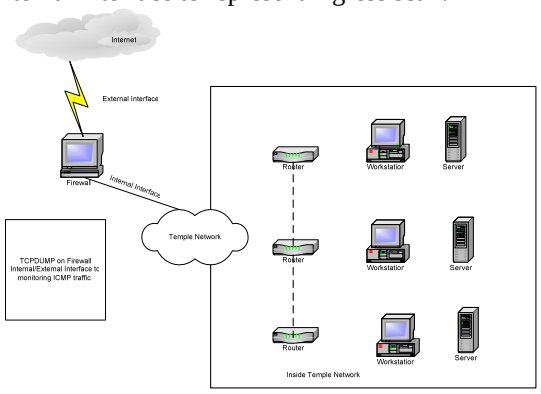

Figure 5.Topology of Capture Configuration on university Network.

On April 17, 2004, ICMP traffic data was collected from inside the university Network, which is represented in Figure 6 as a scatter plot of scan vs. delta scan. This figure shows that someone from inside the university network was sending ICMP sweeps, which was also confirmed by the university Computer Services. Periodic nature of the ICMP sweep was clear from the scatter plot of scan and delta scan which grows and loops back on a regular basis.

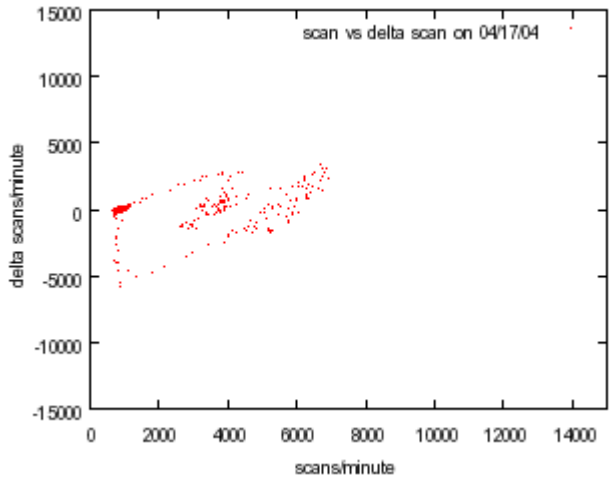

Figure 6 Delta scans versus scan on 04-17-2004

Temple University Computer Services noticed unusual network traffic from April 29th to May 7th. The scatter plot of May 1st ICMP data at the external interface is shown in Figure 7, which signifies a worm attack.

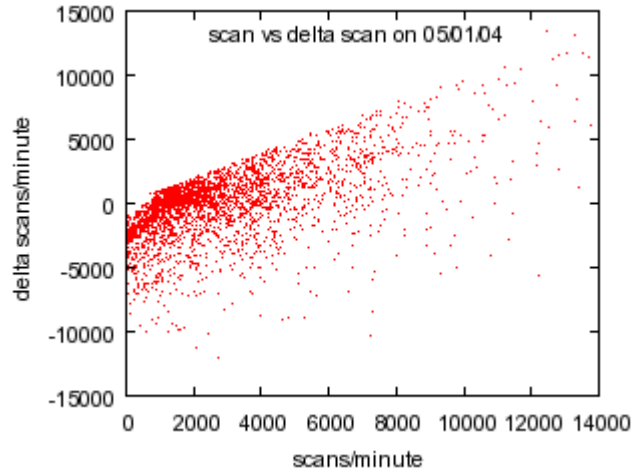

Figure 7. Plot of Scans and Delta Scan Outside university Network on May 1th 2004.

V. Conclusion

In this research, scatter plot of ICMP scan and delta scan was used to detect worm attacks on the Internet. We used three types of data: worm data from simulation of an epidemic model, simulated data of Code Red worm, and ICMP traffic data collected at Temple University firewall. In all three cases, it was observed that under normal network traffic condition, scatter plot of scan and delta scan remained confined in a small region near the origin, whereas when a worm attacks the network, the scatter plot grows by many orders of magnitude. This method presents a simple and effect way of designing an early warning system for worm attacks on the Internet. For worm detection, the network manager monitors the ICMP port scan data in real time, and plots in the port-scan plane on the computer monitor screen.

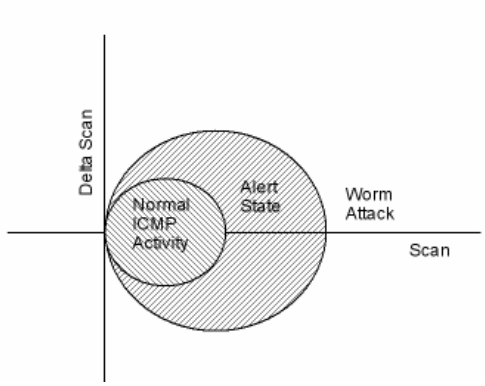

Fig 8 ICMP Port Scan Monitoring System for Worm Detection

The boundary of the normal port scan activity is determined from historical network data; an alert zone is set which could be about double the size of the normal zone. When the ICMP activity exceeds the alert zone, the network manager declares a worm attack. The size of the alert zone should not be too small or too big; a too small alert zone will cause many false alarms whereas a too large alert zone will miss actual worm attacks.

A Cost-Efficient Algorithm for Arbitrary CRCW PRAM Simulation

Martti Forsell
Platform Architectures Team, VTT Technical Research Center of Finland,
Box 1100, FI 90571 Oulu, Finland

***Abstract*—The arbitrary concurrent read concurrent write (CRCW) parallel random access machine (PRAM) is a very strong model of parallel computing. Direct realization of the model is not feasible with current silicon technologies but there exists a well-known indirect realization on a top of a physically distributed memory machine via simulation known as Ranade's algorithm. Unfortunately it requires expensive sorting networks prior to a combining network and takes at least two steps per reference. In this paper we propose a novel single step algorithm for arbitrary CRCW PRAM simulation based on processor-level filtering and combining. We apply the algorithm to our scalable MP-SOC framework and give early simulation results.**

I. Introduction

As the CMOS technology is approaching the nanometer domain computer architects and chip designers are facing hard challenges: Superscalar processor architectures relying on aggressive *instruction-level parallelism* (ILP) exploitation do not scale to future technologies due to quadratic increase of the area of the forwarding network and issue logic [1], increasing complexity of future chips is invalidating current single chip system design methodologies due to raising costs and longer time-to-market delay [2], clock frequency does not any more increase in pace with shrinking feature size due to raising power consumption per silicon area ratio [3], and power saving possibilities in single processor designs are limited due to small number of independent units. To overcome these problems major processor manufacturers, e.g. Intel, IBM, AMD, Sun, ARM, have made a radical change of paradigm from sequential computing exploiting ILP towards *thread-level parallel* (TLP) computing in which multiple threads are executed in multiple processor cores [4]. Unfortunately, foreseeable TLP designs rely on *symmetrical multiprocessing* (SMP), asynchronous *coarse-grained message passing* (CMP), or locality-aware *non-uniform memory access* (NUMA) that are either hard to program or provide poor performance in fine-grained communication intensive computations utilized e.g. in general purpose applications. This is because there is no support for fine-grained interprocess communication in SMP, a programmer has to explicitly take care of data and program partitioning, subtask synchronization, and communication in the CMP model, and cache coherency maintenance generates extensive traffic that slows down radically the communication channels in the NUMA model. The best candidate to eliminate these problems is an architecture providing explicit TLP computing and realizing a strong model of computing, e.g. the *parallel random access machine* (PRAM) model [5] since it guarantees synchronous operation at the model level, makes partitioning easy allowing a programmer to allocate shared variables from shared memory and map the subtasks to threads in an arbitrary way [6]. Unfortunately PRAM has turned out to be very difficult to implement [7, 8, 6]. Therefore it is now used mostly for exploring and analyzing the intrinsic parallelism of computational problems [9]. However, in our earlier investigations, we have described a way to implement the *exclusive read exclusive write* (EREW) PRAM model on a scalable *multiprocessor system on chip* (MP-SOC) architecture [10]. In EREW PRAM all threads can refer to the shared memory in parallel but at most one reference per a single memory location is allowed. The arbitrary *concurrent read concurrent write* (CRCW) PRAM is a variant of the PRAM model in which this limitation is lifted so that in the case of multiple writes to a location an arbitrary thread succeeds. It provides up to a logarithmic factor faster execution than EREW PRAM [11, 6]. Direct realization of the model is not feasible with current silicon technologies [8] but there is a well-known indirect realization on a top of a physically distributed memory machine via simulation known as Ranade's algorithm [12]. Unfortunately it requires expensive sorting networks prior to a combining network, assumes non-scalable network topology, and takes at least two steps per operation. In this paper we propose a novel single step algorithm for arbitrary CRCW PRAM simulation based on processor-level filtering and combining. We apply the algorithm to our scalable MP-SOC framework and give early simulation results.

The rest of the paper is organized so that in section 2 existing CRCW PRAM simulation algorithms are described. In section 3, we introduce our novel single step CRCW PRAM simulation algorithm. Evaluation of the algorithm on our MP-SOC framework is given in section 4. Finally in section 5, we give our conclusions.

II. Related work

Attempts to realize CRCW PRAM include Ranade's fluent machine [Ranade88], SB-PRAM [6], and still on-going investigations of the XMT framework [13] and Eclipse MP-SOC architecture [10, 14]. All these are based on simulation of a PRAM model on top of a physically distributed memory machine since the direct implementation of the PRAM model requiring P-ported memories has turned out to be infeasible since the area of the memories would be P^2 times larger than that of a single port memory of the same number of cells [8]. The central part of PRAM realization is the simulation algorithm requiring efficient latency hiding and congestion avoiding. So far the only known technique is to exploit parallel slackness in a form of multithreading to hide the latency: Assume that a parallel machine consists of P T_p-threaded

processors and P memory modules. Let a *step* of execution be a period of time during which all T_p threads of a processor execute a single instruction. Now, the latency of the network can be hidden if the memory system can process references before their reply results are used by subsequent instructions. Congestion of messages can avoided with a high probability by using a randomized hashing of memory locations [15].

The two ongoing projects do not present full realization of the CRCW PRAM model: Vishkin does not implement fully synchronous model but assumes that synchronizations happen less frequently [13]. In our previous work we describe a partial and limited CRCW PRAM realization for our MP-SOC framework [14]. It provides only a very limited number CRCW locations (e.g. eight per thread) and full concurrent access takes three steps. Ranade has presented an algorithm for randomized simulation of CRCW PRAM requiring only constant sized queues to store memory requests [12]. The algorithm is originally targeted for priority CRCW model selecting the data of the thread with a lowest ID in the case of concurrent write but implements also the arbitrary CRCW model if the secondary sorting based on thread numbering is dropped. The algorithm is based on a butterfly network and thus executes in O(log P) time. The algorithm describes routing of a reference targeted to address x and consists of six consecutive phases:

1. Inject and sort. All processors of each row, which want to access the shared memory, insert a request into the network. All requests within a row are forwarded towards the end of the row and thereby sorted according to their destination, which is the concatenation of hashed address *h(x)* and address x.
2. Route. All requests are routed to the row in which module $h(x)$ lies. During the routing, the sorted order is maintained, because each routing switch selects from its input buffers always the request with smaller destination if two requests are destined for the same output.
3. Find and access memory. Each request moves along the row until it reaches module *h(x)*, where the memory access takes place, and then moves to the end of the row.
4-6. Reply. These phases are only necessary for read and multiprefix operations and they reverse the movements of requests in phases 1 to 3. Thus, no routing decisions are made here.

A straightforward realization of Ranade's algorithm consisting of set of processing elements connected to each other via a bidirectional butterfly network has been proposed in [16]. Each processing element emulates a single PRAM processor and switch. An optimized version of Ranade's algorithm has been developed in the University of Saarbrücken [6]. It eliminates phases 3 and 4, replaces the networked sorting of phases 1 and 6 with hardware sorting arrays, and uses a latency hiding technique in which a processor emulates multiple virtual processors or threads. The algorithm has been realized as SB-PRAM prototype computer [6]. Unfortunately the butterfly topology that does not scale in the 3D physical word. It is however quite easy to implement these algorithms on scalable topologies like coated mesh or sparse mesh [17]. Another problem is related to the utilization of the resources, which is potentially low due to two-phase (sort-route) approach relying on combining of sorted references requiring at least two steps per operation. There exists no workaround for this since two-phase execution is a fundamental property of the algorithm. Finally, an implementation of a combining network with sorting networks is potentially expensive in terms of silicon area.

III. Proposed algorithm

Consider a baseline parallel machine for which there exists an EREW PRAM simulation algorithm. Such a machine consists of P T_p threaded processors and P memory modules interconnect by a high-bandwidth network, e.g. coated mesh, sparse mesh, butterfly, or hybercube [17]. We propose an algorithm for randomized arbitrary CRCW simulation on the machine executing always in single step with a help of a special hardware called step caches in which cache lines remain valid only until the end of ongoing step of multithreaded execution [18]. The principle of the algorithm is simple: Each time a processor refers the memory a step cache search is performed. In the case of a hit, a write is just ignored and a read is just completed by accessing the data from the cache. If the access address in memory is currently being accessed by an earlier reference, the thread waits until the data becomes available. This waiting does not normally degrade the performance since the processor is T_p-threaded and will execute other threads wile one is accessing memory. In the case of a miss, the reference is stored into the cache and set into pending state (for reads). At the same time with writing information to the cache line, the reference is sent to the memory system. When a reply arrives from the memory, the data is put into the cache and the pending state is cleared. Step caches avoid cache coherency problems since the references within a single step of multithreaded execution are independent by definition. Similarly, there is no need to write any data from a step cache to the memory since its content is always coherent. During a step a thread either refers to an internal step cache of the processor or to the external shared memory. An external memory reference is processed in seven parts:

1. Inject. This part injects the reference to a randomly selected switch of the processor superswitch of the reference network.
2. Route. This part routes the reference with a greedy algorithm to a randomly selected destination switch of the memory module superswitch in the reference network.
3. Eject. This part inputs the reference from the switch to the memory module.
4. Memory access. This part accesses the target memory module.
5. Inject reply. This part injects the possible reply to a randomly selected switch of the memory module superswitch of the reply network.
6. Route reply. This part routes the reply with a greedy algorithm to a randomly selected switch of the processor superswitch in the reply network.
7. Eject reply. This part inputs the reply from the switch to the processor.

The proposed algorithm will simulate arbitrary CRCW PRAM efficiently with a high probability assuming $T_p \geq O(P \log P)$ and memory banks are as fast as processors. Given the limited space, we will not present a mathematical proof of that but refer to simulation results of section 4.

IV. Evaluation

We evaluated the proposed algorithm by measuring the key properties of parallel execution of three two-component programs (see Table 1) mixing the CRCW and EREW memory access components in 0%-100% (ea), 50%-50% (ea+ca), 100%-0% (ca) ratio on three step cached systems (see Table 2) based on our sparse mesh Eclipse MP-SOC framework [10] modified to implement the algorithm with 4-way set associative step caches with step aware FIFO replacement policy (see Figure 1). For reference purposes we made similar measurements on similarly configured non-step cached systems and ideal shared memory systems.

ca	A parallel program component that reads and writes concurrently a given sequence of locations in the shared memory
ea	A parallel program component issuing a memory pattern extracted from random SPEC CPU 2000 data reference trace on Alpha architecture [20] for each thread.

Table 1. The program components that are mixed in 0%-100%, 50%-50%, and 100%-0% ratios to form three benchmark programs.

	E4	E16	E64	C4	C16	C64
Processors	4	16	64	4	16	64
Functional units	5	5	5	5	5	5
Bank access time	1	1	1	1	1	1
Model	EREW	EREW	EREW	CRCW	CRCW	CRCW

Table 2. The configurations of machines used in evaluation.

The benchmark program components were written in assembler. The concurrent component performs a series of concurrent reads and writes for each thread and the exclusive component performs memory patterns extracted from random SPEC CPU 2000 memory access traces on Alpha processor and shifted by a random constant for each thread. The two-component trace-based benchmarking approach was used to be able to determine the effect of concurrent memory access in various use cases and to overcome the practical limitations of the application development system. This kind of an evaluation method gives quite reliable on results on performance and usability of the proposed solution for a wide range of applications utilizing different degree of concurrent memory access. Since the actual SPEC programs are not likely to refer memory as often as the traces executed at the rate of one reference per step, the obtained results may be a bit too pessimistic for EREW-intensive cases. The measurements were made with a modified Eclipse simulator. For each evaluated benchmark-configuration pair we measured the execution time, step cache hit rate, and maximum latency of memory references. The results of measurements are shown in Figure 2. We can make the following observations from the results:

- The overhead of PRAM simulation in concurrent access is very low (even lower than in exclusive access) if there is enough threads while the overhead explodes close to the number of processors without the algorithm
- The step cache hit rates comes close to the fraction of ca benchmark component if the number of threads is high enough

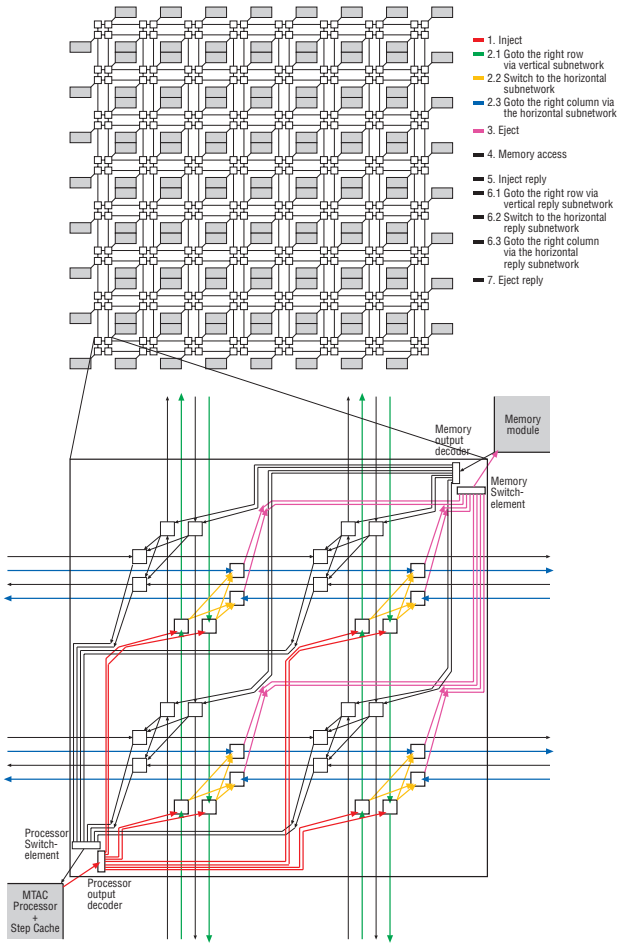

Figure 1. Algorithm applied to our MP-SOC framework with 64-processor architecture and routings.

- The maximum latency of memory references increases as the fraction of concurrent access increases for without the algorithm but decreases with the algorithm
- Changing the length of queues between 6 and 16 did not show notable effect on performance

We estimated the silicon area of the evaluated machines using our performance-area-power model for the family of MP-SOC architecture [19]. According to it the area overhead with respect to the baseline in typical MP-SOC configurations is less than 1%. Finally, we did not measure the execution times using the SB-PRAM variant of Ranade's algorithm but based on investigations about 30% of memory reads in general purpose code, like c-compiler, are dependent on the other instructions so that it is not possible to hide the delay by instruction scheduling 1]. Assuming that 2/3 of the memory references are reads, we estimate that a machine with the SB-PRAM variant runs about 20% (100%) slower than the proposed machine with (without) delayed load, respectively.

V. Conclusions

We have proposed a novel algorithm to simulate arbitrary CRCW PRAM with single step operations based on processor-level filtering and combining with a help of step caches. We applied the algorithm to our scalable MP-SOC framework and

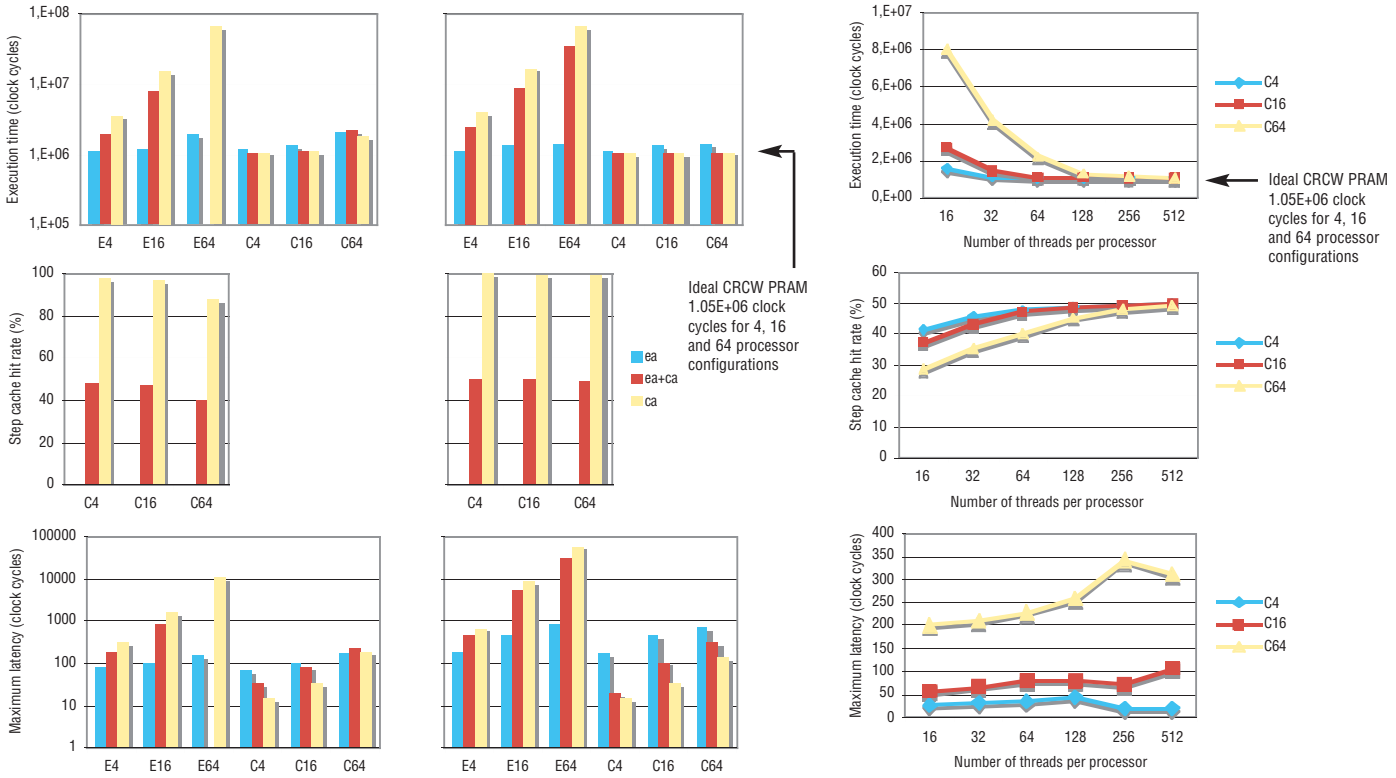

Figure 2. Execution time, step cache hit rate, and maximum latency for the baseline EREW architecture (E4, E16, E64) and modified architecture employing the proposed algorithm (C4, C16, C64) for 64 thread (left) and 512 thread configurations (middle) and in the ea+ca case (right).

performed early simulations. The results are encouraging: The proposed algorithm indeed implements the arbitrary CRCW PRAM model and the overhead of PRAM simulation for code employing concurrent access is even lower than for exclusive parallel access. Our future work includes extension of the proposed algorithm to slow memories and realization of priority CRCW PRAM using a modified version of the proposed algorithm.

***Abstract*- This research was inspired by the problem in parachute training program in the Thai military training curriculum. The normal training routine consists of a physical training unit which suspends the body of the trainee while the trainer rotates the training set according to the given instruction routine. The current training system does not sufficiently provide the trainee the realistic perception of parachute flight operation. The parachute training simulation system is proposed to be the low-cost interactive training platform that enhances user's perception of motion and control of the parachute. The simulation system consists of the graphical user interface module that displays and updates the 3D scene according to the physical model of the parachute and the control of the steering line by the user. The parachute training simulation system is designed for parachute control practice for ground descending mission in windy situation.**

Keywords : Parachute Simulation , Parachute Training

I. INTRODUCTION

Currently, the parachute training curriculum for military training are classified into 4 steps.

Step 1: The theory of parachute control.

Step 2: Training and testing of trainee physical performance.

Step 3: Ground-based training of parachute control skill which includes.

3.1 Jumping from 34 feet tower.

3.2 Jumping 2 and 4 feet stage .

3.3 Ground-based parachute control skill training

Step 4: Air-based parachute training.

In the current training curriculum, the problem usually occurred on step 3.3 as shown in Fig. 1 ,when the trainee is unable to perceive the realistic motion of the parachute which is controlled by the trainer e.g. the trainee will control the direction of parachute by pulling the steering line and the trainer will rotate the training stage accordingly.

(A) (B)

Figure 1. (A) Training Style ,(B) Tools for Training

The lack of realistic perception of motion and control in the existing training system caused the trainee to have insufficient experience in controlling the parachute and could lead to accident in the real air-based parachute training step.

II. CONCEPTUAL FRAMEWORK

A. The interative parachute training simulation system

Parachute training system in virtual environment have been developed and improved over years for the use in military [1][2][3][6] and for sport and entertainment applications [4] [6]. Hi-speed computer, Hi-definition sensors and Head Mounted Display (HMD) have been used extensively in these research. These equipment usage results in the high cost of these existing simulation systems. The interactive parachute training simulation system consists of two majors elements: the graphical user-interface technology (software) and the steering input system (hardware). The 3D graphical scene is created by an environment simulation engine based on the real-time physical based simulation of the parachute motion in the air and the head motion of the user. The motion of the parachute is controlled by the user from the steering input system. Therefore, we propose the low-cost alternative of the parachute simulation system which is much cheaper and only required commodity equipment such as LCD projector as shown in Fig. 2. The graphical viewing system have the structure as shown Fig. 3.

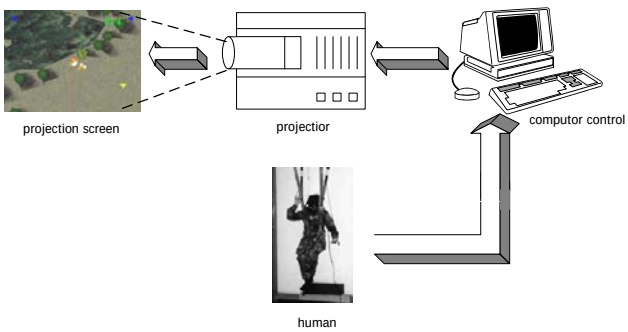

Figure 2. Design of Parachute Simulation System

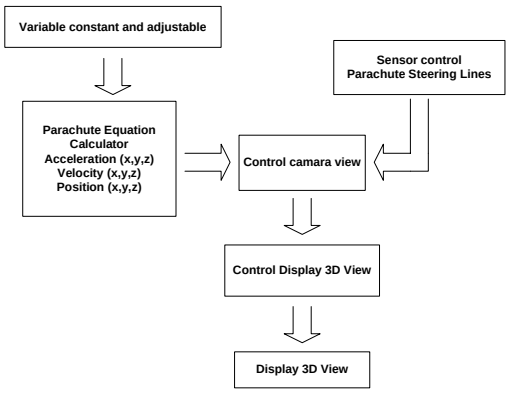

Figure 3. The design of a graphical viewing system

III. THEORY

A. Parachute physical based simulation

The motion of the parachute can be explained as 5 states as shown in Table 1 [8]. Parachute jump starts from the beginning of the jump until the point where the parachute is fully inflate and finally descend to the ground as shown Fig. 4 .

Table 1.
Function of Parachute Full Inflates [8]

	Time	Body	Status of Situation	Remark
1	$t \leq t_0$	Horizontal position	Freefall	
2	$t_0 < t \leq t_1$		Lines Extend	$t_1 - t_0 = 0.5$ sec
3	$t_1 < t \leq t_2$	Vertical position	Parachute Inflates	$t_2 - t_1 = 1.0$ sec
4	$t_2 < t \leq t_3$		Parachute Over Inflates	$t_3 - t_2 = 1.7$ sec
5	$t > t_3$		Final Descent	

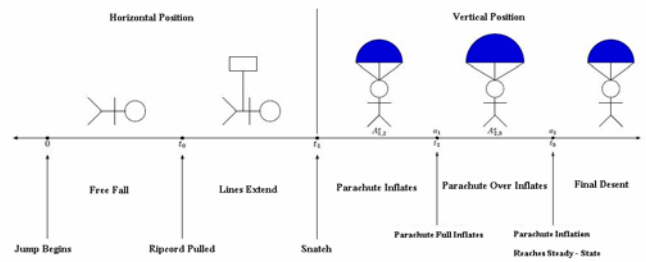

Figure 4. The 5 states of parachute jump cycle

Motion of parachute is affected by the gravity force: F_g. and the drag force: F_d. The sum of these forces are shown in (1).

$$\sum F = F_g + F_d \tag{1}$$

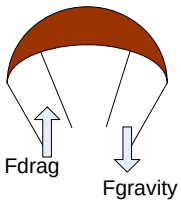

Figure 5. Forces affecting on the parachute

From these states of parachute jump cycle, the drag force is defined in (2). However, base on the condition of parachute jump, there are other factors that affects the forces acting to the body and the equipment which is given in (3).

F = total force, F_g = gravitational force, F_d = drag force, C_d = coefficient of drag, C_d^b = drag coefficient of skydiver body, C_d^e = drag coefficient of skydiver equipment, ρ = density of air flow, A^b = area of skydiver body, A^e = area of equipment ; $A_{1,2}^e$ on (t_1,t_2); $A_{2,3}^e$ on (t_2,t_3), h = height of jumper, H = height of jumping, a_1 = area of parachute, L = length of parachute lines, b_0 = area of body in horizontal position, b_1 = area of body in vertical position, m= weight of jumper include weight of parachute body, *v* and *a* are velocity and acceleration of the body.

$$F_d = \frac{1}{2}\left[C_d A \rho v^2\right] \tag{2}$$

Acceleration is given by the equation derived from sum of the force on the parachute body as in (4). Value of k in (4) derived from value of resistant force occurred from parachute body in (5).

$$F_d = F_d^b + F_d^e = \frac{1}{2}\rho\left[C_d^b A^b + C_d^e A^e\right]v^2 \tag{3}$$

$$a = \left[-g + \frac{kv^2}{m}\right] \tag{4}$$

$$k = \frac{1}{2}\rho\left[C_d^b A^b + C_d^e A^e\right] \tag{5}$$

The value of k is different at each state of the process of each as shown in (6). The velocity of the parachute in (4) can be calculated by (7).

$$k = \frac{1}{2}\rho\begin{cases} 1.95b_0 & , t \leq t_0 \\ 1.95b_0 + 0.35b_1 l\dfrac{t - t_0}{t_1 - t_0} & , t_0 < t \leq t_1 \\ 0.35b_1 h + 1.33A_{1,2}^e(t) & , t_1 < t \leq t_2 \\ 0.35b_1 h + 1.33A_{2,3}^e(t) & , t_2 < t \leq t_3 \\ 0.35b_1 h + 1.33a_1 & , t > t_3 \end{cases} \tag{6}$$

$$v(t) = \eta\left[\frac{1-e^{-\sigma t}}{1+e^{-\sigma t}}\right] \quad ,v(0) = 0 \tag{7}$$

when, $\eta = \sqrt{\frac{gm}{k}}$ $\quad ;\sigma = \frac{2\eta k}{m}$

B. 3D graphical viewing system & steering and head motion input system

3D graphical view rendering system is developed in C language using OpenGL library. The scene is updated from the viewpoint generated from the parachute equation of motion as shown in the previous section. The 3D graphical scene when the parachute descending is tested by rendering a 3D cone on the ground plane at various positions as shown Fig. 6. Steering and head motion input system is the electronic device that senses the motion of the steering line when the user pulls the steering line of the parachute in order to control the parachute and sense the head motion of the user . For the low-cost version of the parachute simulation system, potentiometers are mounted at the pulleys connected to the steering lines and the body-head suspension support. The potentiometer senses the motion of the left and right steering line then the data is used to update the physical based simulation of the parachute. The design of the low-cost parachute training simulation system is shown in Fig. 7.

Figure 6. Test of the 3D viewing System together with the steering and head motion input systems

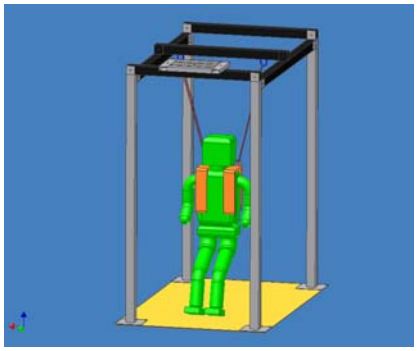

Figure 7. The model of low-cost parachute training simulation system

When the user pulls the steering line, it will cause the rotation motion of the parachute toward the pulling direction. The force equation of the parachute in (2) is modified by the angle of rotation caused by pulling the steering line(ϕ) and the turning radius (R) as described by (8) and (9) as show Fig.8 v and ω is the linear and rotational velocity of the parachute body.

$$\omega = \frac{g \times \tan\phi}{v} \tag{8}$$

$$R = \frac{v}{\omega} \tag{9}$$

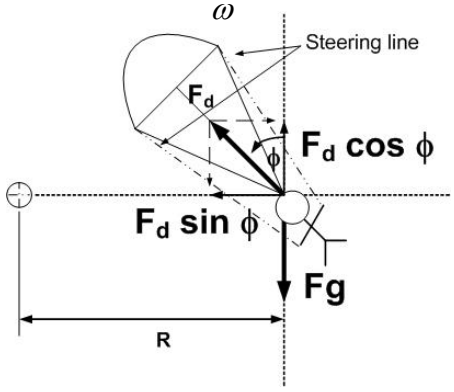

Figure 8. Parachute turning with the steering line control

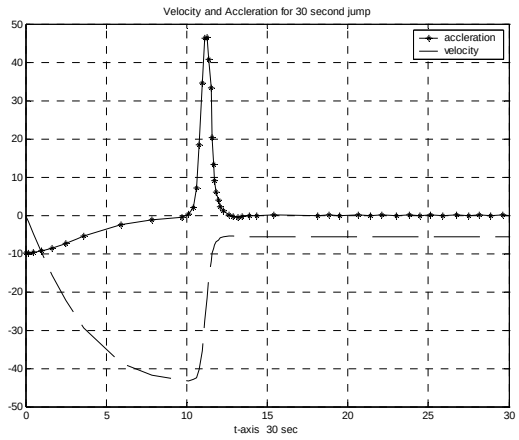
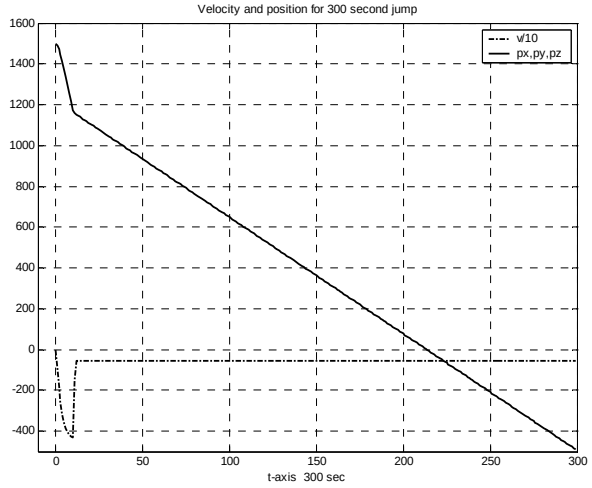
IV. SIMULATION RESULT

The parachute model MC1-1C is used in this simulation. The MC1-1C model has the area of parachute (a_1) = 43.8 m^2 , length of parachute lines (L) = 8.96 m , area of body in horizontal position (b_0) = 0.5 m^2 , area of body in vertical position (b_1) = 0.1 m^2 , height of jumper (h) = 1.78 m , weight of jumper include weight of parachute body (m) = 97.2 kg , height of jumping (H) = 1,500 m (≈ 4922 ft). The simulated jump begins from time t_0 until the final decent at time t_3 as shown in figure 3.2. Different states of jump is defined by time: t_0 to t_1 = 0.5 second (Lines Extend) , time: t_1 to t_2 = 1.05 second (Parachute Inflates) , time: t_2 to t_3 = 1.7 second (Parachute Over Inflates). Take these values into parachute equations (4), (7) which can find the answer by using mathematical analysis program (MATLAB) as below Fig. 9.



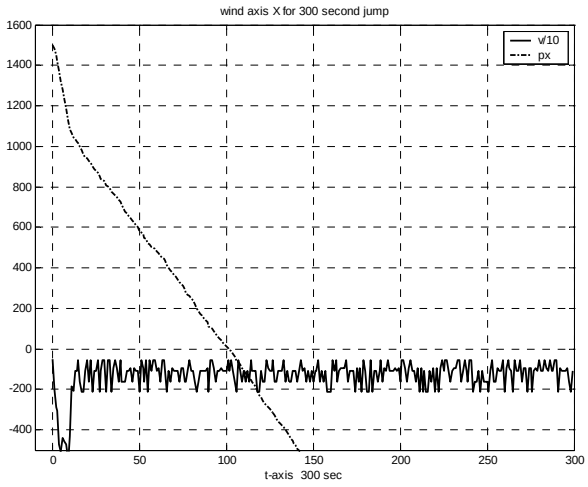
(a)



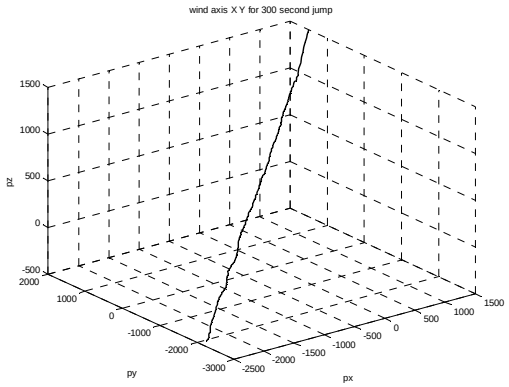
(b)

Figure 9. (a) Acceleration and velocity of parachute movement
(b) Position and velocity of parachute without external wind forces

In order to simulate windy situation necessary in parachute training exercise, the wind force is added into the parachute equation of motion. The wind force is added in axis X and Y. We can observe that when the wind force is added, the wind force directly affects the velocity and the position of parachute as shown in Fig. 10.



(a)



(b)

Figure 10. (a) Position and Velocity of parachute when the wind force is added in X axis (b) Position of parachute when the wind force is added in both X and Y axis

V. CONCLUSION

The low-cost parachute training simulation system consists of the physical based simulation of the parachute motion and the user interface subsystem including a 3D graphical viewing system and the steering & head motion input system. The physical based simulation of the parachute is tested with and without external wind force. The next step of this research is to test the overall performance of the low-cost parachute training system whether it can improve the skill of the trainee for ground descending mission in windy situation.

Separation of Concerns in Modeling System Software for Automate Code Generation

Paniti Netinant
Computer Sceince Departmnet
Bangkok University
Bangkok, Thailand
paniti.n@bu.ac.th

Abstract

Aspect-oriented programming is a new paradigm that complements the object-oriented technology. The premise of aspect-oriented technology is the separation of concerns. Certain system properties tend to cut across group of functional components such as concurrency, security, and fault tolerance are examples of these crosscutting concerns. Aspect orientation attempts to modularize these crosscutting properties in order to avoid the code-tangling phenomena. Objects are independent entities that cooperate together t0achieve a certain task, how can we mange object interaction without violating basic object orientation principles like abstraction, what triggers an object to perform its functionality, what constraints that an object must consider before performing its task(s) are, how an object behavior impacts other object(s) behavior, how we can model our aspect oriented system with all the above questions in mind using existing CASE tools and guarantee separation of concerns at the implementation (automatic code generation).

In this position paper presents a formal methodology that addresses the above questions and supports separation of concerns for system software. The paper demonstrates aspect-oriented framework applying at the design and implementation phase with separation of system properties. Our approach uses CASE tools supporting UML without any extensions to it. Rhapsody CASE tool has been used to model and automatically generate code since it supports UML diagrams which enable us to present different views using different UML diagrams (OMD, SD, Statecharts, and Use Case diagrams).

1. Introduction

Recent advances in the software technology have reaffirmed the need for building component-oriented software systems. Object-oriented technology has delivered sound results regard supporting code reuse, and design patterns have demonstrated that large-scale software systems can benefit the most from the best documented design structures. Despite the tremendous success of object-oriented technology and design patterns to support code reusability and design reusability, little has been said regard the separation of concerns within the context of these technologies. Recent research in the separation of concerns has demonstrated the need for the separation of the functional requirements from the non-functional requirements in order to maximize code reuse and design reuse; non-functional requirements tend to cut-across the functional components. Till now aspect-oriented technology has offered very little to support the system engineer with a formal modeling technique in order to verify and validate the system design against its requirements. Experience shows that verification and validation of concurrent software systems is the most time consuming process in the software lifecycle. Modeling the behavior of concurrent software system based on aspect-orientation attempts to shorten this interval and improve software quality. The UML [1, 2] is a graphical language for specifying, visualizing, constructing, and documenting the artifacts of software systems. UML is a standard modeling language endorsed by Object Management Group (OMG) in 1997 as UML 1.1. UML is the graphical notation that defines the semantics of the object meta-model (model of UML itself), and defines a Notation for capturing and communicating object structure and behavior. UML relied heavily on (and support) Finite State Machines, UML state machine model is based on David Harels Statecharts.

Our research is bout bringing a formal methodology to automate the implementation of concurrent software systems based on aspect-orientation. In our modeling approach we distinguish between static, dynamic, inter, and intra object behavioral modeling. We believe that automatic code generation is only possible with intra object behavioral modeling, we use statecharts to describe the behavior of each object in the system, we also address inter object communication via both awareness of object state changes and message passing. An important element of a sound behavioral modeling approach is a rigorous methodology that ensures the semantics of the constructed model based on requirements. These models can be used to automatically generate code and guaranteeing that the generated code confirms to Aspect oriented principles, by that we mean separating aspectual components from main functional components at the generated code. Concurrent software systems are composed of functional requirements and concurrency requirements, like synchronization constraints, and scheduling policies. Aspect-oriented technology is an ideal solution for modeling such systems, since the distinguishing between aspects and functional requirements is at the heart of such technology.

What motivated our work is the need for a complete end-to-end requirement modeling technique that will guide the designer in the design of concurrent software systems and automate their implementations. Behavioral modeling based on requirements is the first step toward formal design methodology based on aspect-orientation.

2. UML

The UML [1, 2] is a graphical language for specifying, visualizing, constructing, and documenting the artifacts of software systems. UML is a standard modeling language endorsed by Object Management Group (OMG) in 1997 as UML 1.1. UML is the graphical

notation that defines the semantics of the object meta-model (model of UML itself), and defines a Notation for capturing and communicating object structure and behavior. UML is suited for modeling real-time and embedded systems. UML relied heavily on (and support) Finite State Machines, UML state machine model is based on David Harels Statecharts.

In UML objects have both structure and behavior, objects work together to implement higher-order behaviors defined in Use cases. UML allows software engineers to analyze and design software systems using standard object-oriented techniques, the main UML tools for analyzing the system are: Use case diagrams show general interactions between the system and external objects/actors who may want to interact with it. Sequence Diagrams show sequences of steps and messages passed between objects when executing a particular instance of a use case. Object model diagrams show the static structure of the system in terms of classes and objects, and define relationships between these objects. Statecharts [2, 9, 10, 11] define the behavior of objects, including the various states that an object can enter into over its lifetime and the messages or events that cause it to transition from one state to another. A state in a state chart is an abstraction of the model in which the object finds itself [2, 3]. A message (such as an event) can trigger a transition from one state to another. A message can be either an event or a triggered operation.

The benefits of modeling have been outlined in the literature [1, 2]. Why do we model? UML introduction [1] outlines the following benefits: Provide structure for problem solving, Experiment to explore multiple solutions, Furnish abstractions to manage complexity, reduce time-to-market for business problem solutions, Decrease development costs, and manage the risk of mistakes. Benefits of modeling Aspect oriented systems also been examined by the researchers, [3] stresses that capturing aspects at the design phase streamlines the process of aspect orientation development; it helps learning and documenting aspects. [4, 5] also outlines that capturing aspects at the design phase makes round trip development possible of aspect orientation systems, and helps to maintain consistency of requirements, design, and implementation. We in this paper also argue that when aspects are identified at an early stage of the development life cycle it makes there design components more Reusable, and it makes automatic code generation possible for AO systems with higher levels of separation of concerns at the generated code.

3. Our Approach

Modeling concurrent software systems with sequence diagrams and class diagrams will not be enough to achieve a full implementation of the system behavior. Sequence diagrams will describe the inter object behavior, it will help in describing scenarios for the system, how objects will interact with each other, but will not allow zooming into the object itself to describe its behavior, for that we need statecharts. Statecharts provide the behavior of a particular object including various states that an object can enter into over its life cycle. As stated in [7, 9, 11] statecharts are mainly used to describe intra-object behavior versus inter object behavior which can be specified using MSCs or Sequence Diagrams. Avery distinguishable characteristic of Statecharts from MSCs or Sequence Diagrams is the fact that Statecharts are part of the system model, which means they can be used to generate code.

Statecharts show the states of an object within a given context, the events that causes an object to go from one state to another, and the actions that can occur as a result of a state transition. Events could be guarded by conditions, which must evaluate to true before a transition takes place. During the object's life cycle an object move from one state to another, and produce some actions as a result of this transition, this is how the behavior of an object should be described and Statecharts does that. Modeling concurrent systems based on aspect-orientation is a new approach that has many benefits: reusability, verification and validation, and automate implementation. UML/Statecharts are used mainly to model the internal behavior of concurrent objects, though this formalism of modeling needs to support aspect orientation. In this paper we outline a modeling standard for concurrent systems based on Aspect-orientation.

Within concurrent objects, state transitions may occur if a method is invoked or a timer expired. Associating aspects that are evaluated when an object method is invoked is a troublesome for system modeler and developer, since the specification and constrains of these aspects are state dependents. For example, in the case where we have a bounded buffer with certain capacity and two methods put and get, we shall allow only put method to proceed when the buffer is an empty state and allow either put or get when we are in a partial state. Synchronization constraints and Scheduling specifications are the main aspects that influence the execution of the invoked methods based on object states. Being able to express the concurrent object behavior as StateChart and augment that by notation that allows the modeler to express aspects explicitly within the models is a step forward to automate the implementation of such systems.

3.1. Aspect Oriented Framework

The Aspect Moderator [13, 14, 15] is a framework-based solution for building concurrent software systems. In this framework, a concurrent system is represented as a cluster of co-operating objects that handle the creation of aspects as well as the interaction between components and aspects. Both analysis and design phases can be studied during two stages of operation: initialization and method invocation. A number of design principles have been taken into account while designing this framework, the first of which is to separate functional from non-functional requirements, and identify cross-cutting concerns (aspects). A functional component provides services. Those services that are associated with some aspectual behavior are referred to as participating services. Each aspectual behavior for each service of each method is extracted from the main functionality and it is treated as a separate concept in the conceptual model of the system.

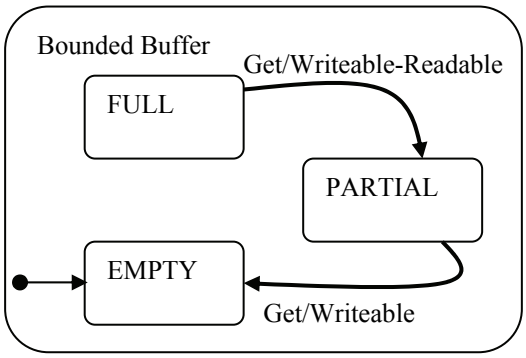
In a concurrent system, a number of services (methods) in a concurrent class will be associated with synchronization constraints. During initialization, the proxy to the functional component will request from the aspect_factory the creation of aspect instances that capture the synchronization constraints associated with services (methods) of the class. Aspect instances implement the aspect-interface which is defined by two methods: precondition( ) and postcondition( ). During design, it is important to identify possible design patterns that might meet any architectural needs. During initialization the Factory Method pattern [16] can be used to create the required aspects for the participating methods of the functionality class. All aspect objects implement the AspectIF interface. The overall class diagram of the Aspect Moderator framework is shown below.

Our work is needed To complete the AM Framework and makes it acceptable by automatic code generators, we will address in this paper issues that are essential to automatic code generation, we need to describe the dynamic behavior of the AM framework objects, we will use statecharts to capture the behavior of the objects in the AM Framework. And we will use state notification mechanisms [6] to describe the coordination and interaction among these objects. [Harel, Executable object modeling, IEEE 1997] states that statecharts can be used to describe both objects communication and objects internal behavior.

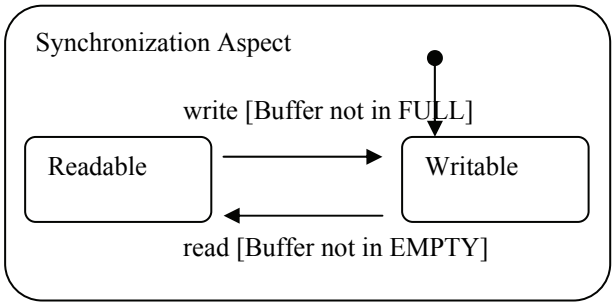
3.2 Applying Our Approach

Our solution relies on the statechart semantics where object state changes are detected by other objects (state notification). When objects behavior is dependent on other objects states, it is essential that objects share their state to other object since this will impose a certain behavior on these objects. State notification [6] allows an object to monitor and synchronize with state changes of other objects. Our approach will not dedicate an object to coordinate object interaction, instead all objects will participate to achieve the coal at hand and to manage the coordination of each other states. Our approach supports the aspectual behavioral modeling for concurrent software systems, we will apply Aspect Oriented at the design phase with object coordination in mind, we guarantees separation of concerns at the implementation. We will apply our approach to the Aspect Moderator Framework described in section 3. We will try to build a complete behavioral model for the AMF using statecharts. We will use advanced features of staecharts to 1st assist in modeling complex dynamic behavior, 2nd describe communications between AM Framework classes, 3rd isolate control from functionality. We will feed the model in any existing CASE tool (Rhapsody) and the output will be classes and interfaces that observe the architecture of the AM Framework.

In this paper we present the Bounded Buffer as a case study. In modeling the behavior of the Functional Bounded Buffer we can control the states of the Synchronization Aspect from the Bounded Buffer state machine, for instance when the Buffer transits from FULL to PARTIAL state as a result of get event we set the Synchronization Aspect state to Writeable-Readable as follows: *Get / [set Synchronization Aspect to Writeable-Readable]*, the buffer state machine is outlined below:



In the AM Framework requests comes in (i.e. from Producers and consumers) to the system and get intercepted by the Aspect Moderator which has a state machine that is dependent on the Synchronization Aspect states described below:



We will use message between the AM and the Synchronization Aspect, and the Buffer regions, by default the message addressed by the synchronization Aspect.

4. Future Work

The next step in our project to start applying the constructed model into existing CASE tools like Rhapsody. Also more work is needed to apply our approach to other Aspect oriented techniques other than the Aspect Moderator Framework.

5. Related Work

Behavioral modeling is getting more attention from researchers as well as practitioners since system engineers and designers describe the system requirements based on the expected system behavior. Modeling concurrent system behavior based on statecharts [7] is the first to address the issue of verification and validation of concurrent object-oriented systems. Though the approach suffers from code-tangling phenomenon where concurrency code is intermixed with the functionality code. UMLAUT is a recent approach based on aspect-oriented modeling that addresses the separation of concerns early in the design phase, though this approach didn't address the intra-object interactions. Our approach addresses aspect-oriented modeling for concurrent systems based on extension to statecharts in order to automate the implementation for such systems. [3] outlines the benefits of capturing aspects in the design phase rather than the implementation phase,

these benefits includes: streamlining the process of aspect orientation development, reuse of aspects, and round-trip development. [4] also stresses on the importance of supporting aspects throughout the development life cycle. In [5] extends the UML metamodel to support subject-oriented and focuses on extensions to UML metamodel to support AO. In [6] Stresses that UML has to be extended to support multi-dimension separation of concerns other than the object dimension. In [7] From Play in Scenarios To Code, argue that automatic code generation only possible with intra object behavioral modeling, inter object behavioral modeling allows us to capture the requirements and are not part of the system model and can't be used to generate code. This approach didn't address AO or SoC. Most of these approaches didn't address behavioral modeling and Automatic code generation, some require developing new tool other require extending UML metamodel to support aspects. We think neither extending UML nor developing a new translation tool is needed to support aspects in the design phase.

6. Conclusion

Aspect-oriented approach is the next wave of development for software systems. This paradigm stresses the separation of the ascpetual code from the functionality code in order to maximize code reusability and minimize changes that are due to code-tangling. Behavioral modeling based on statecharts are getting more popular since it addresses modeling the system behavior early in the design stage and automate the implementation of such systems. Our approach is an aspect-oriented modeling technique that uses statechart constructs like and/or states to describe the coordination between objects in concurrent software systems. We applied our modeling technique to the Aspect Moderator Framework. Our approach supports the aspectual behavioral modeling for concurrent software systems, by applying aspect-oriented techniques at the design phase with object coordination in mind. We present an approach that guarantees separation of concerns at the design and implementation phase.

***Abstract*-Multidimensional Binary Clustering Tree (MBC Tree) is an algorithm that adapts the Multidimensional Binary Search Tree (Kd-tree), which is generally used in nearest neighbor search problem for the use of surface simplification whereas a surface is generated from a cloud of points in 3D space. MBC Tree is an algorithm for data clustering. The algorithm separates data along chosen axis and splits them with their centroid. This paper aims to compare the effectiveness of divisive hierarchical clustering (DHC) and MBC Tree for point cloud simplification. The experimental results show that MBC Tree is faster than DHC and its algorithm is easy to implement. MBC Tree is also capable of producing high-quality surface approximations.**

I. INTRODUCTION

Surface simplification is used to reduce a geometric description of point-sampled surface in order to produce a new description that is similar in appearance to the original and that has fewer geometric primitives [1] helping to speed up the rendering process, especially for real-time rendering. Surface simplification algorithm can be broadly categorized into 3 classes: Vertex Decimation, Vertex Clustering, and Edge Contraction [2], which each class has its own quality and different disadvantages.

From their research [3], Pauly et al. present various algorithms for surface simplification and also show their efficiency. The algorithms, such as, Incremental, Divisive Hierarchical Clustering (DHC), Iterative Simplification, and Particle Simulation are listed in their paper. From this research, the surface simplification with the DHC algorithm takes the least amount of time in processing, while the iterative simplification algorithm can produce higher quality surfaces.

In our paper, we present our surface simplification algorithm, which we call our algorithm the Multidimensional Binary Clustering Tree (MBC Tree). The algorithm is categorized as a data clustering algorithm and is adapted from the Multidimensional Binary Search Tree (Kd-tree), which is generally used in nearest neighbor search problem. It works directly on sampled-point cloud and no filtering preprocess is required on the input sample points. In our paper, we also compare the efficiency of the MBC Tree algorithm with of the DHC algorithm. We find that the MBC Tree algorithm is faster than DHC algorithm, and can also procduce a good quality surfaces.

II. MULTIDIMENSIONAL BINARY CLUSTERING TREE

Multidimensional Binary Clustering Tree (MBC Tree) is adapted from Kd-tree [4], and MBC Tree algorithm is to separate sampled-point data along the chosen axis and splits them with their centroid.

1) (Initial step) Put all points into a single cluster. A user-specifies cluster size n and split axis k and $k \in \{0, 1, 2\}$ where a value of 0, 1, and 2 means the aligned axis X, Y and Z respectively.
2) Create parent node of the tree by using a centroid of cluster as the node value.
3) Create child nodes by dividing points in parent node into two subcluster along axis k.
   3.1) Left child node is a subcluster that contains points of which have value of axis k less than or equal to value of axis k of parent node.
   3.2) Right child node is subcluster that contains points of which have value of axis k more than value of axis k of parent node.
4) Increment k (k = (k+1) mod 3)
5) Repeat step 2-4 until size of the cluster less than or equal to the user-specified cluster size n.
6) For each cluster, compute its centroid and use the centroid as a new simplified point.

Figure 1. MBC Tree Algorithm

As shown in Figure 1, our algorithm starts by taking a user-specified cluster size and a split axis and then creates a tree with two major differences from Kd-tree as follows:

1) Parent node of Kd-tree is come from a median of sorted data, while MBC Tree uses data centroid as a value of the parent node.

2) Kd-tree repeatedly subdivides point data until each data point becomes a leaf node in the tree, while MBC Tree repeatedly subdivides point data until the leaf node has the number of points less than or equal to the user-specified cluster size.

III. METHODOLOGY

As data input, we use 3D points sampled from a real surface using a modern 3D scanning device. We then compare efficiencies between of the MBC Tree and of the DHC algorithm by measuring the time spent for point simplification process and surface quality. We measure the quality of surfaces by using Metro [5] which can measure distances between two surfaces. We perform MBC Tree and DHC algorithms on point clouds of different sizes as well as different cluster sizes. We conduct our experiment as follows:

For the first part of our experiment, we use point clouds of difference sizes as input into both MBC Tree and DHC in order to run these two algorithms with fixed cluster size of 10 points to produce new simplified point clouds.

For the second part, as an algorithm input, we use the fixed size point cloud of Buddha that has 543,652 points and variable cluster sizes of 5, 10, 15, 20, and 25 points. We also run both algorithms on these data sets to produce simplified point clouds.

For the last part of our experiment, we use Tight Cocone algorithm [6] to produce surfaces from original point sets as well as simplified point sets obtained from the first part and second part of our experiment. By using Metro, we measure distance between these surfaces: one created from an original point set and another created from a simplified point set.

IV. EXPERIMENTAL RESULT

Figure 2 (a) shows time spent in point simplification process using MBC Tree and DHC algorithms; the input data are point clouds of various sizes of sample points. The cluster size for these algorithms is a size of 10 points. The experimental results show that MBC Tree outperforms DHC on all input data.

Figure 2 (b) also shows time taken for MBC Tree and DHC algorithms to simplify points where the point set is a Buddha point cloud containing 543,652 points. We use various cluster sizes of 5, 10, 15, 20, and 25 points on the algorithms as the results are shown in the figure. The results also show that MBC Tree outruns DHC on all cluster sizes.

In the last part of our experiment, we use Metro to measure distance between a surface created from an original point set and a surface created from a simplified point set. The measurements are shown in Table I. The table shows values of maximum distance (Max.) and average distance (Avg.) between original point-sampled surface and point-simplified surface. The table also shows that maximum distance and average distance measured from surfaces simplified by MBC Tree algorithm are slightly different from ones simplified by DHC algorithm.

Figure 3, 4, and 5 shows a visual measurement of quantitative error for Bunny, Armadillo and Dragon point clouds, where the magenta highlights on the point-simplified surface indicate the areas of differences from the original point-sampled surface.

V. CONCLUSION

The MBC Tree is algorithm for point simplification which can be used for an unstructured point cloud sampled from a real surface using a 3D scanning device. The algorithm is easy to implement. Our experimental results show that the MBC Tree is faster than DHC and capable of producing good quality surfaces.

ACKNOWLEDGMENT

This work is supported by the Department of Computer Science at Kasetsart University. Input data sets, used in this project, come from various sources. The bunny, Buddha, dragon, and armadillo point sets are courtesy of the Stanford Graphics Lab. The horse, skeleton hand, and blade point sets are courtesy of Georgia Institute of Technology. We would like to thank Tamal K. Dey for providing us his Cocone software to be used for surface reconstruction.

***Abstract*—Traditional forecasting methodologies use historical data for predicting future values. However, using only historical data does not guarantee accurate prediction results. It results in incomplete matching between historical and real target space due to the effect of pattern shifting. In this paper we propose a way to lessen this problem by analyzing the output component base applying support vector regression model (SVR). This applied method can give more general accurate prediction than traditional SVR model.**

I. INTRODUCTION

Solving a prediction problem is a critical task in those real-world applications where accuracy is strictly related to the management of economic resources. The price to pay in this case is usually an increased complexity of the computing system. Thus, the trade-off between cost and benefits must always be taken into account. [1]

A prominent time series model like Autoregressive Integrated Moving Average (ARIMA) model was introduced by G. Box and G. Jenkins in the early 1970s [2]. This time series analysis is attractive because it can capture complex arrival patterns, including those that are stationary, non-stationary, and seasonal (periodic) ones [3]. This elaborate and nice crafted technique requires an advanced level of knowledge, labor-intensive tasks, and sophistication only available from specialists [4]-[6]. However, it is more suitable if one who does not familiar with complex forecasting models can use a simple equation like applied exponential smoothing model for forecasting. [7]

In case of advance methods, artificial intelligences are alternative good techniques that can be applied in forecasting by using of prior distributed data learning. The main methods are Bayesian, fuzzy models, and neural networks.

Bayesian method assumes that past data follows a particular probability distribution [8] with simple formula can provide a good prediction. However, it requires a substantially larger inventory investment. This is much more complex and expensive [4] and impacts the risk averse pattern is not good enough [9]. Fuzzy models are particularly well suited for human decision making. Most fuzzy applications are popular in control and engineering, and even larger potential exist in business and finance [10]. Neural networks are very efficient adaptive forecasting models and superior to time series because of their excellent performances of treating non-linear data with self learning capability. However, with the effects of "black box," slow convergence, local optimal solution, it occasionally produces some very wild forecasting values [5] which strongly limited its applications in practice [11]. If the training dataset does not cover the full range of operating conditions, the model may perform badly when deployed [12]. Hybrid systems can be applied to overcome these drawbacks. The result gives better than any single algorithm, or sometimes very similar to the best prediction method [19].

Studying the historical background of abnormal behaviors of patterns is effective in prediction. Dealing with unusual, there are some effects when data are not applicable to an entire range of applications. Special neural networks and prediction systems need to have an individual standard as well [13].

Windowing is a method to discover optimal local patterns, which concisely describe the main trends in a time series at multiple time scales. It can capture meaningful patterns in a variety of settings [14]. Also, an internal structure within the time series data can be used to improve the performance [15]. In some cases, a large fraction of the training data can be discarded to improve the performance while maintaining high accuracy [16].

Some forecasting methods, such as neural networks and ARIMA model, which are based on historical data, cannot find out the hidden remarkable features or signal decomposition behind the data. Forecasting is not based on only historical data but also the understanding of the significant factors hidden in the data; thereby it greatly improves the forecast accuracy [17].

Some disadvantages of NNs, such as the ease over training or the lack of training data, the ease of relapse into local minimization, have not been solved until 1995, when Cortes and Vapnik [18] introduced a new theory named Support Vector Machine (SVM). This concept is applied to a regression model for approximate prediction, and it was named Support Vector Regression (SVR).

The successful impact of forecasting is tied directly to the one's need, understanding, and involvement for forecasts. In this paper, we propose Output Component-Based Support Vector Regression (OCB-SVR) model, applied-SVR model with, a technique for mapping better prediction in jittering domain between the historical space and target space.

The remains of this paper are organized as follows. In Section II describes the OCB-SVR model. Finally, concluding remark discussions and further studies are given in Section III. Finally, Section IV concludes the study.

II. OCB-SVR MODEL

The OCB-SVR model proposed herein is derived from the fact that the time series data with the pattern $trnX_i$ in Historical space (H-space) may be different both shape and size even providing similar patterns. In this case, if we try to train SVR, the resulting minimum error of the SVR does not always guarantee to provide accurate output prediction. This also occurs in most kinds of prediction models.

Fig. 1 shows SVR model in training mode which input of both mapping vector sets come from the same train data. If $\phi()$ is a Gaussian function for training, the user needs to define the constant σ. Another two pre-defined parameters required are C and ε for SVR's risk optimized solution in (1) and (2).

$$R = \frac{1}{2}\|\boldsymbol{w}\|^2 + C\left(\sum_{i=1}^{n}\phi\left(y_i - f\left(\boldsymbol{x}_i, \boldsymbol{w}\right)\right)\right) \quad (1)$$

$$\left|y - f\left(\boldsymbol{x}, \boldsymbol{w}\right)\right|_{\varepsilon} = \begin{cases} 0 & ; \left|y - f\left(\boldsymbol{x}, \boldsymbol{w}\right)\right| \le \varepsilon, \\ \left|y - f\left(\boldsymbol{x}, \boldsymbol{w}\right)\right| - \varepsilon & otherwise \end{cases} \quad (2)$$

where w is weighting parameter and equivalent optimizing to β in fig. 1, constant C for balancing value between maximized margin and minimized empirical risk, and ε insensitive error found in (2).

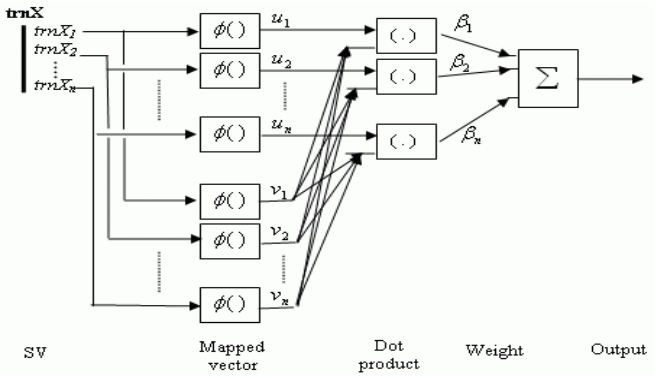

Figure 1. SVR structure model in training mode.

In testing mode, the SVR output is based on suitable weighting factors of training data in H-space, $trn = \left\{\left(X_1, Y_1\right), \left(X_2, Y_2\right), \ldots, \left(X_n, Y_n\right) \in \Re^l \times \Re\right\}$. The adjustment depends on appropriate parameters: C, ε, and σ. However, when it is evaluated with test data ($tstX$), the results may not provide good accuracy. Fortunately, the enveloped output is similar to real patterns in the Target space (T-space). The major effect comes from partial matching between H-space and T-space domain. Another factor is an optimized effect that it gives approximate outputs, which tend to be delay outputs. Another disadvantage is that it is most critical in prediction focused.

Optimizing parameters of the SVR model is depended on support vector points selected from representative multivariate in H-space. By a constraint when solving the quadratic equation, there are some dimensions of input variables scattering nearby root values.

The analysis decomposition of based inputs on output components explores significant hidden patterns. The jittering effect can be selected to final output as representative mapping from H- to T-space. We name this new method as Output Component Based–SVR (OCB-SVR). Fig. 2 shows network diagram of the proposed model.

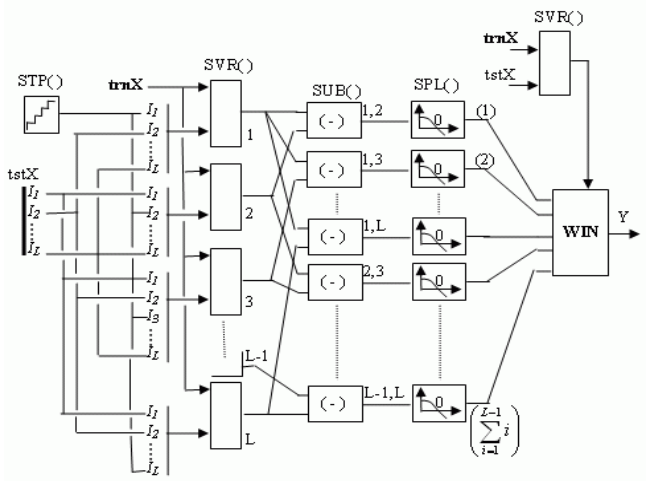

Figure 2. OCB-SVR structure model.

In Fig. 2, SVR is a standard ε-SVR module; STP stands for a stepping function; SUB stands for a subtractive function; SPL represents a spline function used to evaluate approximate root values; and WIN function represents a selector, which selects an appropriate winner output.

Train data $trnX$ has n records with L dimensions. Both $trnX_i$ and $tstX_j$ have $\{I_1, I_2, \ldots, I_L\}$ format. The evaluations of each input component are performed for curve fitting function in SPL. The expected values of each compared dimension will close to 0. The SVR function is defined as ε-SVR in (3).

$$SVR_i = \beta \cdot k(trnX \cdot vtstX_i) + b \quad (3)$$

$$vtstX_i = \begin{Bmatrix} tstX_j & : i \ne j \\ 0..1 & : i = j \end{Bmatrix} \quad (4)$$

where $\beta = \alpha - \alpha^*$, α_i, α_i^* are Largrange multiplier pairs, and b is a constant. As we use Gaussian for $k()$ function, b is closed to 0 by constraint of $1 \le i < j \le L$.

The result of stepping of each input component in (4) gives output SVR_i in (3), which is a directly related value. In case of complete mapping, all output graph lines of each component input will have the same intersection point as shown in Fig. 3. This point can represent the most suitable evaluated output value of $tstX_j$.

To compare the results of each input vector dimension, each output pair is compared using SUB function in (5). Fig. 4 shows example result of SUB function.

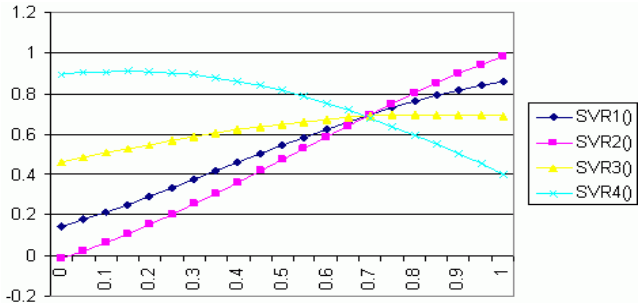

Figure 3. Example of completed intersection graph of stepping value of SVR function

$$SUB_k = SVR_i - SVR_j \tag{5}$$

where $k = \left\{ \begin{array}{c} j-i : i=1 \\ j-i+\sum_{m=1}^{L-1}(L-m) : i>1 \end{array} \right\}$ and the number of SUB value is equal to $\sum_{i=1}^{L-1} i$.

Fig. 4 illustrates a case example of SUB functions. The case example in Fig. 4 uses input vector dimension $L = 4$. This number resulting of compared value is 6, more compared dimensions.

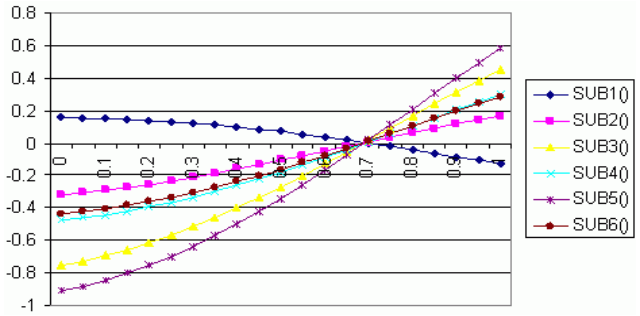

Figure 4. Example of SUB function graph lines

However, in practice, all of graph lines are not a properly intersection. This effect comes from optimizing results that $tstX_j$ is incompletely represented by $trnX$. In general case, incomplete matching between T- and H-space is resulted from the uncontrolled effect of instant environment variables.

If high accuracy is needed, an increase of precision of stepping in (4) is required. However, this leads to a large consumption of the processing time. To reduce this effect we use cubic spline interpolation technique by defining knot point (x, y) with x = SUB, y = input step values and evaluate the result at point $x = 0$. The example interpolation points near $x = 0$ of each line are shown in Fig. 5. All outputs of SPL function are candidate values. The final output is processed and selected by WIN function shown in Fig. 6.

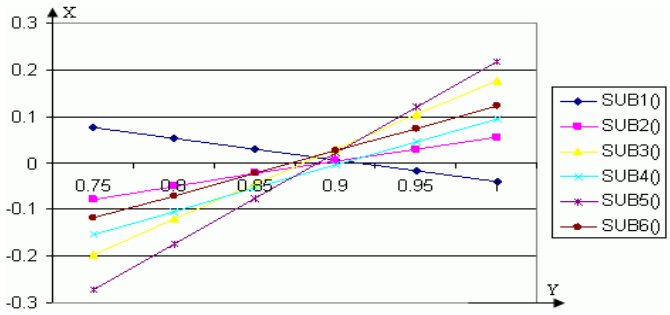

Figure 5. Example of uncompleted result of SUB function graph lines.

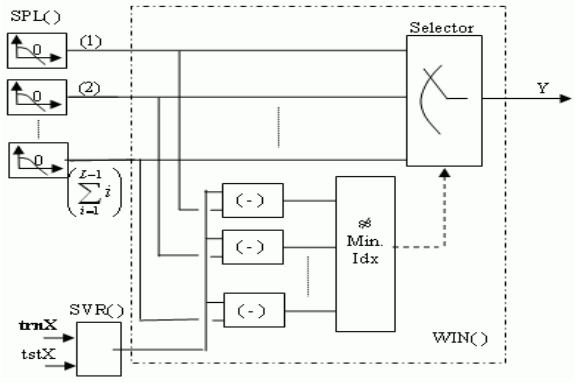

Figure 6. Structure of WIN function.

During prediction processes in T-space the system is not know the actual value. So, all outputs from SPL function can represented of OCB-SVR output. At this state, the suitable value may refer to standard SVR output for comparisons in WIN function. The closest output of SPL to SVR reference is select to final output of OCB-SVR model. Fig. 6 is equivalent to (6).

$$WIN = SPL_{(idx \min(|SUB_i - SVR(tstX, \boldsymbol{trnX})|))} \tag{6}$$

where idx is index at lowest comparison between SUB and SVR. The description of OCB-SVR algorithm in (6) assumes that all SVR models are already training with $trnX$ as standard SVR for pre-defined β parameter.

III. Experiment Case and Discussion

To evaluate OCB-SVR, we tested with a real stock data from Thailand stock market. The "PTT" stock was collected in 2 data sets: 65 records for training data and 34 records for test data. We use ε-SVR model for the same data sets as for comparison purposes. In addition, to demonstrate how OCB-SVR insists with space shifting; we separate 1 year of these two data sets. Training data were collected from 04/01/2005 to 01/04/2005, and test data were collected from 03/07/2006 to 22/08/2006. Both data sets have the same format i.e., {*close*, *high*, *low*, *open*}. The data were transformed to unit values by dividing with the maximum value equal to 302.4. Defining initial SVR's parameters: C = 100, ε = 0.001, and σ = 1, the

system was trained with *trnX* . Learning results are shown in Fig. 7. The mean square error (mse) of SVR is 32.4297 whereas OCB-SVR equals to 13.0087. Both models have similar learning result because both models used training and testing data in the same H-space.

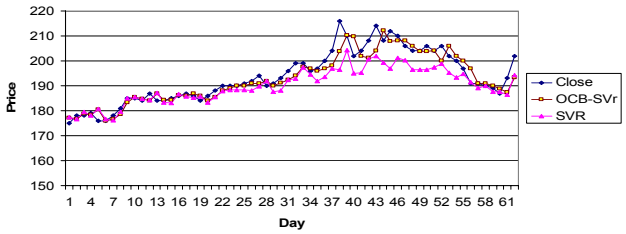

Figure 7. Learning comparison of SVR and OCB-SVR to actual PTT's closing stock price.

The trained system was tested with *tstX* as the results shown in Fig. 8. There are significant different comparisons in Fig. 8. The SVR has an optimal MSE value equal to 22.9887, while OCB-SVR has an MSE equal to 18.593. Both models have similar enveloped patterns which are related to actual patterns.

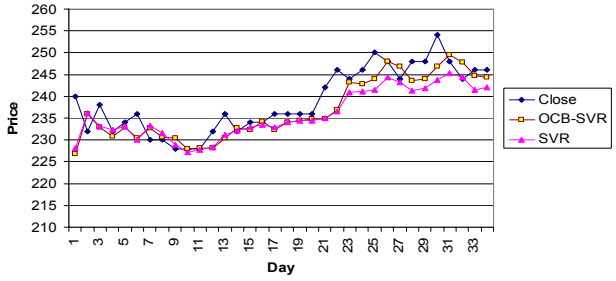

Figure 8. Testing comparison of SVR and OCB-SVR to actual PTT's closing stock price.

This is confirmed that the decomposition technique of output component base can support SVR model resulting in a better accuracy prediction mode for unmatched mapping space between training sets and test sets.

OCB-SVR still has SVRs' limitation effects: initial parameters, pattern delay prediction, and non re-trainable high dynamic input-output pair of training data because of SVR core model usage.

IV. Conclusion and Further Study

In this paper, we propose Output Component-Based Support Vector Regression (OCB-SVR) model for time series data prediction. The local optimized limitation in NNs can be eliminated by SVR's optimizing method which combines both maximize margin and minimize empirical error. Because of incomplete matching of train sets and test sets, SVR solution does not guarantee accuracy prediction result. However the enveloped pattern is similar. An appropriate target output based on historical datasets by decomposition of closest candidate value of optimizing output can improve the standard SVR prediction. Because OCB-SVR uses SVR core model, the limitation effects from SVR still exist and need to improve.

Our further study shall focus on applying hybrid fuzzy networks. Data prediction by support vector regression with decomposition method may provide a better improvement to most kinds of uncompleted matching to T-space.

***Abstract*- The Knowledge Management in terms of business recommended that knowledge is the organizational asset that enables sustainable competitive advantage. Besides, an increasing demand of IT outsourcing to deliver quality services, ITIL Best practice framework is an essential key success factor for IT outsourcing quality service approach. IT Service Desk is a crucial function to the whole concept of IT service management. In this paper, we propose an enhanced model called Knowledge Management system with Root Cause Analysis, or KMRCA, IT Service Desk applied to improve the IT Service Desk. The performance of the KMRCA IT Service Desk are evaluated using a simulation study with actual data from IT Service Desk in banking business, and the experimental results indicate the KMRCA IT Service Desk approach would significantly enhance the performance and quality of the throughput of the traditional IT Service Desk, reduce times in resolving the problems, and eliminate the recurring problems.**

I. INTRODUCTION

Knowledge Management is the process of managing the organization's knowledge by means of systematic and organizational specific processes for acquiring, organizing, sustaining, applying, sharing, and renewing both tacit knowledge and explicit knowledge by employees to enhance the organizational performance and create value. [1], [2], [3].

The problem is that in today's business environment employee turnover is very high, especially for technical employees [4]. Help desk agents store significant knowledge concerning the systems, business processes, and technologies and if they leave their knowledge often goes with them [5].

An increasing in demands of customers and the delivery of a world class service are becoming a major competitive advantage. According to Gartner [6], spending on outsourcing is set for steady growth 7.2 percent from 2003 to 2008 [6]. A key success driver for efficiency and effectiveness of IT outsourcing over the next three years will be aligned on an ITIL Best practice. In addition, an IT service desk is probably the most significant in the organizational outsourcing.

The primary objective of the IT Service Desk is to resolve problems related to IT operations. Furthermore, the agents in the service desk must be very knowledgeable of their service supports, applications, and support teams. Most efforts at improving service desk performance have been to make the current system more efficient through applications of information technologies [7] and to conduct the way to eliminate the recurring problems.

Computer Telephony Integration (CTI), one of technologies is available to assist the Service desk to blend of technology, process and service desk staff will meet the needs of both the business and the users [8], [9].

In this research, we propose a new model approach called *KMRCA IT Service Desk*, Knowledge Management System (KMS) with root cause analysis (RCA) adapted to IT Service Desk. The KMRCA IT Service Desk attracts diverse knowledge and root cause sources in the service desk databases, files, domain experts, and knowledge bases. With the RCA is used to eliminate the recurring incidents and its result provides a resolution plan. However, the resolution plan has been kept tracking until its activities completed and updated the result into the KMS Database. The KMRCA IT Service Desk is designed for daily operations of service desk to ensure high utilization and maintenance of the knowledge stores.

II. KNOWLEDGE MANAGEMENT

The study of knowledge management has begun on Polanyi's Tacit Dimension. His analysis emphasized several key concepts. Firstly, the ability to identify the outside objects, and hence to know, is learned through a process of personal experience. Secondly, tacitness and explicitness are distinct dimensions; the increase of one does not come at the decrease of the other. Thirdly, since tacit knowing is an essential element of any kind of knowledge and is acquired through personal experience called indwelling, any effort to achieve absolute detachment, the objective of knowledge is mis-directed and self-defeating. Polanyi's work is situated in a philosophical context, and focuses on the definition of knowledge but not on the systematic effort of managing it [10].

The conceptualization of knowledge management did not develop; however, until knowledge became central to production and innovation in the 1990s. Peter Drucker [11] is among the first who advocated the advent of a knowledge society. In the Post-Capitalist Society [11], Drucker documented the transformation from a capitalist to a Knowledge Society, which began shortly after World War II, noting that the foremost economic resource is no longer capital, land, or labor. Rather, it is and will be knowledge [11]. The field of knowledge management has also been developed by the experience and philosophy of Eastern society.

Nonaka and Takeuchi's Knowledge-Creating Company [12], based on experience in Japanese companies, is a pioneer

work in mapping explicit and implicit knowledge, as well as individual, group, and organizational knowledge into one matrix describing called the dynamics of knowledge creation.

Stenmark [13] discovered how tacit knowledge in the form of professional interests could be shared among the organisational members in an unobtrusive way. Based on these empirical findings, and informed by Polanyi's theory of tacit knowledge, He claimed that agent-based retrieval systems could be used to capture and visualize the professional interests, thus making otherwise elusive tacit knowledge tangible so that it can benefit others.

Knowledge Management is the process of managing the organization's knowledge by means of systematic and organizational processes conducted by employees to enhance the organizational performance and create value. [1], [2], [12].

The development of knowledge management, on the other hand, has been driven by practices and development in information and data management [14]. Organizations should therefore seek and share a combination of tacit and explicit knowledge with suppliers and other parties in the value chain to satisfy customer needs in a highly competitive environment.

The Knowledge Management System (KMS) composes of five processes, knowledge capturing or knowledge discovery, knowledge creation, knowledge inventory, knowledge sharing, and knowledge transfer, applied to the community of practice. IT is related to just knowledge creation and knowledge inventory that are becoming an organisational memory (OM) and enable to competitive advantage sources.

III. Root Cause Analysis

A root cause analysis (RCA) is the process to identify the action or condition that, when eliminated or changed, will prevent the recurrence of the specific or similar problems, and therefore the benefits of the RCA are to improve the service level agreement (SLA) attainment and to enhance quality services as well as customer satisfaction.

The knowledge-based library of RCA models could be in the form of hierarchically structured and interconnected failure trees, the abnormalities in process operations and output quality can originate from abnormalities in equipment or in process conditions possibly due to basic failures [15].

IV. KMRCA IT Service Desk

A. IT Service Desk of IT Outsourcing

The first level support bank owner provides a vital day-to-day contact point between Customers, Users, IT services and third-party support organisations using the Tivoli CTI system and assigns if the particular IT incidents to IT Service Desk of IT strategic outsourcing as the second level support (SLS) to find out the proper resolution according to the service level agreement (SLA) between the Bank and its IT outsourcer. Strategically, for the Bank the IT Service Desk of IT outsourcing is the most important function in the organization that required to be improved. Hence, we propose the KMRCA IT Service Desk Concept to enhance the IT Service Desk of the IT outsourcing who is not the Tivoli software owner.

The KMRCA IT Service Desk Outsourcing concept is shown in Fig. 1.

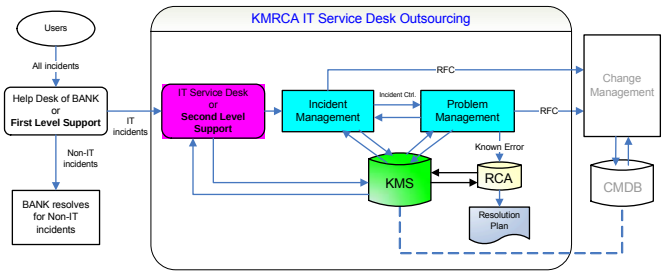

Figure 1. KMRCA IT Service Desk Outsourcing Concept.

The KMRCA IT Service Desk Outsourcing Concept embraces not just IT Service Desk and Incident Management interfacing Problem Management, but also KMS database communicating with RCA database that called *KMRCA*.

B. Conceptual Simulation Model for IT Service Desk

When Users call to the first level support with diverse incidents, the Bank staff clarify and try to resolve those incidents meanwhile the problem tickets are being opened for monitoring and tracking by Tivoli CTI. We met that more than 87% of the incidents are IT related. Consequently the first level support staff will assign severity for each IT incident and pass it on the SLS to resolve within the SLA.

Fig. 2 shows the conceptual model of IT service desk operation as the modeled simulation.

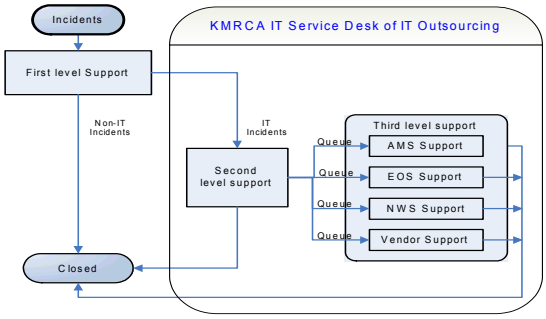

Figure 2. Conceptual model of IT Service Desk operations.

Likewise, the agents of SLS will clarify and attempt to resolve IT incidents. If there are some incidents are still not resolved, they will be escalated to Third Level Support teams, composing of AMS Support, EOS Support, NWS Support, and Vendors Support. Consequently, the details of the KMRCA IT Service Desk concept could be explained by its process shown in Fig. 3.

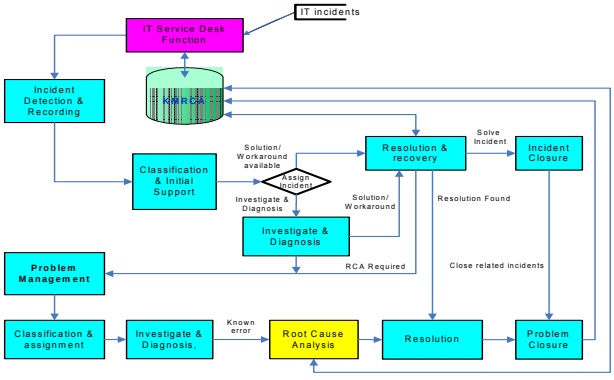

Figure 3. KMRCA IT Service Desk Process.

The IT Service Desk team is also responsible for monitoring and tracking of the assigned IT incidents until those incidents are closed. They are able to find out the resolution by searching from the KMRCA database. If the incident cannot be resolved immediately, it will be escalated to the specific specialist groups [16] or the third level support teams to handle the incident by the incident management process, including classification, investigation, and diagnosis to resolve the incident until incident closure. If the diagnosis required knowing a known error identified by means of the root cause analysis. After resolution of the cause of the incident and restoration of the agreed service, the incident is closed.

C. The Comparison of IT Service Desk with against without KMRCA

The comparison of a Typical IT Service Desk versus the KMRCA IT Service Desk is shown in Fig. 4.

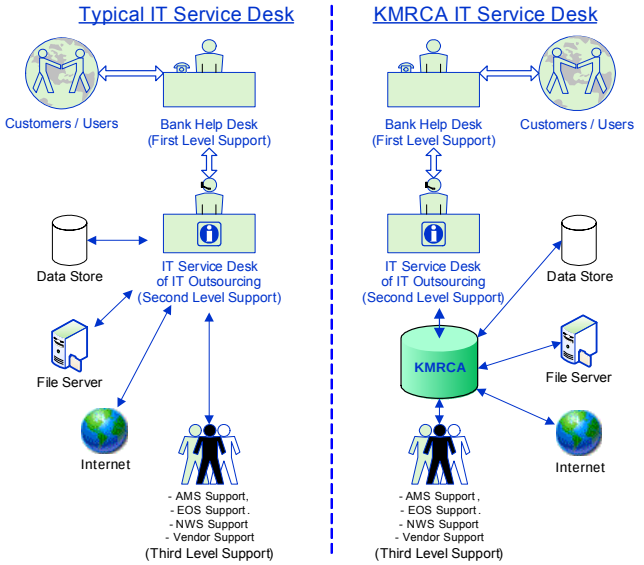

Figure 4. IT Service Desk with against without KMRCA

The KMRCA IT Service Desk, IT Service Desk of IT outsourcing communicates just KMRCA instead of several getting data sources such as data store, file server, and third level support domains.

There are at least three problems within the Service Desk without KMS and RCA. Firstly, service desk personnel report about 70% of their time is spent on solving repeat problem [17]. Secondly, in business environment today employee turnover is very high, especially for technical employees [17]. Finally, some incidents may have the same causes and they may occur again because their root causes are not eliminated.

V. Performance Evaluation

To demonstrate the concept of KMRCA IT Service Desk, we evaluate the system performance using a simulation method. The research hypothesis is that the system will have a shorter problem resolution time and will enable to eliminate the recurring problems.

A. Hypothesis

The time in system for all incidents calls except for critical severity calls will be lower in KMRCA IT Service Desk system than the previous one. The developed simulation model is to test the hypothesis that describes both systems. A simulation enables service desks to perform analysis that captures the entire interrelationship between callers, agents, skills, and technology [4].

In this case, the simulation model approach is adopted so that it can be conducted by experiments and evaluated the KMS without interrupting the IT service desk's daily operations.

B. Data Collection

The data was collected from the Tivoli, CTI for everyday from a six-month period starting from May to October 2006. The collected data in spreadsheet form was for a total of 36,981 assigned calls and consisted of problem ticket no., calling date, arrival time, resolved time, assigned resources, defined severity, identified system problem. The frequency of each severity is shown in Table I. The service times for each problem category were analyzed and determined.

TABLE I
CLASSIFICATION OF CALL BY SEVERITY

Severity	Number of Calls	Percentage (%)
1	458	1.239
2	1533	4.145
3, 4	34990	94.616
Total	36,981	100.00

C. Simulation Model

A discrete event simulation package called *Arena*™ [18] is used to imitate the conceptual models of IT Service Desk agents both with and without KMRCA. A full exposition of the simulation model is available in Simulation with Arena. The simulation model was verified to ensure that it works properly in terms of Arena functionalities and the entities of the problem calls follow the same path as described in the conceptual model shown in Fig. 2. The verification was done using the TRACE element which is used within a discrete model to generate a detailed trace report of entity processing. The TRACE was run for one replication for 6 weeks of operation time. The TRACE output allows following the sequence of an entity as it flows through the system, from entity creation until entity disposal.

The entity process flow was intended design and verifying the Trace output, the model run with different replication numbers to verify that it works properly under the different conditions. After verifying operation of the simulation model it was validated. In order to reduce variation, four replications were conducted with different random number streams on the simulation model. A t-test with a 95% confidence level was conducted to compare the results of the simulation model with the results recorded for the actual system based on the data collected from Tivoli CTI system. For each variable the null hypothesis of no difference between the systems was rejected with a 95% confidence level which indicates the simulation model adequately represents the actual system's behaviours.

D. Design of Experimental Design and Analysis

Experiments include the study of more than one factor. They are often used to study the performance of the process and the system [19]. The objective of this experiment is to determine the variables are most influential on the response of the system. By using the experimental 2^3 factorial design

which is to identify the effects of three different interesting factors, A, B and C for each at two levels of the factors and eight treatment combinations run in the 2^3 design.

In this research, three factors, time in minutes, are:

Factor A: Time to type problem information and search the relevant knowledge from the KMS.
Factor B: Time to resolve a problem using the KMS.
Factor C: Time to add new information into the KMS.

In addition, the dependent output variables are:

O1: Throughput, total no. of calls resolved in time period
O2: Time in the system of Severity 1
O3: Time in the system of Severity 2
O4: Time in the system of Severity 3 and Severity 4
O5: Number of problem calls in AMS queue.
O6: Number of problem calls in EOS queue.
O7: Number of problem calls in NWS queue.
O8: Number of problem calls in Vendors queue.

According to Gonza´lez [7] these dependent variables are performance variables tracked by the service desk which are common performance measurement.

TABLE II
INDEPENDENT VARIABLE FACTORS AND THEIRS VALUES IN TWO LEVELS

Factor	Low (min.)	High (min.)
A	1	3
B Triangular	(1,3,6)	(2,5,8)
C	2	4

Table II shows the factors and their respective levels. A different output variable is needed for each problem severity since they follow different paths through the service desk. The factors are analyzed with two levels (low and high) and their values were determined by expert opinion obtained during the interviews and by observing the service desk operations.

Replications of each experiment were run for one month (43,200 minutes) in a random order and the results were recorded for further statistical analysis.

TABLE III
STATISTICAL T-TEST FOR COMPARISON OF THE PREVIOUS IT SERVICE DESK AND THE KMRCA IT SERVICE DESK

($\alpha/2 = 0.025$ and degree of freedom = 7)

Variables	Observed *t*-value	Critical *t*-value
1) Throughput	85.139	2.365
2) Time System for Severity 1	1.318	2.365
3) Time System for Severity 2	0.702	2.365
4) Time System for Severity 3, 4	29.560	2.365

The same random number seed was used for the normal agent service desk and the KMRCA IT Service Desk conceptual models.

E. Experimental Results

The summarized results are shown in Table IV. The analysis of variance (ANOVA) for full factorial design is done to test that the main effects or interaction parameters are equal to zero. In statistical analysis, the factors with a *p*-value lower than 0.05 are considered as important factors that significantly influence the results. The ANOVA analysis shows that only the dependent variable Throughput (O1) and Time system for Severities 3, and 4 are significantly influenced by Factors A, B, and C. The other dependent variables do not have any factors that affect them significantly.

TABLE IV
SUMMARY OF KMRCA IT SERVICE DESK VERSUS IT SERVICE DESK IN AVERAGE

Variables	IT Service Desk	KMRCA IT Service Desk
Throughput (calls/time period)	12904	15185
Time System for Severity 1 (min.)	82	76
Time System for Severity 2 (min.)	140	128
Time System for Severity 3, 4 (min.)	341	293

VI. CONCLUSIONS

In the study, we conducted a computer simulation to quantitatively compare the typical IT Service Desk against a new proposed KMRCA IT Service Desk. The simulation study result showed 17.4 % increase in throughput, greater than 7.3%, around 8.5%, and 15.4% decrease in average time to resolve assigned problem of Severities 1, 2, 3 and 4, respectively. The improvements are significant and provide justification for implementing the knowledge management system with root cause analysis. Furthermore, the advantage of the simulation is that we can perform a study without disrupting the day-to-day IT Service Desk operations.

***Abstract*— Nowadays, there are many tools have been offered to webmasters to build their websites. Therefore, Web administrators still have to cope with many problems, such as ensuring validity of available documents or changing many content and restoring data. To resolve this problem, we need Web Metadata which could be used by Web Content Management (WCM) to maintenance web structure and its content and representing schedule. In this paper, we propose a temporal database design for Web Metadata by using NIAM model, which can be used for solving problems in monitoring, designing and retrieval efficiency of the website structure and its contents.**

Keywords. Web Metadata ,Web Content Management, Temporal web database, NIAM.

1. INTRODUCTION

Since the invention of websites, this technology has affected to most people's daily life. At the beginning, it was used by government and large business sectors only. However, the popularity of this technology spreads to small business and also private sectors.

There are varieties of contents, for instance: texts, images, audio clips, videos etc. Moreover, these contents have some changes regularly. The best example is portal websites, which have varieties of information, e.g. News, petrol rates, stock exchange rates, movie and music hits charts, etc. As can be seen from examples above, website management is not easy. There are so many information and data that needed to be monitored and updated very frequently. Thus, webmasters need powerful tools that can help them to manage and organize their works.

A website can be conceptually divided in the following four basic parts, like in [1]

- Content
- Structure
- Functionality
- Presentation

According to our studies, we founded that there are 2 parts of website components that are very important:

- Content
- Structure

Firstly, content is basic information that can be seen and heard from the website. In other words, all visual and audio information appeared on the website. Secondly, structure is the directions of how information is represented on the websites. Basically, the most common standard of structure is written by using HTML specifications [2]. As we have studied the HTML structure carefully, we can design the relationship of web metadata. Moreover, daily website contents and structures can also be tracked and traced. As a result, we chose NIAM model to represent database structure, which could handle temporal data for web content management.

This paper will focus on relationship of web metadata, especially in design, management and maintenance. To gain more understanding towards this research, it is needed to understand basic concepts, overview and implementation methods. The guide below described our methodology we applied on this research.

2. OVERVIEW AND RELATE WORK.

2.1 HTML Structure

HTML is a popular and powerful of computer language devised to allow website creation. These websites can then be viewed by anyone else connected to the Internet. It is constantly undergoing revision and evolution to meet the demands and requirements of the growing Internet audience under the direction of the World Wide Web Consortium (W3C), the organization charged with designing and maintaining the language.

New HTML version supports more multimedia options, scripting languages, style sheets, better printing facilities, and documents that are more accessible to users with disabilities. HTML also takes great strides towards the internationalization of documents, with the goal of making the Web truly World Wide.

HTML structure consists of elements and attributes. Elements are a part of HTML structure. They include 2 important properties, which are attributes and content. To make HTML document, these properties are used for parameter defining and follow HTML structure. An element usually has a start tag (<tag>) and an end tag (</tag>), such as <Font color="black">Content</Font>.

Attribute are used to define Element's parameter and contain 2 parts. First part is attribute name for define property's element. Another part is attribute value. Attributes are placed in the start tag (<TD width=300>) and content is located between the tags (<tag>Content</tag>). And some elements don't have any content and do not need closing tags, such as <HR>.

We can study all details of HTML structure in HTML specifications in WC3's website for this paper.

2.2. Concept of Temporal database by NIAM

In temporal relational databases [3], it consists of several types of time include this.

- Lifespan time
- Valid time
- Transaction time

Lifespan Time, Valid Time and Transaction Time are vital factors of time components in temporal databases.

Lifespan time is the period of time between the Entity type starts until its end. Any Entity type that is measured by time, will be collected in database. The components of Lifespan Time are Life Span Start (LSs), and Life Span End (LSe). The symbol for represent in NIAM model is shown below in Figure 2(a)

Valid time is the period of time, it consists of Valid Time start (VTs) and Valid Time end (VTe) are attached to each temporal fact so that the state of the fact is shown with the valid time. This enables historical facts to be manipulated as well as current facts. The symbol for represent in NIAM model is shown below in Figure 2(b)

Transaction time is simply the time that the fact is recorded into the database, which consists of Transaction Time Start (TTs) and Transaction Time End (TTe).

In temporal relational databases, lifespan, valid and transaction time are attached to each tuple.

3. IMPLEMENTATION

After carefully analyzed HTML Structure, it is very flexible and may hand to design a concrete database model for. We tried to make the most appropriate data model to handle all possible relations of HTML structure and content, e.g. retrieval speed, indexes and data constraints. Relational structure that would satisfy our common structure is shown in Figure. 3. After that we will Transformation from NIAM to Object Database Schema and mapping in tables for implement in web content management system. We will develop a tool to transform HTML code of webpages into tuples of these tables.

Figure 5. A part of sample database for storing content structures.

We have proved that the designed schema could store various arbitrary styles of HTML structure by analyzing many webpages of popular websites such as index.html of www.google.co.th [5], www.cnn.com, www.msn.com. We found that all analyzed structures, can be filled in the database schema. As to show some of the success experiment, we present structure include page of www.google.co.th as relational data in the Figure 5.

In Figure 5 in ELEMENT_ATTRIBUTE_VALUE Table and other tables show example records set from www.google.co.th in different time. As can be seen from set ①, it is represented the google webpage at 15/6/2006, by using Google's logo, which collected as logo_pain.png (in Figure 6(a)). In set ②, on Mother Day: 12/6/2006, the logo of the webpage has changed to mothers_day06.png (in Figure 6(b)). According to record ③ (in Figure 6(c)), on 1/1/2007 (New Year 2007), the logo has changed for celebration of New Year. The logo file became newyear07.png. After the new year's celebrations ended, the logo has changed to default logo. The file became "logo_pain.png" as it was on 20/1/2007 (in Figure 6(a)).

4. CONCLUSIONS AND FURTHER WORK.

In this paper, we have presented the Web Metadata model that useful for Web Content Management. By adding temporal feature, In the near future we will develop Web Content Management System (WCMS). The database model can maintain HTML Structure, Content and retrieval features. These may be changed time by time.

Abstract- **The availability of contents, user profile and usage pattern in a digital library in machine understandable formats paves the way of processing these information further using state-of-the-art technologies to introduce intelligent digital library services. Annotating, organizing and analyzing contents based on a domain-ontology give us the ability to make topic inference through content relationships. User's inaccurate and incomplete profile can also be augmented with the help of a domain-ontology and usage pattern analysis using collaborative-filtering algorithms. Nevertheless, we can also use sophisticated mathematical models to process usage-pattern data for making content recommendations that reflects user's interest-drift. In this research, we integrate DL contents with a domain-ontology, user-profile and usage-pattern data by means of intelligent algorithms and techniques. On top of an open-source digital library system, we developed required modules to capture and manipulate necessary data with the help of efficient techniques such as ontology-driven topic inference, collaborative filtering, single exponential smoothing, etc. Our prototype can demonstrate that the retrieval results for the same query by a particular user, but on different time, may yield different result-sets (in terms of ranking) since the query, profile and contents are treated in a unified manner. We also verified that the same query from different users may yield different result sets as justified by differences in user profile and usage history. Our prototype can also recommend digital library items to users by using collaborative-filtering based usage-pattern analysis that takes user's interest-drift in consideration.**

I. INTRODUCTION

A digital library (DL) is a collection of documents in organized electronic form and accessible via search and browsing interfaces. The availability of contents, user profile and usage pattern in a digital library in machine understandable formats paves the way of processing these information further using state-of-the-art technologies to introduce intelligent services in digital library. Annotating, organizing and analyzing contents based on a domain-ontology [1] give us the ability to make topic inference through content relationships. User's inaccurate or incomplete profile can also be augmented with the help of a domain-ontology and usage pattern analysis using collaborative-filtering algorithms. Nevertheless, we can also use sophisticated mathematical models to *process* usage-pattern data for making content recommendations that reflect user's interest-drift [2]. Serving DL users with the right information which best reflect their query, profile, usage history and content relationships is only possible when we process heterogeneous information in a unified manner. In this research, we try to present such a unified approach towards developing adaptive and intelligent digital library services.

On top of an open-source digital library system, we developed required modules to capture and manipulate necessary data with the help of efficient techniques and algorithms such as ontology-driven topic inference, collaborative-filtering, single exponential smoothing, etc. Our prototype can demonstrate that the retrieval results for the same query by a particular user, but on different time, may yield different result-sets (in terms of ranking) since the query, profile and contents are treated in a unified manner. We also verified that the same query from different users may yield different result sets as justified by differences in user profile and usage history. Our prototype can also recommend digital library items to users by using collaborative-filtering based usage-pattern analysis that takes user's interest-drift in consideration.

II. MATERIAL AND METHODOLOGY

A. Digital Library Services

Being organized and focused collections of information, digital libraries concentrate on a particular topic or theme; and good digital libraries will articulate the principles governing what is included there and how are they organized. Typical DL Systems provide searching and browsing interfaces. Searching implies that the user knows exactly what to look for, while browsing should assist users navigating among correlated searchable terms to look for something new or interesting. Searching interface may range from basic keyword search to field-specific advanced search, etc. Browsing interface includes categorical navigation based on certain taxonomy and meta-data such as browse by author, category and the like [3][4].

Most digital libraries provide basic search and navigation functions which maybe adequate in WWW context but are merely sufficient in the context of a digital library. In DL context, we have been continuously failing to take advantage of electronic contents using advanced content processing techniques, and also

failing to make use of user profile and usage history, etc. We argue that what makes a digital library unique is the availability of content in electronic form (which can be processed automatically and inferences can be made), and the availability of user profile and usage patterns. Unlike the WWW, Google-like Keyword Search or Yahoo-like Directory Hierarchy is certainly not adequate for harnessing information in the context of a digital library. Therefore, we tried to make use of DL content, domain-ontology, user-profile and usage patterns; and developed necessary algorithms to facilitate intelligent and adaptive services for digital library.

In a digital library, keyword search and navigation may only facilitate and entry-level access to the content. Efficient access to DL contents is only possible when we succeed to make use of heterogeneous information and facets under a unified framework. For example, (1) keyword-based search often produces enormous amount of irrelevant hits. Different users may target different information when using the same keyword to search. (2) When a DL users signs up, they may inadvertently provide incomplete or inaccurate profile information about themselves. Moreover, (3) user's profile, information-seeking behavior and information-needs, etc. change over time (a.k.a. user interest-drift). In our research, we try to augment user profile adaptively using domain-ontology and usage history. We also analyze DL contents and usage-pattern to make ontology-driven topic inference through content and usage associations. Interest-drift modeling using single exponential smoothing techniques tries to capture interest-drift in DL users adaptively.

B. The Domain Ontology

The domain-ontology helps us organizing the DL contents and representing the user profile. We used a modified version of *ACM Computing Classification System* (ACM-CCS) Ontology [5][6] in our work. The schema of the ontology is presented in Fig. 1, where each node represents a topic. It should be noted that the `hasKeyword` attribute is very useful in making topic-inference from usage-patterns and through full-text analysis. DL user's search history and bookshelf items are analyzed to extract keywords and those keywords are associated against related nodes in the domain ontology.

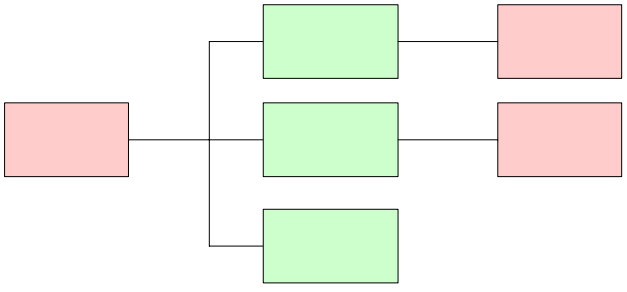

Figure 1. Schema for ACM-CCS Ontology based on CCS Taxonomy

C. Dynamic User Profile

The classes (topic nodes) defined in the ACM-CCS ontology is used to represent user profile. In the DL context, typically a user will specify their interests as they sign-up. However, such a raw profile is usually incomplete or inaccurate [7]; and requires further refinements and enhancement. We used a weight-based topic vector to represent user profile. The initial weights for each selected topic can be assigned rudimentarily. The subsequent augmented profile consists of topics and their weights as normalized and adjusted via the domain ontology by considering topic interrelationships and temporal usage history. Such a dynamic user-profile may be computed off-line in batch mode; and may more accurately reflect a user's interest and context. By keeping extra information such as user access logs including user's keyword-sets and bookshelf-items along with timestamps, we can capture user's interest-drift over time and re-weight the user-profile dynamically [2]. The mathematical formalism of interest-drift is explained below.

D. Interest-Drift Modeling

In a digital library, the user interests, information needs and information seeking behavior change over time. We adopt a policy on assigning higher weights on recent usages since topics related to recent usages reflect user's present context. We also assign exponentially weighted weights on older usage to reflect a user's general context. We use *Single Exponential Smoothing* technique (a well-known smoothing technique used in financial forecasting and engineering applications) to assign *exponentially adjusted weights* to estimate adaptive weights for each topic [8].

The smoothing is done as follows:

$$S_t = \alpha y_{t-1} + (1 - \alpha) S_{t-1} \qquad 0 < \alpha \leq 1$$

where t = any time period

S_t = the smoothed value

A = smoothing constant

y_{t-1} = the current observation

In the DL context, the frequency of a user login and user activities are directly related to the choice of the smoothing constant, α. The α values can be different for each user; and are estimated using a normalized frequency measure, fi as derived in Table 1.

$$f_i = N_i \;/\; Max_N$$

where N_i = # of transactions for $user_i$

Max_N = # of transactions for the most active user

TABLE 1
ESTIMATION OF SMOOTHING CONSTANT , α

Frequency (f_i)	Alpha (α)
frequency = 0	0
frequency < 0.3	0.05
0.3 <=frequency<0.5	0.1
0.5 <=frequency<0.7	0.2
0.7 <=frequency<0.9	0.3
frequency > = 0.9	0.4

E. Usage-Pattern Analysis using Collaborative Filtering

Collaborative Filtering (CF) is one of the key techniques for implementing a recommender system that recommends to a user a set of candidate items, which may be preferable or useful to the user based on similarity analysis with other users [9]. Collaborative Filtering techniques have been intensively used in E-commerce. The idea is easily extendable in the context of digital library. In the DL context, we can take advantage of both usage-pattern based and content-based collaborative filtering algorithms. It is interesting to note that in DL context, CF can be *bidirectional* – that is, it is not only possible to recommend new DL items for a user by analyzing profile similarity and looking at their bookshelves; but also it is possible to analyze bookshelf-item similarity and augment user-profile. We use a time-sensitive CF algorithm (similar to [2] for our purpose) to achieve adaptive effects on recommendations made.

F. Intelligent and Adaptive Digital Library Services

As a DL user undertakes new tasks or switches to new projects, an intelligent digital library should be able to adapt to such changes in the context and preference of that user. In another word, a user searching for information with the *same keyword but on different point of time* should not be served with the same retrieval results (at least the ranking of item should vary). Similarly, *two different users* searching the DL using the *same keyword at the same time* may not be served with the retrieval results. At least the ranking of the retrieval result should take into account of their profiles. We illustrated such adaptive digital library scenario in Fig. 2.

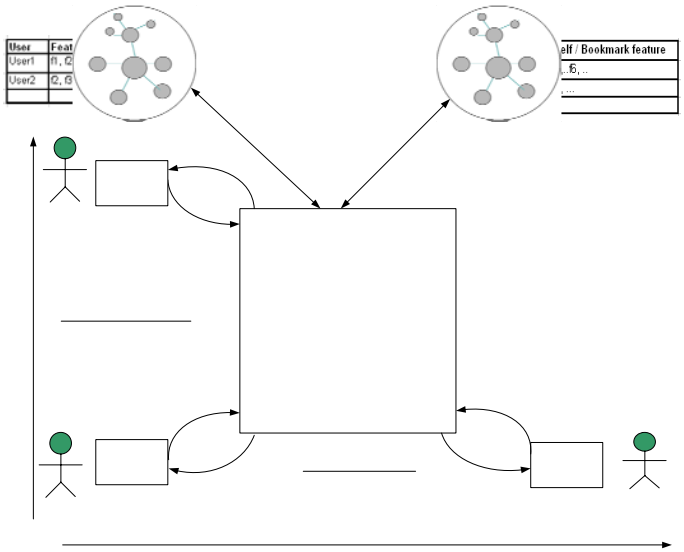

Figure 2. Intelligent and Adaptive Features in Digital Library Services
(a) Horizontal Axis illustrates that search results for a particular user using the same keyword at different time yield different retrieval results.
(b) Vertical Axis illustrates that search results for different users based on the same keyword may yield different retrieval results.

Using our prototype we try to verify that the retrieval results for the same query by a particular user, but on different time, may yield different result-sets (in terms of *ranking*) since the query; profile and contents are dynamically enhanced using intelligent algorithms based on ontology-driven topic inference, time-weighted user profile adjustment, CF-based similarity analysis and the like. We also verify that the same query from different users may yield different result sets as justified by the differences in their profiles and content relationships. Our prototype can also recommend digital library items to users by using collaborative filtering–based usage pattern analysis that reflects user's interest-drift. We test our approach using a partially synthetic datasets and analyzed the results through human judgments.

III. EXPERIMENTAL SETUP AND RESULT ANALYSIS

In order to demonstrate our proposed approach, we conducted experiments with semi-synthetic data. In this section, we will highlight some observations from those experiments.

A. User Similarity

To start with we generated random profiles for 10 users. These profiles are augmented though ontology-driven topic inference and usage pattern analysis. We use this information to find the similarity among users. Fig. 3, shows an example raw profile of users. The value '1' means a user is interested in that topic (category). The value "0" means that a user is not interested in that topic. We calculate vector similarity to find similarity among users. Fig. 4, shows user similarity. It should be noted that the profiles are continuously augmented using ontology-driven topic inference module and usage pattern analysis modules. Therefore, our CF-based recommendations reflect dynamic usage pattern of DL users and the topic associations in the DL domain.

Figure 4. Similarity among user s

B. Time-weight Smoothing

From DL user's access-log, we calculate α value for each user to continuously augment user's raw-profile that reflects user's context and interest-drift. If α value is small, the weight changes

faster than a bigger α value. From Fig. 5, we see that the weights are changed sharply for more active DL users (with smaller α).

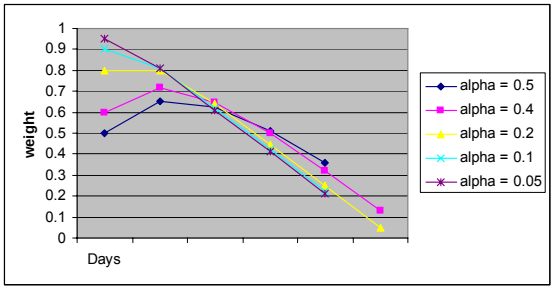

Figure 5. Graphical representations the relation between topic weight and α

In Fig. 6, we illustrate how topic-weight changes when a user starts searching the DL with new items (originally not reflected in his or her profile and usage).

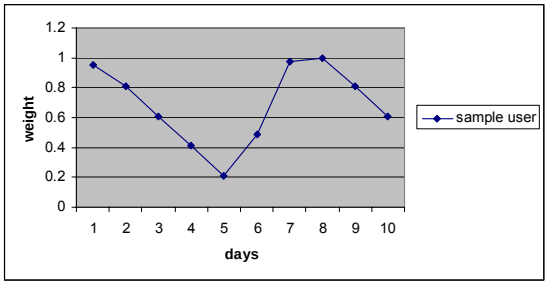

Figure 6. Weight of a topic for a particular user changing over time

IV. Conclusions and Future Work

In this paper, we presented a novel approach to associate contents with user profile and usage pattern and modeling interest-drift in Digital Libraries. Our prototype is based on a *3-Layer Architecture* as shown in Fig. 7. The core of the 3-Layer architecture is an open-source DL system surrounded by series of Add-on Modules to capture further information about contents, users and usages in Layer 2. The outer-most layer (Layer 3) consists of services developed by making intelligent use of those information with the help of efficient techniques and algorithms.

We validated our approach with preliminary experiments using synthetic data and prototype algorithms. At the moment, we are setting up a digital library with sizeable amount of contents and real users; and planning to put our prototype into practical operation. Our present experimental setup and analysis using synthetic dataset showed that our approach integrates several facets of DL information seeking scenario; and is capable of providing personalized services for digital library users. Two different users searching with the same query yield different hits. The same user searching with the same query but at different point of time, may get different hits depending on his or her recent context. For the future work, we will include systematic evaluation based on real digital library usage data.

Improve XML Web Services' Performance By Compressing XML Schema tag

Tanakorn Wichaiwong and Chuleerat Jaruskulchai
Department Of Computer Science, Faculty of Science, Kasetsart University, Bangkok Thailand

Abstract **The standard of data transfer and exchange between organizations through web services has become exceedingly popular, especially in electronic commerce. Data transferred through web services is in the form of XML (Extensible Markup Language). Even though XML tag can be beneficial, it can be spaced and time consuming as well and also influences the effectiveness of the system as a whole.**

In this paper presents algorithm in improving the effectiveness of XML data transferring through the network by compression under the service of Web Services which supports compression and decompress of data. The mechanism composes of 3 steps: 1) data structure analyzes 2) data compression and 3) decompress of data after compression. It has been discovered that these steps reduces the size of the data down to 35 – 47 % and uses less data exchange time when compared to before the compression. In addition, it can also send data through web services with efficiency without losing standards of data transfer.

Keywords: Compression, Web Services, XML, Data exchange

I. INTRODUCTION

A web service is a collection of protocols and standards used for exchanging data between applications or systems uses a standardized XML messaging system. Its objective is to enable interoperability by using the central technique standard which causes data exchange. As a result, web services is widely used at present and is expected to become even more popular in the future. Web services composes of UDDI (Universal Description Discovery and Integration) [1] which informs about the organization's products and services, it is composed of 3 main parts: 1) information on how to contact service provider 2) the group of service provider 3) technical data on communication, SOAP (Simple Object Access Protocol) [1] is a form of XML data reception and transfer with web services. Application will send a SOAP request to the web services and the web service will send the result back in SOAP response, WSDL (Web Services Description Schema) [1] is a manual on web services usage which includes the location of the web services, list of functions in service, list of each function's parameter, as well as the structures of SOAP Message, XML [2] the basic layers of web services as show in "Fig.1".

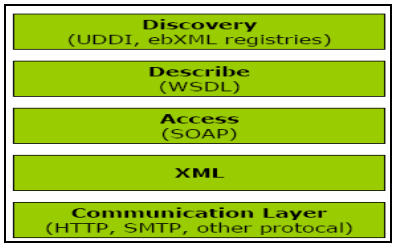

Figure 1. Basic layers of web services

<Book>
  <Author>
    <Name>Pissamai</Name>
  </Author>
</Book>
```

Figure 2. Example of XML document

XML plays a role and is a standard in exchanging data as it is a schema that can explain the definition of the data and its usage is also very flexible by having tag as a director. Also naming the tag that defines the data makes the documents that have been created easy to understand. This is a crucial part which makes data access and the automatic compilation of such structured data an easy and fast process.

Although XML'tag describes meaningful structure and semantics for humans understanding, it requires extra space to store the XML'tag. As a result, the size of the data is big and uses up a lot of space and time in data transfer when it is necessary to exchange data between organizations though network system. From the problem of data size, the methods to solve the problem is the compression of data which can be done in two ways: lossless, is when the data remains exactly the same before compression and after the decompress and lossly, is when the data before the compression and after the decompress does not need to be the same but can still be used. XML data compression is a lossless compression. It reduces the size of the data. If it is specifically XML data compression, it can increase the effectiveness of the compression when compared to general data compression.

Details of data structure mostly uses the DTD (Document Type Definition) or XML Schema. This makes the data exchange simple as it's been specified which tag to have and how the relationships between data should be. But the construction of DTD is very complicated and detailed which unable DTD to examine the type and boundary of the data. Therefore, XML Schema has been designed to solve these problems as it is written by the grammar of XML schema. It can also specify the type of data by using Namespace and specify the attribute and element values.

```
<!ELEMENT Book (Author+)>
<!ELEMENT Author (Name)>
<!ELEMENT Name (#PCDATA)>
```

Figure 3. DTD of XML document from Figure 2

From the "Fig.2" shows XML and "Fig.3", we can see that <Book> is an element that has at least one Author and the Author element has a reference of the Name element which keeps the data with the contents of PCDATA (Parsed Character Data)

The second part of this report is a presentation on XML compression at present time which are XMill [3], XGrind [4], XPRESS [5], XPACK [6], Web services compression by SharpZipLib library [7], XBrevity [8]. Part three of this report shows the development of a new way of compression. Part four contains the results of experiments and part five is the summary.

II. Related Works

At present, researches on XML data compression stress the reduction of XML data size. Each method has its own techniques. XML data compression can be divided into 3 types: 1) data compression 2) tag compression and 3) data and tag compression

XMill [3] is a technique which compresses both data and tag in order to reduce the size by starting with separating the tag, which is composed of elements and attributes, from the data which is a character. After that, the data groups' relationships will be organized. The same data will be in the same group. The next step is the data compression by using gzip [9] so that the data will come out in the same file since grouping requires understanding of the data definitions which depends on the application type. XMill allows user check the data definition. The disvantage of XMill that data cannot be search through the compressed data. However, XMill is the first research that made researchers realizes the importance of the problem and how to solve it in XML data compression. Data that has been compressed is not in the form of XML schema structure.

XGrind [4] is a technique which compressed data and tag but the user can still search for data after the compression. This qualification results from the fact that the compressed data still maintain the structure of the old data. However, XGrind will compress only XML data that has DTD structure so some data set that does not have DTD will result in having the user waste time in creating DTD for XML data set that they wanted to compress.

XPRESS [5] uses the technique in compressing both the data and the tag. Its advantages are the same as XGrind: it can search for the data after the compression. But XPRESS does not use DTD. In addition, XPRESS presented a new idea which uses reverse arithmetic encoding which is a method in organizing data so that the search for XPath expressions can be done effectively. Also, XPRESS has developed the search of data type without having to use the information from users. However, the use of XPRESS is limited because XPRESS cannot understand documents that use ID and IDREF. It also does not have a way to decompress data back into normal XML.

XPACK [6] is a way to compress XML data which uses grammatical approaches in XML data compression and decompress. The main component of XPACK is the Grammar Generator which creates grammar. The second component is the Compressor which compresses the data. The last component is the Decompressor which decompresses the compressed data by using the old structure of the data. However, XPACK cannot manage XML data that has mixed content element (which is an element composed of element and characters), limiting users to search for data in compressed XML.

Web services compression by SharpZipLib library [7] is a technique that compresses both data and tag so that the sizes can be reduced before data. However, the process in compression and decompress is time consuming. It also requires resources from units that use high efficiency web service as well. This reduces the web services' function's effectiveness.

XBrevity [8] is a technique that compresses tag. The quality comes from compressed data which has the old data structure. However, with XBrevity, data after the compression is still quite big and there was no usage of Schema tag in data compilation.

III. XML Schema Tag Compression Technique

This research stresses the compression of tag because in electronic commerce application, most data sent through web services has many complicated elements. XML compression by using XML Schema tag compression has main components as follow 1) Schema tag Scanner which reads the data structure 2) Compressor, which compresses data and 3) Decompressor, which decompress the compression

3.1 Schema tag Scanner reads the XML data structure by analyzing all structure of all XML data.

3.2 Compressor compresses the data by compressing the data at the structure of XML Schema. The result of compression is a data that resulted from compression that can be used on web services in the future.

*3.3 Decompressor w*hen it is needed to use the data that has been compressed from the web services, it is necessary to first decompress the data by using Decompressor which will read the structure of the XML schema and decompress it back to the same data that was received from the web services by lossless compression.

This research focuses on compression of XML schema. In "Fig.5" shows an example of XML schema and their corresponding XML data in "Fig.6". It can be seen that it is using the same tag but the data inside is different. This makes the schema looks complicated and data too large.

Before sending this data over on the internet, the compressor is processed to remapping XML'tag to shorter one. In "Fig. 7 and 8" are the results of compressing the XML schema and their XML data. The redesign XML schema maintains the XML standard properties and can be exchanged through web servers. When client receives this data, Decompressor will remap back to the original.

Figure 8. Compressed XML data

IV. EXPERIMENT

In the experiment of data compression, there was development in the web services system in which there were methods of compression and non-compression. This experiment was done on 1) the database SQL Server on Intel Xeon 2.33 GHz Dual with the memory of 3.5 GB, Windows Server 2003 with Service Pack 1 2) The web services was on Intel Xeon 3.00 GHz with the memory of 2.5 GB, Windows Server 2003 with Service Pack 1 and 3) the application was on Intel Pentium M 1.70 GHz with the memory of 512 MB, Windows XP Professional with Service Pack 2 and developing all 2 systems by Microsoft Visual C#.NET 2005. This experiment was not tested with XMill, XGrind, XPRESS, XPACK, and XBrevity since there wasn't a system that support working on web services. So, there was an effectiveness test by developing XML compression and non-XML compression methods for XML on the same web services.

4.1 Effectiveness Measurement The data used in experimenting is AdventureWorks database on Microsoft SQL Server 2005 and the characteristics of example document as show in TABLE I. The effectiveness in data compression is the proportion of compression which can be found by using:

Size Proportion = [1 - (size of compressed data / size of actual data)]

As shown in TABLE II or "Fig.9", the use of XML Schema tag compression technique with web services reduces the data size down to 35 - 47 % and the effectiveness of data exchange is the proportion in data exchange which can be found by using:

Proportion = [1 – (the time used in exchanging compressed data / the actual time used in data exchange)]

As shown in TABLE III or "Fig.10", usage of XML schema tag compression technique with web services reduces the length of time in data exchange when compared to the data before compression.

4.2 Affecting Factors

To get benefit of this algorithm, the XML data should have the following characteristics:

1. The XML data should compose of many elements and few attributes of elements.
2. The XML data should have few dependent on elements.

TABLE I
CHARACTERISTICS OF EXAMPLE DOCUMENT

File Name	Size (KB)	Attribute	Record
Products	387	25	504

SaleOrderDetail	9,012	8,011
Customer	1,001	1,001

V. CONCLUSION

XML data compression is important because XML is a schema that has several advantages and it is used widely in the present days. But there are also limits of XML. Normally, data in the form of XML has a bigger size than text files since XML data usually uses tag to direct the data definitions. Data transfer by XML schema results in the need of large Network Bandwidth because of the data size. Web services is a service that is widely used at present and is expected to become more popular in the future that uses XML schema to transfer data. A way to increase the effectiveness of web services is to reduce the data by compression. Past researches on XML data compression, prove that the size can be reduced but it's difficult to use with web services.

The techniques presented in this paper is on XML data compression by using XML schema tag compression to reduce the data size, but still enables the easy understanding of documents because the data is already in the form of XML schema so it can maintain the advantages of being in XML schema. It is also easy to use. This research stresses the importance of tag structure compression but the characters which are inside the tag have not been compressed. Therefore, the effectiveness of compression technique can still be more and more developed because character data compression within the tag will result in the reduction of data size in the web services.

***Abstract*-We propose a new reliable and precise classification classifier for breast cancer diagnosis. The proposed classifier, which is called an Incremental Learning algorithm based-on Mahalanobis distance (ILM), employs a Mahalanobis Radial Basis Function Network to be an activation function in order to classify cancer data. The ILM uses the Mahalanobis distance to measure a similarity and dissimilarity among data, and identifies a threshold distance. An efficient covariance computation is used for avoiding a singular covariance matrix. It is also an incremental learning utilizing recurrent computation of covariance matrix based on a Simplified Fuzzy ARTMAP Network (SFAM) [1]. For evaluation, the proposed classifier is tested with the Winconsin Diagnosis Breast Cancer datasets and compared the performance with other existing classifiers.**

***Keywords*-Classification, Mahalanobis Radial Basis Function Network, Mahalanobis Distance, Similarity, Incremental Learning, Recurrent Computation**

I. INTRODUCTION

Cancer is a group of disease that occurs when any cells in the body changing or growing out of control. Most of abnormal cells are a tumor, which is called in different cancer name based on the part of body [2]. Breast cancer is the most common type of cancer in women in the United States. In Thailand, the ratio of breast cancer is 16.3:100,000 women and Bangkok has the highest number of patients [3]. "During 1998-2002, 97% of breast cancer deaths occur in women aged 40 and older"[2]. According to the problem of breast cancer, we try to develop the classification algorithm from the experiment dataset; Wisconsin diagnosis breast cancer database obtained from the University of Wisconsin Hospital by Dr. William H. Wolberg [4]. Breast cancer is classified into benign and malignancy, which is composed of 699 patterns. Each pattern consists of 10 attributes: *sample code number*, *clump thickness*, *uniformity of cell size*, *uniformity of cell shape*, *marginal adhesion*, *single epithelial cell size*, *bare nuclei*, *bland chromatin*, *normal nucleoli*, and *mitoses*.

At present, many researchers focus on the breast cancer diagnosis by using difference techniques combined several existing classifiers to generate the new one such as Hybrid Fuzzy-Genetic methodology [5], Fuzzy-ARTMAP [6], and ILFN [7] etc. to improve the reliable and accuracy.

In this research, we propose a new incremental supervised learning based on the correlation measurement between patterns that is an Incremental Learning algorithm based-on Mahalanobis distance (ILM). The details are described in Section III.

The remains of this paper are organized as follows. Section II shows the literature reviews of the related works. Section III describes the details of the proposed algorithm. Experimental results are shown in Section IV. Finally, Section V concludes the study.

II. LITERATURE REVIEWS

A. Pattern Classification

Pattern classification is a well-known technique in machine learning and data mining. It is to classify datasets into related set of class. It is divided into two types: supervised and unsupervised learning [8]. For supervised learning, the aim is to teach the network to predict an unknown input by using training data both input patterns and target group to create the prototype of system. In contrast, the unsupervised learning uses only input patterns and similarity measures to build the trained network. This is a natural way to find classes of datasets.

B. Similarity Measure

The similarity is quantity that reflects the strength of relationship between two objects or two features. This quantity is usually having range of either -1 to +1 or normalized into 0 to 1[8-9]. The similarity between feature i and feature j is denoted by $\mathbf{S}_{ij}$. On the other hand, dissimilarity is viewed as measure of disorder between two objects. Dissimilarity between object i and object j is denoted by $\boldsymbol{\delta}_{ij}$. The relationship between dissimilarity and similarity is given by

$$\mathbf{S}_{ij} = 1 - \boldsymbol{\delta}_{ij} \quad (1)$$

Where $\mathbf{S}_{ij}$ is a similarity between features i and j and $\boldsymbol{\delta}_{ij}$ is a dissimilarity between features i and j.

Distance is used for representing the similarity and dissimilarity between objects. If the objects are most similar then the distance between them is minimized; the objects are

most dissimilarity when the distance between them is maximized.

$d_{ij} \geq 0$ distance is always positive or zero
$d_{ij} = 0$ distance is zero if it measured to itself
$d_{ij} = d_{ji}$ distance is symmetry
d_{ij} : Distance between features *i* and *j*
d_{ji} : Distance between features *j* and *i* ($d_{ji} = d_{ij}$)
d_{ii} : Distance between itself (always = 0)

There are many ways to measure the similarity and dissimilarity between objects based on the types of features or variables such as quantitative variable, ordinal variable, binary variable, and nominal variable [9]. In this paper, we focus on the quantitative variable for instance: Euclidean Distance, Manhattan Distance, and Mahalanobis distance.

Mahalanobis distance is different from the Euclidean distance, which is the most popular similarity measure. It considers the orientation of data in the sample space grouping them by mean and covariance matrixes. The shape of a cluster is hyper-ellipsoids rather than hyper-spheres as Euclidean distance. The difference of them is described in mathematic function as follow [1, 9]:

Input pattern denotes by $p_n = (p^1, p^2, ..., p^d)$, while the sample set of input pattern belong to the cluster j will be denoted as: $P_j = \{p_j^{(1)}, p_j^{(2)}, ..., p_j^{(n)}\}$ by P_j is called cluster *j*, and p is an unknown pattern.

For Euclidean Distance:

$$\min_j R(p, P_j) = \min_j (p - W_j)^T (p - W_j) \qquad (2)$$

where W_j is the center of the cluster *j*.

$$W_j = \frac{1}{n} \sum_{k=1}^{n} P_j^{(k)} \qquad (3)$$

For Mahalanobis Distance:

$$\min_j R(p, P_j) = \min_j (p - W_j)^T S^{-1} (p - W_j) \qquad (4)$$

where S_j is the covariance matrix of cluster *j*.

$$S_j = \frac{1}{n-1} \sum_{k=1}^{n} (p_j^{(k)} - W_i)(p_j^{(k)} - W_j)^T \qquad (5)$$

The Mahalanobis distance calculation is more complicated than the Euclidean distance because the covariance matrix has to be as follow [8]:

1. The determinant of S is positive
2. The S^{-1} is positive
3. The determinant of S^{-1} is positive
4. All of the main diagonal elements of S is positive
5. All of the eigenvalues of S are positive
6. S is nonsingular and has S^{-1}

C. Incremental Learning

There two well-known techniques for parameter estimation: off-line learning and on-line learning [7-8]. The off-line learning sometimes is called block-wise or batch learning**.** It requires the total learning set to be available and compute the statistical moments by summation over all elements of the learning set. On the other hand, on-line learning, there are many names such as iterative learning, recursive learning, and incremental learning [7-8]. This technique differs from the previous one. It learns continuously without forgetting the previous learned knowledge. It means when training is done, new instances can be inserted to the training data at any time. This technique closes to the human learning concept because it is "the capability of continuously improving one's skills by being taught or simply by doing" [9].

The updated parameter estimation of Euclidean and Mahalanobis distance are as follow:

For Euclidean Distance:
From (2) the recurrent computation (update function) of W_j is

$$W_j = (1 - \beta) W_j + \beta\, p \qquad (6)$$

where β is the learning rate.

For Mahalanobis Distance:
From (4) the updated function of W_j and S_j are:

$$W_j = (1 - \beta) W_j + \beta\, p \qquad (7)$$

$$S_j = (1 - \beta) S_j + \beta(1 - \beta^2)(p - W_j)(p - W_j)^T \qquad (8)$$

where β is the learning rate.

From (6) to (8) [1], they can reduce the processing time of both training and classification. The success rate of Euclidean and Mahalanobis distance comparing with the off-line learning also improved one percent and 8 to 17 %, respectively.

III. Development of an Incremental Learning Algorithm Based-on Mahalanobis Distance

ILM has three different modes: Training mode, Prediction mode and Incremental learning mode shown in Fig. 1.

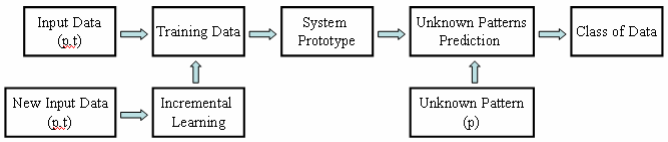

Figure 1. Architecture of ILM.

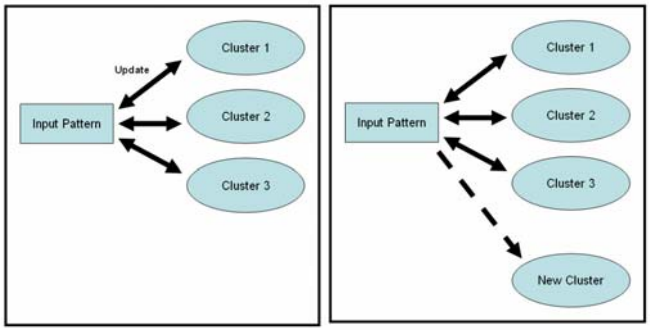
In supervised learning mode, ILM requires both input data and target data. When the algorithm learns the data, it uses the Mahalanobis distance to create the prototype of each cluster according to the degree of similarity and based on the defined threshold distance. In prediction mode, ILM will classify the unknown pattern arriving to the system to one of known classes. While predicting the unknown pattern, if it is very different from existing prototypes, the new input data can be learned to include into the system as new knowledge at anytime using the concept of the incremental learning. The output of this algorithm is the target class of each testing pattern (unknown pattern).

According to the concept of similarity measure in section B, we define the threshold distance to compare with the measured distance between data. This is to create the prototype of each cluster using the most similar data. The measured distance between data is d_m, and the defined threshold distance is d_h, where $0 < d_h < 1$. If $d_m > d_h$ then the data are less similar, in contrast if $d_m \leq d_h$ then the data are most similar.

For example, if there are three existing prototypes of clusters. If the winner cluster is the Cluster 1, and the distance between the input pattern and the Cluster 1 is less than or equal to the defined threshold distance then update the parameters in Cluster 1 (see Fig 2(a)). It means that the input pattern is most similar to the prototype of Cluster1. On the other hand, if the winner node is Cluster 1 but the distance is higher than the defined threshold distance. It shows that the input pattern is less similar to Cluster1 then a prototype of new cluster is created showing in Fig 2(b).



(a) (b)

Figure 2. The Threshold Distance Identification Concept.

A. Details of the Proposed Algorithm

ILM is divided into a learning phase, and a testing phase. Firstly, the system will create the system prototype using the learning phase after that classify the unknown pattern by the testing phase. The detail of each phase is described as follow:

Learning Phase

Step 1: Set up the initial value: the threshold distance (d_h), where $0 < d_h < 1$, and the covariance matrix ($S_{j,initial}$) as follow:

$$S_{j,initial} = \text{x.}(I_n) \tag{9}$$

where $I_n = \begin{bmatrix} 1 & 0 & \dots & 0 \\ 0 & 1 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 1 \end{bmatrix}$, and $0 < x < 1$

$$\text{x.}(I_n) = \text{x.}\begin{bmatrix} 1 & 0 & \dots & 0 \\ 0 & 1 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 1 \end{bmatrix} = \begin{bmatrix} x & 0 & \dots & 0 \\ 0 & x & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & x \end{bmatrix}$$

Step 2: Read the first input (p) and target (t) pattern to be the mean (W_j), and target of the cluster, then set up count.

$$C_{j,initial} = 1 \tag{10}$$

Step 3: Read next input pattern

Step 4: Similarity measure between p and W_j using the nonsingular covariance matrix to calculate the Mahalanobis distance (d)

$$S_{j,new} = S_{j,old} + \text{x.}(I_n) \tag{11}$$

$$\text{d} = (p - W_j)^T S^{-1} (p - W_j) \tag{12}$$

Step 5: Calculate the membership value of each cluster using Mahalanobis RBF

$$mem(p, W_j) = \exp\left(- \frac{(p - W_j)^T S^{-1} (p - W_j)}{2} \right) \tag{13}$$

Step 6: find the winner cluster that has the maximum membership value identified by fuzzy OR operator

$$winner = \arg\max(mem) = mem_1 \vee mem_2 \vee \dots \vee mem_n$$

Step 7: Update parameters: count, mean, and covariance matrix, at the winner cluster:

- if the distance between the input pattern and the winner cluster is less than or equal to the defined threshold distance

$$C_{j,new} = C_{j,old} + 1 \tag{14}$$

$$W_{j,new} = (1 - \beta) W_{j,old} + \beta p \tag{15}$$

Where: $\beta = 1 / C_{j,new}$

$$S_{j,new} = (1-\beta) S_{j,old} + \beta(1-\beta^2)(p - W_{j,new})(p - W_{j,new})^T \tag{16}$$

- if the distance between the input pattern and the winner cluster is higher than the defined threshold distance, then new cluster is created

Testing Phase

Step 1: Read the testing pattern

Step 2: Similarity measure between the testing pattern and the prototype of each cluster

$$d = (p - W_j)^T S^{-1} (p - W_j) \quad (17)$$

Step 3: Assign the membership value in each cluster using Mahalanobis RBF

$$mem(p, W_j) = \exp\left(- \frac{(p - W_j)^T S^{-1} (p - W_j)}{2} \right) \quad (18)$$

Step 4: Find the winner cluster using fuzzy OR operator

$$winner = \arg\max(mem) = mem_1 \vee mem_2 \vee \ldots \vee mem_n$$

Step 5: Assign the target class to the testing pattern

Target Class = Target of Winner Cluster

IV. EXPERIMENTAL RESULTS

In this section we show two experiments: threshold distance identification and efficiency comparison between ILM and existing classifiers.

For the threshold distance identification, we found the threshold distance that suitable for the breast cancer diagnosis. We tested it ten times to vary from 0 to 1. The result showed that 0.001 can illustrate the high performance of algorithm in the breast cancer diagnosis. Before using the threshold distance identification concept, the classification correctness is 97.633 after that the efficiency is improved to be 98.71 that shown in Table 1.

Table II

Effect of Threshold Distance Identification.

ILM	Classification Correctness (%)
Without Threshold Distance Identification	97.633
With Threshold Distance Identification	98.71

To demonstrate the performance of ILM in breast cancer diagnosis the well-known benchmark data Winsconsis Breast Cancer Database (WBCD) is used to compare our performance with other existing classifiers such as SVM [10], LVQ [10-11], Naïve Bayes [10], SOM [10-11], and SOM-RBF [10-11]. The comparison results are illustrated in Table 2.

In table 2, we try to compare ILM with the varieties types of classifiers based on different methods such as the Euclidean RBF, statistical method, fuzzy, and genetic algorithm. The results show that the classification correctness of most classifiers is more than 95. The efficiency performance of ILM is the highest correctness, it is 98.71.

Table II

The Comparison of Performance between ILM and Existing Classifiers.

Classifiers	Classification Correctness (%)
Hybrid Fuzzy-Genetic	97.8
FAM	94.29
SVM	97.20
LVQ	96.60
Naïve Bayes	96.40
SOM	97.4
SOM-RBF	97.5
ILM	**98.71**

V. CONCLUSIONS

This algorithm is a new classifier for elliptical cluster shape using Mahalanobis RBF to create the prototype of each cluster. It also supports the supervised and incremental learning to improve the success rate of performance. It uses the efficient covariance computation to avoid the singular covariance matrix. Experimental results demonstrate that this proposed algorithm is powerful and effective tool to diagnose the breast cancer with performance of over 98 and it also is the highest accuracy classification.

***Abstract*-This paper presents the use of a neural network and a decision tree in thalassaemia classification. The aim is to differentiate between thalassaemic patients, persons with thalassaemia trait and normal subjects by inspecting types of haemoglobin. C4.5 is the chosen architecture for decision tree implementation. For comparison, multilayer perceptrons are explored in classification via a neural network. The classification results indicate that the performance of the C4.5 decision tree is significantly higher than that of the multilayer perceptrons. Detailed analysis of the classification errors of the C4.5 decision tree is also included. The analysis reveals that the false-positive and false-negative errors are the main cause of classification errors. These results suggest that a combination of a C4.5 decision tree with haemoglobin typing may give rise to a guideline for further investigation of thalassaemia classification.**

I. Introduction

Thalassaemia is a genetic disease that causes a reduction in the life span of a red blood cell [1]. The disease is a result of an abnormality in the genes that regulate the formation of haemoglobin (Hb)–a core component of the red blood cell. In order to make the diagnosis, the blood characteristics must be analysed. A complete blood count (CBC) and haemoglobin typing is the primary screening test for a laboratory diagnosis of thalassaemia. However, there is still a limitation in the analysis of data due to a large number of possible candidate characteristics. In addition, there are various types of thalassaemia and thalassaemia trait. (Persons with thalassaemia trait do not have the disease but inherit genes that cause the disease.) As a result, a manual diagnostic process can only be carried out by specialists [2, 3].

Early attempts to formulate an automated diagnostic tool employed image analysis [4], statistical [5] and clustering techniques [6]. Later, the implementation protocol has shifted to the expert systems, in which both rule-based [7, 8, 9] and hybrid neural network/rule-based systems [10] have been successfully tested in clinical trials. Nonetheless, these tools broadly differentiate between a wide range of blood-related diseases including various types of anaemia. In order to narrow the diagnostic target down to the differentiation between thalassaemic patients, persons with thalassaemia trait and normal subjects, an alternative automated diagnostic tool is required. Recently, a successful implementation of a neural network [11, 12], a *k*-nearest neighbour technique [12] and a support vector machine [12] as a thalassaemic diagnostic tool has been reported. However, the tool can only differentiate between two types of thalassaemic gene carriers and normal subjects. Further works are required in order to expand the tool capability to cover all major types of thalassaemic patients and persons with thalassaemia trait that are commonly found in Thailand where the total number of types is much larger [13].

The thalassaemia classification can generally be formulated into a pattern recognition problem. The input patterns or samples in this case would be blood-related data covering the blood characteristics. These characteristics can be directly obtained from haemoglobin typing. On the other hand, the target classification output would be either the disease/trait type or a normal-subject flag. The use of a neural network and a C4.5 decision tree as the classifiers is proposed. This will provide direct evidence on the suitability of both parametric and non-parametric approaches to the task.

This paper is organised as follows. The thalassaemia data and classification techniques are explained in section 2. Next, the classification results are discussed in section 3. Finally, the conclusions are drawn in section 4.

II. Materials and Methods

In this section, the thalassaemia data set and the classification techniques will be explained; the details about the data set will be covered in section 2.A while a brief explanation about the classifiers will be given in section 2.B.

A. Data Set

Thalassaemia is a form of chronic anaemia that reduces the life span of red blood cells [1]. The disease stems from an abnormality in the genes that regulate the formation of a protein called globin, which is a major component of haemoglobin. Each red blood cell contains approximately 300 million molecules of haemoglobin. Hence, a change in the structure of globin affects the structure and functionality of a red blood cell. A globin molecule contains two parts: α-globin and β-globin. The α-globin contains 141 amino acids, which are regulated by genes on chromosome 16. The β-globin consists of 146 amino acids, which are governed by genes on chromosome 11. Since the regulatory genes reside on two autosomes, the transmission mode of abnormal genes is autosomal recessive. Hence, a person must have two copies of a recessive gene on the same chromosome in order to have the disease. The types of thalassaemic patient and person with

7	A2	277-289
8	D/S/CS/C/Unknown	290-300

thalassaemia trait summarised in Table 1 are commonly found in Thailand and will be covered in this investigation. From Table 1, it can be clearly seen that there are many types of abnormality. The most reliable method for the diagnosis is to determine the genetic makeup of the person in question. However, this process is costly and time-consuming. An alternative approach is to make a diagnosis based on the characteristics of human blood.

In this study, the data set for thalassaemia diagnosis consists of blood characteristics obtained through haemoglobin typing. Each type of haemoglobin, expressed in terms of percentage of total haemoglobin in the sample, is identified based on its chromatographic retention time. The resulting characteristics or attributes that can be extracted from the blood samples are summarised in Table 2.

B. Classifiers

Two candidate classifiers are considered in this investigation: a neural network and a C4.5 decision tree. A neural network is an interconnected group of artificial neurons that uses a mathematical or computational model for information processing based on a connectionist approach. The neural network that is selected for this implementation is a multilayer perceptron [14]. In the implementation, the number of network inputs is equal to the number of input attributes while the number of network outputs is equal to the number of output classes. Specifically, the aimed network output for each target class takes the form of a unit vector where the vector aligns with a principal axis of the output vector space. The network can have one or two hidden layers in which the number of nodes in each hidden layer can vary. As a result, the observation displays the effect of network non-linearity on the classification performance. The multilayer perceptron will be trained by a back-propagation algorithm.

C4.5 decision tree is one of the most widely used and practiced tools for inductive inference [15]. A decision tree is generally constructed in a top-down manner. The tree construction begins at the root node where each input feature or attribute is evaluated using a statistical test to determine how well it alone classifies the training samples. The best attribute is selected and used as the test at the root node of the tree. A descendant of the root node is then created for either each possible value of this attribute if the attribute value is discrete or each possible discretised range of this attribute if the attribute value is continuous. Next, the training samples are sorted to the appropriate descendant node. The entire process is subsequently repeated using the training samples associated with each descendant node to select the best attribute to test at that point in the tree. This forms a greedy search for an acceptable decision tree, in which the algorithm never backtracks to reconsider earlier choices. In this paper, the continuous attribute value is partitioned into a discrete set of intervals using an information-theoretic technique proposed by Fayyad and Irani [16].

III. RESULTS AND DISCUSSIONS

The results from the experiment using the thalassaemia classifiers will be presented in section 3.A. Furthermore, a detailed classification accuracy analysis emphasising on the classification errors will be given in section 3.B.

A. Classification Experiment and Results

The data presented in section 2.A are used to train and test a neural network and a C4.5 decision tree. The performance comparison will be carried out by a *k*-fold cross-validation technique [17]. In this investigation, *k* is set to 10, which indicates that for each fold the numbers of training and testing samples are 135 and 15, respectively. The classification performance of the multilayer perceptron (MLP) and C4.5 decision tree is summarised in Table 3. From Table 3, the results reveal that the most suitable classifier for the current scenario is the C4.5 decision tree as the classification accuracy is higher than both multilayer perceptrons with one and two hidden layers. In addition, the classification performances of the best multilayer perceptrons with one and two hidden layers are approximately the same. These results can be interpreted as follows.

Firstly, consider the results received from multilayer perceptrons with different numbers of hidden layers and hidden nodes. By increasing the number of hidden nodes, the level of non-linearity within the network will increase, implying that the network would be capable of capturing a more complex input-output relationship. However, this also means that there

is an increase in the number of connection weights, which require an adjustment via the back-propagation algorithm. For this study, it is observable that poor accuracy can be observed when the number of hidden nodes is either too low or too high. Further, both multilayer perceptrons with one and two hidden layers appear to have an adequate memory capacity to capture the required input-output characteristics. As a result, the use of two hidden layers appears unnecessary since no further improvement is observed with increasing number of hidden layers.

Figure 1. C4.5 decision tree. A_i, I_i and C_i denote the ith attribute, the ith interval and the ith output class, respectively.

The result from the C4.5 decision tree is now analysed. Table 4 illustrates the discrete interval of each input attribute, which is obtained after the application of the attribute discretisation technique [16] to the data. From Table 4, the number of discrete intervals varies from two to seven. The C4.5 decision tree that utilises these discrete attributes is given in Figure 1. It is noticeable that the tree does not cover all attributes; the missing attributes are attributes 3 and 5. Recall from Table 2 that these two attributes are unknown types of haemoglobin. The absence of these attributes from the decision tree signifies that these attributes have no effects on the diagnosis capability of the decision tree. It may be possible to increase the classification performance of the multilayer perceptron after removing these attributes from the network input. In addition, the use of CBC data as additional input may also improve the performances of both classifiers [18]. These speculations will be investigated in the future work.

B. Classification Accuracy Analysis

In the previous sub-section, the classification performance of the multilayer perceptron and C4.5 decision tree has been obtained from the cross-validation analysis. The classification accuracy of the C4.5 decision tree is 95.33%. On the other hand, the accuracy of the best multilayer perceptron with one hidden layer is 80.67%. The classification errors from both classifiers can be divided into four main categories: a rejection, a misclassification within the same super-group, a false-positive error and a false-negative error. These classification errors can be explained as follows.

The classification rejection occurs when the classifier output is ambiguous. This can be either no output response or more than one output class being reported from the classifier. In contrast, the misclassification within the same super-group occurs when either a person with thalassaemia trait is identified as being a person with another type of thalassaemia trait, or a thalassaemic patient is misdiagnosed as being another type of patient. In this study, the persons with thalassaemia trait, thalassaemic patients and normal subjects are clustered into three super-groups based upon the severity of the exhibited blood characteristics. The details of all three super-groups are given in Table 5. From Table 5, the super-groups are made up from the minor trait/normal super-group, the major trait super-group and the disease super-group.

The last two types of classification error are the false-positive and false-negative errors. In this study, the false-positive error refers to the situation when a sample is misidentified as belonging to a super-group with a higher severity of thalassaemic characteristics. On the other hand, the false-negative error refers to the case when a sample is misclassified as being a member of a super-group with a lower severity of thalassaemic characteristics.

The summary of classification errors from the multilayer perceptron with 25 hidden nodes reveals that the majority of errors come from sample rejections and misclassification within the same super-group. In contrast, the majority of decision tree's classification errors come from false-positive and false-negative errors. However, the combined false-positive and false-negative error is less than 3%. This confirms the suitability of the C4.5 decision tree for this task.

IV. Conclusions

In this paper, a thalassaemia classification problem is investigated. The objective is to automatically identify whether the human subject is a person with thalassaemia trait, a thalassaemic patient, or a normal person using blood data from haemoglobin typing. The collected blood samples are divided into 14 groups where the significant blood characteristics are based on attributes of haemoglobin's types. The classification results indicate that the accuracy of the C4.5 decision tree is significantly higher than that of the multilayer perceptron. This helps emphasise the reliability of a C4.5 decision tree as an automated thalassaemic classification tool.

***Abstract*- This paper purposes a numerical model of magnetic fluid flow using nail-like magnetic device. The magnetic liquids play an important role as drug carriers in the human body. The nail-like magnetic is also utilized to focus magnetic liquids. The Finite Element Method, FEM, is developed to solve two important sets of partial differential equation. Electromagnetic field is governed by Maxwell equation and velocity field is obtained by Navier-Stoke equation. The result shows the potential to target drug in the tumor cell locally.**

I. INTRODUCTION

In the recent years, the area of Finite Element Method (FEM) has been widely interest in biomedical engineering. Some researchers use FEM as a tool to design polymer-coated targeted drug delivery systems [1]. Based on Laplace-Beltrami operator, the geometry model of human brain is analyzed [2]. In drug delivery system, an integrated system use superparamagnetic, biocompatible nano drug carriers for targeted but non-invasive delivery [3]. Additionally, drug deliver is based on nanotechnology using magnetic guidance of drug loaded magnetic carriers to the targeted site and thereafter released by external ultrasound energy [4]. There are many alternative methods for the treatment of cancer or tumor in human body such as tumor ablation [5] and chemotherapy [6]. To avoid side effect on healthy human cells, which are made by chemotherapy, physician always face with an upper limit in the treatment dose. This limit obstructs the chance of successful treatment of the tumor cells. The objective of modern cancer researches is to focus chemotherapy drugs locally to tumor tissue and to stop the global exposure to the organism. This computational model investigates an external magnetic field that interacts with blood flow with ferrofluids. The magnetic field is described by Maxwell's equation and the dynamic flow is illustrated by Navier-Stoke equations.

In this paper, the velocity field of magnetic fluid is purposed. Based on Partial Differential Equation (PDE), the development of this algorithm comprises with equation of conservation of mass in fluid dynamic, Navier-Stokes equations, and Maxwell's equations. These nonlinear equations are analyzed by FEM. The simulated system is numerically computed to investigate the effect of nail–like magnetic potential with magnetic fluid flow in time dependent model.

II. NAVIER-STOKES EQUATIONS

A dynamic equation describing fluid motion [7] is a momentum equation that can be solved to incompressible Newtonian flow. The most famous equations in fluid dynamics are Navier-Stokes equations. A set of equations composes of three velocity equations in the rectangular coordinates (1-3) and the continuity in (4).

$$\rho\left[\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}+w\frac{\partial u}{\partial z}\right]=\rho g_x-\frac{\partial p}{\partial x}+\eta\left[\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}+\frac{\partial^2 u}{\partial z^2}\right] \quad (1)$$

$$\rho\left[\frac{\partial v}{\partial t}+u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}+w\frac{\partial v}{\partial z}\right]=\rho g_y-\frac{\partial p}{\partial y}+\eta\left[\frac{\partial^2 v}{\partial x^2}+\frac{\partial^2 v}{\partial y^2}+\frac{\partial^2 v}{\partial z^2}\right] \quad (2)$$

$$\rho\left[\frac{\partial w}{\partial t}+u\frac{\partial w}{\partial x}+v\frac{\partial w}{\partial y}+w\frac{\partial w}{\partial z}\right]=\rho g_z-\frac{\partial p}{\partial z}+\eta\left[\frac{\partial^2 w}{\partial x^2}+\frac{\partial^2 w}{\partial y^2}+\frac{\partial^2 w}{\partial z^2}\right] \quad (3)$$

$$\frac{\partial \rho u}{\partial x}+\frac{\partial \rho v}{\partial y}+\frac{\partial \rho w}{\partial z}=\nabla\cdot\rho\,\mathbf{u}=0 \quad (4)$$

The equations are nonlinear partial differential equations where *u, v, w,* are velocity in *x,* y, *z* direction respectively. ρ is density of material. g_x, g_y, g_z are gravitational force field in *x,* y, *z* as well. *t* is time. To observe fluid motion in blood vessel model, Navier-Stokes equation can be resolved and reduced to time dependent as shown in (5).

$$\rho\frac{\partial \mathbf{u}}{\partial t}=\mathbf{F}+\eta\nabla^2\mathbf{u}-\rho(\mathbf{u}\cdot\nabla)\mathbf{u}-\nabla p \quad (5)$$

Equation (5) is used to compute a fluid flow direction in the model assumed that the fluid is an incompressible flow. The significant parameter, $\mathbf{F}=(F_x,F_y)$, of this section is a volume force field. The relation between **F** and Maxwell's equation is described in (9) and (10).

III. MAXWELL'S EQUATIONS

The magnetic vector potential generated by magnet is calculated. The magnetic volume force created by magnetic field is affected the flow field in the blood vessel as shown in (6). A magnetic potential vector is **A** and the magnetization vector is **M**. Equation (7) and (8) [9] describe magnetization in x and y direction that is used in (9) and (10)[10]. To simulate blood flow in model, the x direction, *v*, follows a sinusoidal expression in time as illustrated in (11).

$$\nabla \times (\frac{1}{\mu_0 \mu_r} \nabla \times \mathbf{A}\text{-}\mathbf{M}) = 0 \tag{6}$$

$$M_x = \alpha \tan^{-1}(\frac{\beta}{\mu_r \mu_0} \frac{\partial A_Z}{\partial y}) \tag{7}$$

$$M_y = \alpha \tan^{-1}(\frac{\beta}{\mu_r \mu_0} \frac{\partial A_Z}{\partial x}) \tag{8}$$

$$F_x = \frac{M_x}{\mu_r} \frac{\partial^2 A_Z}{\partial x \partial y} \tag{9}$$

$$F_y = -\frac{M_y}{\mu_r} \frac{\partial^2 A_Z}{\partial y \partial x} \tag{10}$$

$$v = \sin(\omega t) + \sqrt{\sin^2(\omega t)} \tag{11}$$

The magnetic field, magnetic vector potential, generated by magnet is calculated. The computed magnetic field generates a magnetic volume force that affects the flow field in the blood vessel.

IV. PHYSICAL CONSTANTS

The important physical constants are shown in Table I for Navier-Stokes equation and Table II for Maxwell's equations.

TABLE I
Fluid Physical Constants [7], [8]

Fluid Physical Constants	Value
Density (ρ)	1,000 kg/m^3
Dynamic Viscosity (η)	5.0×10^{-3} Ns/m^2

TABLE II
Magnetic Constants

Magnetic Constants	Value
Magnetic fluid parameter (α)	1×10^{-4}
Magnetic fluid parameter (β)	3×10^{-5}
Magnet magnetization	0.5e-5 A/m
Magnet relative permeability	5e3
Tissue relative permeability	0.9998

V. FINITE ELEMENT METHOD

A. Geometry Model and Assumption

To observe magnetic potential and fluid velocity field, the model of blood vessel is created in 3D. The model consists of blood vessel, tissue and magnetic device as shown in Figure 1. The inflow of fluid comes from left side and outflow is to the right side. The magnetic device is placed on the tissue to distribute magnetic potential interacting with ferrofluids carrier in blood vessel. To reduce calculating time, 2D model is created in Figure 2 and magnetic device is assumed to be permanent magnet. The 2D geometry model is approximated by many triangles called a mesh model as shown in Figure 3. A model represents the fluid velocity field computed by mesh model. Because the Navier-Stokes equations are computationally arduous, it is considerable to utilize an appropriate mesh. If the mesh is too rough, the solution might not coverage at all or errors might be large. Contrastly, if the mesh is too fine, the solution time for the nonlinear system of equations might be unnecessarily long.

B. Boundary Condition, Initial Condition

Boundary conditions are most described by considering the magnetostatic and fluid dynamics shown in Table III-IV. For time dependent analysis, a set of initial conditions is necessary for the dependent variable. The calculation process comprise with two steps. Firstly, magnetic potential is computed. Secondly, the result of magnetic potential is used as initial condition to calculate fluid velocity field. The wall applies no-slip condition. The out flow is set to pressure condition, $p = 0$.

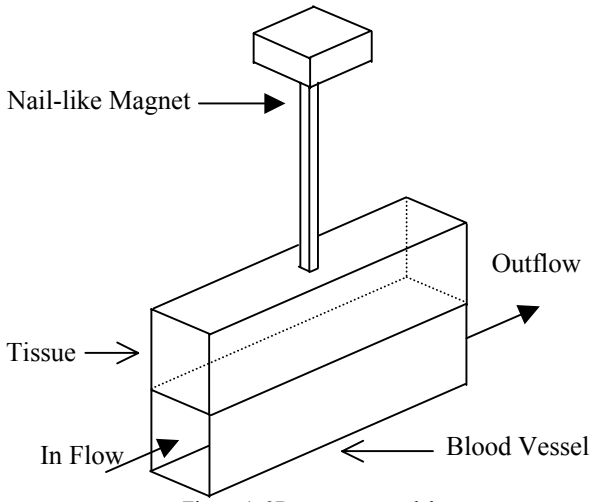

Figure 1. 3D geometry model

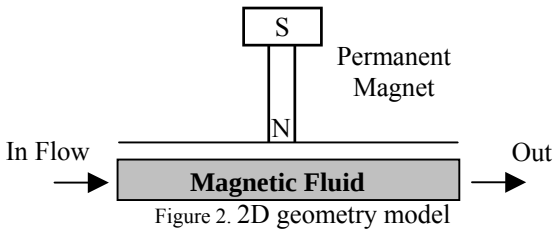

Figure 2. 2D geometry model

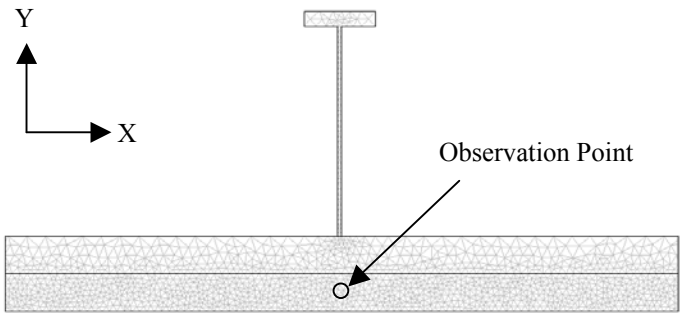

Figure 3. Mesh model

The mesh model is computed with Pentium® IV 3.2 GHz, DDR RAM 1.5 GB. The calculation time of time-dependent is around 1.5 hours per model.

TABLE III
Boundary condition of magnetostatic

Magnetostatic Equations	Boundary Condition
Magnetic Insulation	$A_Z = 0$
Constitutive Relation	$B_0=\mu_0\mu_r H+B_r$
Relative Permeability	Isotropic

TABLE IV
Boundary condition of fluid dynamics

Fluid Dynamics	Boundary Condition
Inflow	u = Heart Beat Equation
Outflow	$P_0=0$
Wall	u=0

VI. Experimental Results

Based on the FEM given in previous section, the observation point is created as shown in Figure 3. That point places on center of blood vessel model. The fluid velocity at observation point is shown in Figure 6 and 7.

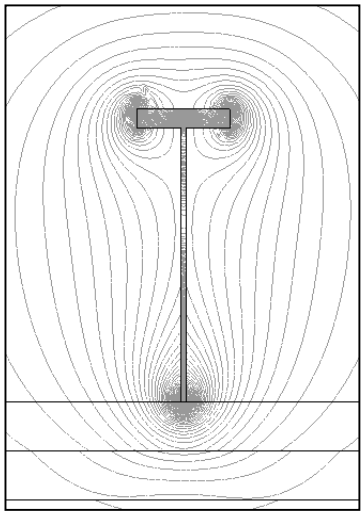

Figure 4 Magnetic flux density

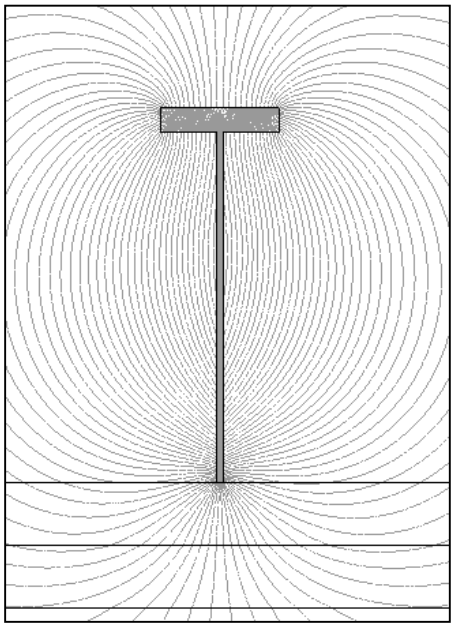

Figure 5 Magnetic potential

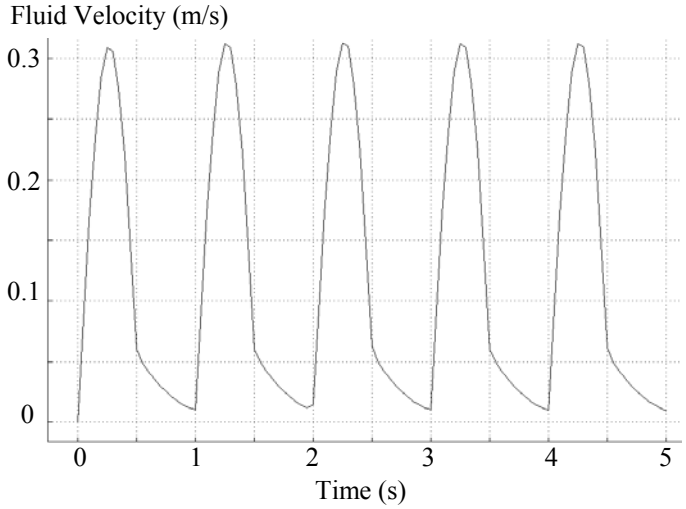

Figure 6 Fluid velocity without magnetic flux density

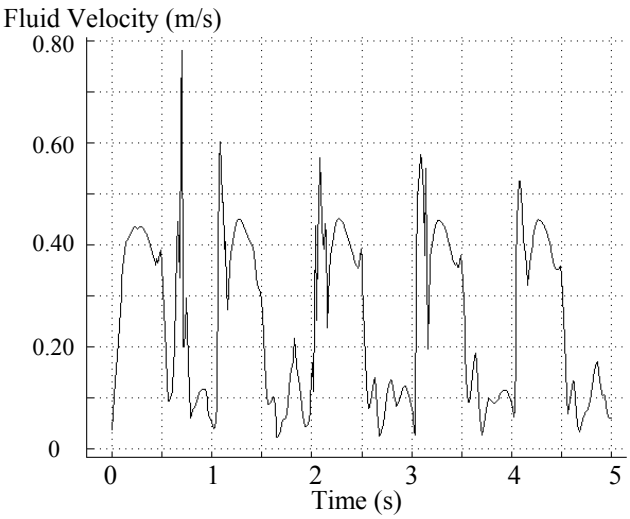

Figure 7 Fluid velocity with magnetic flux density

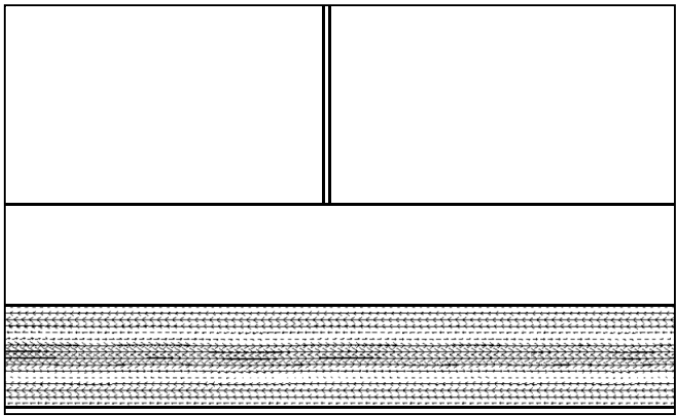

Figure 8 Fluid velocity field without magnetic flux density

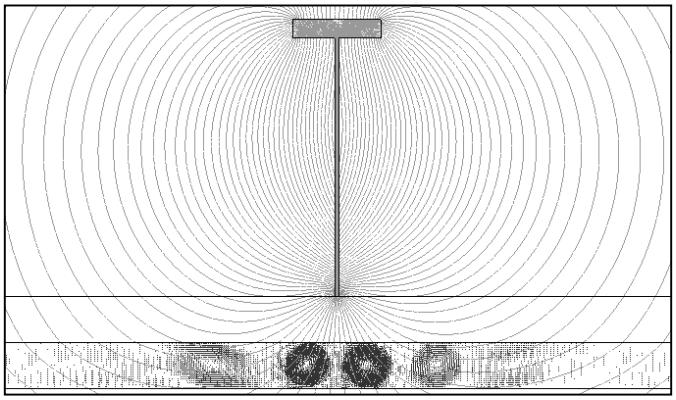

Figure 9 Fluid velocity field with magnetic potential

The experimentation is divided in two important parts. Firstly, only magnetic potential is computed with time independent, stationary state. The magnetic flux density is shown in Figure 4 and magnetic potential is shown in Figure 5. Secondly, the results of first step are applied to calculate velocity field by Navier-Stokes equations in time dependent. In Figure 6, only fluid field velocity is computed without external magnetic field. Because inflow boundary use heart beat equation, fluid velocity field is nearly sinusoidal wave at observation point. The peak velocity of fluid velocity is around 0.31 m/s and not turbulent flow as shown in Figure 8. Then, the magnetic potential field is applied to monitor fluid velocity field. The results show that peak velocity field increases from 0.31 to 0.80 m/s and decrease to 0.6 m/s at time=2 sec. The fluid velocity field after applying magnetic potential field is eddy flow. The area of eddy flow is focused only in the area that magnet is place as shown in Figure 9. The nail-like model improves resolution of focal area compared with two magnets model [11].

VII. CONCLUSION

In this model, two famous types of PDE equation are coupled together to approximate ferro-hydro-dynamic behavior. A computational algorithm of FEM is applied to compute fluid velocity field with interacted magnetic field. To reduce computational time, 2D model of blood vessel is created. The heart beat equation is created at inlet boundary. Pressure condition boundary is also used at the outlet. To improve focal resolution, the nail-like magnet is designed. The experimental results show the difference of fluid field velocity and fluid flow pattern when apply magnetic potential field. The fluid velocity field is eddied flow from magnetic potential field. This method shows the potential to target chemotherapy drug in the human body locally.

Reversal Transform for Prokaryotic Organisms

Noppadon Khiripet and Jutarat Maneewattanapluk

National Electronics and Computer Technology Center

Pathumthani, 12120 Thailand

***Abstract*- For decades, evolution studies focus on the mutations of molecular clock genes, such as 16s rRNA. This is partly due to the relatively expensive to obtain any segment of DNA sequence. However, modern sequencing techniques have been rapidly advanced and give rise not only to the ability to decipher a larger block of DNA sequences but also to the availability of numerous complete genomic sequences. This new information is changing the way how biologists look at the evolution. This paper investigated the problem of how to transform one genome into another based on a reversal distance approach. The method was tested with 200+ complete bacterial genomic sequences and was found that it efficiently captured the evolution between and within bacterial phylums.**

I. INTRODUCTION

Evolution can be considered at many different scales: sequences, genes, gene families, genomes and species. Recently, there has been a rapid progress in this area, with models and methods becoming more powerful and complex. The flood of data demands the development and use of mathematical and computational tools to handle the analysis of evolution more efficiently.

Although the traditional study of 16s rRNA [1] suggests a model for the evolution, phylogenetic analysis of other genes and gene families has revealed that evolution is probably more complex and that a more appropriate evolutionary model might exist.

The availability of many whole genome sequences provides a promising new kind of data for evolution study [2]. This gene-order data, where the location of the gene sequence can also be integrated in the analysis, give rise to a modern day of phylogeny. In particular, whole genome alignment methods have recently been developed and applied to the comparison of the human and mouse genome [3]. Other methods have been used to detect regions of conserved synteny and orthologous genes between two genomes [4]. These methods formally represent chromosome as a linear order of genes.

This paper investigated the genomes of prokaryotic organisms (bacteria), all of which are known to be linear, by a sorting by reversal approach. It is organized as follows, in Section II, the method for orthologous gene detection is briefly introduced, followed by the synteny block construction. Then, the mathematical model of genome rearrangement is discussed. The method is tested with bacterial genome data in Section III. Finally, discussion and conclusions are drawn in Section IV.

II. METHOD

A. Orthologous gene matching

Two genes are to be orthologous if they diverged after a speciation event. To computationally detect orthologous genes, a pair of genes from two different genomes is aligned together with a program called NCBI BLASTP [8]. Reciprocal best hits of the pair implied that they are orthologous.

B. Synteny Blocks

Besides the gene content that is considered as the basis of evolution distance. Evidence from the study of human and mouse genome [4] shows that, in some ways, the human genome is just the mouse genome cut into about 300 large genomic fragments, called synteny blocks, which have been pasted together in a different order. These synteny blocks have been shuffled through evolution. The different order of genes is the result of genome rearrangement and a series of these rearrangements can alter the genomic architecture of one specie into another specie.

C. Genome Rearrangement

Analyzing the rearrangement history is a challenging problem and can be thought of as a reversal sorting problem. As shown in Figure 1, a rearrangement scenario depicted that there are three steps in transforming the mouse X chromosome into the human X chromosome.

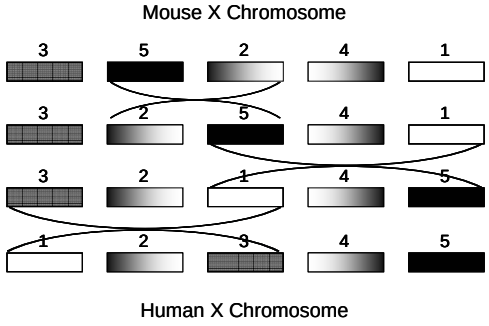

Figure 1. Transforming Mouse X chromosome to Human X chromosome (only five synteny blocks are shown).

The formal definition of a reversal can be stated as follows.

Definition 1: A reversal $\rho(i, j)$ has the effect of reversing the order synteny blocks

$$\pi_i \pi_{i+1} \pi_{i+2} \ldots \pi_{j-1} \pi_j$$

In effect, this transforms

$$\pi = \pi_1 \ldots \pi_{i-1} \pi_i \pi_{i+1} \ldots \pi_{j-1} \pi_j \pi_{j+1} \ldots \pi_n$$

into

$$\pi \cdot \rho(i, j) = \pi_1 \ldots \pi_{i-1} \pi_j \pi_{j-1} \ldots \pi_{i+1} \pi_i \pi_{j+1} \ldots \pi_n$$

For example, if $\pi = 1243756$, then $\pi \cdot \rho(3,6) = 1257346$.

We can extend the idea of reversal steps in sorting to represent the distance between a pair of genomes. However, the distance between two permutation sequences is not so straight forward. This problem can be formulated as:

Definition 2: Reversal Distance Problem

Given two permutations, find a shortest series of reversals that transforms one permutation into another

Input: Permutations π and δ.

Output: A series of reversals $\rho_1, \rho_2, \ldots \rho_t$ transforming π into δ (i.e., $\pi \cdot \rho_1 \cdot \rho_2 \cdots \rho_t = \delta$), such that t is minimum.

The distance t is called *reversal distance* or *inversion distance*. For unsigned permutation, in fact, the problem is very difficult to compute (NP-hard). For signed permutations, it can be computed in linear time [5], using the deep theoretical results of Hannenhalli and Pevzner [6]. The inversion distance between two signed permutations of *n* genes is given by

n - #cycle + #hurdles + (fortress) (1)

In our case of reversal transform from one genome into another, using the above theory, we obtained results illustrated as follows. When comparing two genomes and considering the orthologous genes, the order of these genes of one genome can be rearranged into the order of genes of another genome by repeatly reversing fragments of its DNA, e.g.

D0: 1,-7,6,-10,9,-8,2,-11,[-3,5],4
D1: 1,-7,6,-10,9,-8,2,-11,-5,[3,4]
D2: 1,-7,6,-10,9,-8,2,[-11,-5,-4,-3]
D3: 1,-7,6,[-10,9,-8,2,3,4,5],11
D4: 1,[-7,6,-5,-4,-3,-2],8,-9,10,11
D5: 1,2,3,4,5,[-6],7,8,-9,10,11
D6: 1,2,3,4,5,6,7,8,[-9],10,11
D7: 1,2,3,4,5,6,7,8,9,10,11

The minimum number of reversing steps is call optimal reversal distance. In the above example, the optimal reversal distance is 7.

III. RESULTS

Public bacterial sequences were downloaded from NCBI [8]. The complete sequences of 228 bacterial genomes are classified into 10 phylums. The results of average reversal distance for every pair of genomes within a phylum, is presented in Figure 2 and 3.

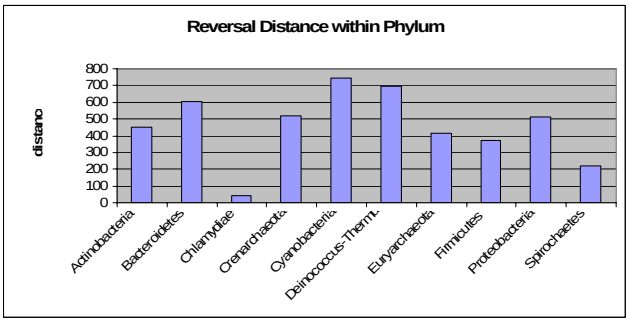

Figure 2 Average reversal distance within phylum.

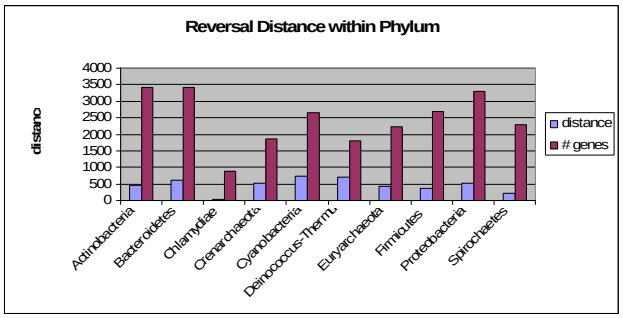

Figure 3 Average reversal distance compared to number of genes.

Applying the Neighbor-Joining [7] method to the adjacency matrix of reversal distance of the 228 baterial genomes yielded the resulting whole genome phylogenetic tree. Due to space limitation, only a subset of the tree is shown as in Figure 4.

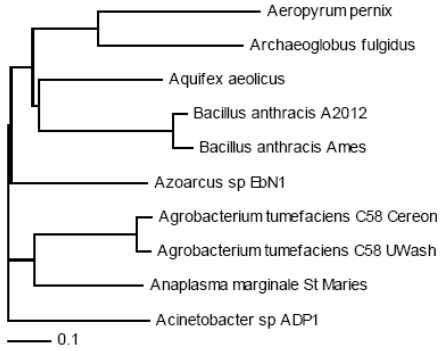

Figure 4.Whole genome phylogeny by reversal transform

IV. DISCUSSION AND FUTURE DIRECTION

The reversal transform revealed that the rates of genome rearrangement of bacterial families are various, some have it higher than the rest, i.e. the Cyanobacteria. The higher value indicates that the organisms within the family are more diverse. This implies that the family may already evolve for a very long time, longer than the family with less genome rearrangement. This finding along with the phylogeny result is consistent with the standard taxonomy [8], indicating that reversal transform is a promising approach in bacterial phylogenetic studies.

Interesting research directions related to present method is how to extend it to discover ancestral genomes, to locate the origin of replications and how to realistically present the transformation scenarios using meaningful biological constraints.

***Abstract*- Given a finite set *P* of *n* points in *d*-dimensional Euclidean space, the diameter is defined as the maximum Euclidean distance between any two points in the set *P*. In this paper we propose an efficient algorithm, which works in any dimension, to compute the diameter of a point set on a theoretical network called a *completely overlapping network (CON)*. This network model has an applicable potential in real-life applications because it is an extension of LANs that are widely used at present. We also show that the running time of this algorithm is O(*n*) where *n* is the number of points in the input set.**

I. INTRODUCTION

Computing the diameter of a point set is one of the classical problems in high dimension computational geometry [1, 5-8]. This problem (Given a finite set *P* of *n* points in *d*-dimensional Euclidean space, the diameter of *P* is defined as the maximum Euclidean distance between any two points of *P*) is actually known as the *diameter problem* or the *farthest pair problem*. There are several interesting applications of the computation of the diameter such as image databases, visualization, clustering, and data mining [4]. Additionally, the diameter is quite useful as it provides a reliable estimate of the point-set extent, it can be used in computing a tight fitting bounding box for the point set.

Computing the diameter of a point set has a long history. Computing the diameter of *n* points in *d* dimensions requires $\Omega(n \log n)$ operations [7] while a trivial $O(n^2)$ upper bound is provided by the brute force algorithm that compares the distance between all pairs of points. In the dimensions 2 and 3, this problem can be solved optimally in $O(n \log n)$ [4] but in the higher dimensions it becomes non-trivial. Note that in such applications the number of dimensions is very high, the complexity due to the dimension must be taken into consideration in the design of efficient algorithms. Thus, this paper presents an algorithm which works in any dimensions for computing the diameter of a point set on a completely overlapping network and provides the concept of parallel computation that can solve this problem efficiently.

Parallel computation has been around for decades. Several parallel applications and architectures are available for use. However, parallel architectures such as hypercube and mesh are generally expensive and hence their use is limited to only those who can afford them. Some attempts have been made to find an alternative to these expensive parallel machines. One alternative is called a cluster of workstations and personal computers. A typical cluster of workstations is essentially a group of numerous workstations and personal computers connected through a single communication line. Each computer can send a message, bit by bit, when the communication line is free. If the communication line is currently occupied, the computer must wait before it is allowed to send its message.

One significant problem with this model of communication via a single communication line is the line can only serve one computer at any time. To lessen this problem, during the recent decade or so, a group of computer scientists in the United States has developed an experimental network called *an overlapping network* [2]. They have worked on the concept of using multiple Ethernet lines in some certain configurations. These configurations are in the general classification of overlapping connectivity networks. Overlapping connectivity networks have the characteristic that regions of connectivity are provided and the regions overlap so as to provide parallelism.

Recently, Kantabutra et al [9-10] extended the network model of Wilkinson one step further to provide complete overlapping of communication. This theoretical network model is more general than but similar to the experimental overlapping network. Henceforth, we will refer to this network as *a completely overlapping network (CON)* and in this paper we use it for computing the diameter of a point set.

In following sections the definition and rules of operations of our completely overlapping network is firstly given. Secondly, the algorithm for computing the diameter of a point set on a completely overlapping network is presented. Also, the proofs of our algorithm are shown. Finally, we conclude our paper and propose a transformation method of our fine-grained model into a course-grain model.

II. COMPLETELY OVERLAPPING NETWORK

In this section we give a review of a completely overlapping network as shown in [9-10]. A completely overlapping network is composed of several overlapped communication lines that connect among several nodes (or processors) to

provide parallelism. There are vertical and horizontal communication lines as shown in Fig. 1.

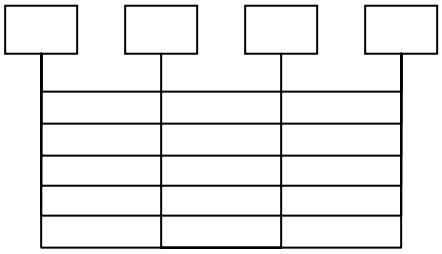

Figure 1. Four-node completely overlapping network.

The number of vertical lines is equal to the number of nodes n and the number of horizontal lines is equal to $\frac{n(n-1)}{2}$. Additionally, one straight line segment equates one step horizontally and vertically. For instance, Fig. 2 shows a communication of 5 steps between the leftmost node and the rightmost node.

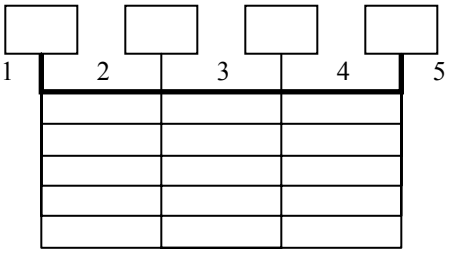

Figure 2. Five-step communication between nodes.

Like any other networks, there are rules of operations which our proposed algorithm runs follow them. The rules are as follows.

- Horizontal and vertical line segments cannot be shared. That is, any line segment can be used only one at a time.
- Each line segment is bidirectional.
- Each node has a constant memory size.
- A same message can be concurrently sent from one source node to several destination nodes as long as there is no collision of messages.
- If there exists contention for a communication line segment, some kind of priority can be applied.

In order to enable readers to understand our communication method, a numbering of both nodes and communication lines is necessary. Our numbering scheme is illustrated in Fig. 3. This figure shows a four-node completely overlapping network with node and line identification numbers, *myID* and *lineID*, respectively. It is easy to generalize this numbering scheme for a *n*-node completely overlapping network. Hereafter, we will regularly refer to this numbering scheme when explaining our algorithm.

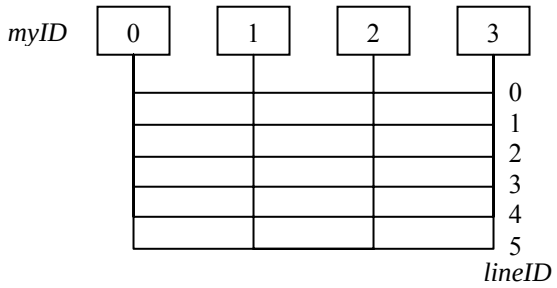

Figure 3. Numbering scheme for a four-node completely overlapping network.

III. ALGORITHM FOR COMPUTING THE DIAMETER OF A POINT SET ON A COMPLETELY OVERLAPPING NETWORK

In this section we will describe an efficient algorithm that solves the diameter problem of a point set on a completely overlapping network. The definition of this problem and our algorithm are given respectively. Then proofs of its correctness and time complexity follow.

Definition 1 (Diameter Problem) Given a finite set P of n distinct points p_i in d dimensions where $n \geq 2$, $0 \leq i \leq n$-1. Let $d(p_i,p_j)$ be a Euclidean distance between two points $p_i(x_1,x_2,\ldots,x_d)$ and $p_j(y_1,y_2,\ldots,y_d)$ when $i \neq j$, and

$$d(p_i,p_j) = \sqrt{\sum_{m=1}^{d} (x_m - y_m)^2}$$

The diameter of the set P is the maximum Euclidean distance between any two points in the set P, or that is, any pair of points of the set P that is farthest away from each other.

Our Diameter Computing Algorithm is specifically designed to suit the completely overlapping network. The following are our assumptions and the description of some variables in the algorithm.

- Each processor (or node) has a point stored in it initially.
- There is a total of $n \geq 2$ processors in the completely overlapping network where n is the number of points to be computed the diameter.
- One point per one processor and *myID* is its own point identification number.
- All processors are fine-grained.
- A variable *S* is a finite set of any pair of points that represents the diameter of the ser *P*.
- A variable *max* is the diameter of the set *P*.

There are two communication subroutines in the algorithm: **send**(*data*, *destination process*, *communication line number*) and **recv**(*data*, *source process*). One of the arguments in subroutine send() indicates the communication lines to use. (There is no such argument in recv().) These subroutines require identification numbers for both lines and nodes. These identification numbers, *myID* and *lineID*, were described in the previous section. Also note that **pack**(*item1*, *item2*,…, *itemN*) is a subroutine that packs all stated items together as one larger

item and the subroutine **unpack**(*packedItems*, *item1*, *item2*,…, *itemN*) does just the opposite.

The definition of our algorithm called *Diameter Computing Algorithm* is given as follows. Some of pseudocode conventions are borrowed from [3].

Diameter Computing Algorithm for Processor Pr_i

1. $S = \emptyset$, $max = -\infty$
2. **for** i = 0 to n-1 and $i \neq myID$
3. **send**(*myPoint*, Pr_i, *myID*)
4. **for** i = 0 to n-2
5. **recv**(*point*, Pr_{ANY})
6. *dist* = **d**(*myPoint*, *point*)
7. **if** (*dist* > *max*)
8. $S = \emptyset$
9. *max* = *dist*
10. $S = \{(myPoint, point)\}$
11. **else if** (*dist* = *max*)
12. $S = S \cup \{(myPoint, point)\}$
13. *twoItems* = **pack**(*max*, *S*)
14. **for** i = 0 to n-1 and $i \neq myID$
15. **send**(*twoItems*, Pr_i, *myID*)
16. **for** i = 0 to n-2
17. **recv**(*packedItems*, Pr_{ANY})
18. **unpack**(*packedItems*, *max_dist*, *SS*)
19. **if** (*max_dist* > *max*)
20. $S = \emptyset$
21. *max* = *max_dist*
22. $S = SS$
23. **else if** *(max_dist = max)*
24. $S = S \cup SS$

Like any communication scheme, it is essential that there be no collision of messages on any of these communication lines (or any line segment) at any point in the algorithm. Kantabutra et al [9-10] showed that this communication scheme produces no collision.

As a computer scientist, after designing the algorithm we would like to know whether this algorithm is provably correct. Theorem 1 shows that our algorithm works correctly.

Theorem 1 (Algorithm's Correctness). *The Diameter Computing Algorithm is correct.*

Proof. Let Pr_i be an arbitrary processor i, $0 \leq i \leq n$-1, in the completely overlapping network. In the algorithm two variables, *S* and *max*, are initially set to ∅ and -∞, respectively (line 1). Then, each processor Pr_i sends out its own point *myPoint* to the other processors Pr_j, $j \neq i$ (lines 2-3). Upon receiving these numbers, each processor Pr_i computes the Euclidean distance between its own point *myPoint* and the just-received point *point*, and then keeps this distance in *dist*. Each processor Pr_i compares *dist* and *max* that if *dist* is greater than *max* then it replaces *max* with the new maximum distance *dist* and also replaces any pair of points in the set *S* with the new pair of points, *myPoint* and *point*, that is just computed. If *dist* is equal to *max*, each processor Pr_i collects that pair of points which also has the maximum distance in the set *S* (lines 4-12). Presently, each processor Pr_i knows that which point is farthest away from its own point and also their corresponding distance. However, it still does not know the exact pair(s) of points which is farthest away from each other. It therefore sends the set of pairs of points *S* and the maximum distance *max* between its own point and the other points as a variable *twoItems* to the other processors Pr_j, $j \neq i$ (lines 13-15). Upon receiving the set *S* and the maximum distance *max* as *SS* and *max_dist*, respectively, each processor Pr_i compares *max_dist* to *max*, if max_dist is greater than *max* then the processor Pr_i replaces *max* with the new maximum distance *max_dist* and also replaces any pair of points in the set *S* with any pair of points in the set *SS*. If *max_dist* is equal to *max*, the processor Pr_i includes the set *SS* in the set *S* (lines 16-24). Eventually, each processor Pr_i knows the maximum distance of the set *P*, that is the diameter, and any pair of points that gives the diameter. Thus, the Diameter Computing Algorithm on completely overlapping network is correct. □

In addition, the algorithm should be also efficient in terms of time complexity. The following theorem shows that our algorithm has a running time of O(*n*).

Theorem 2 (Time Complexity). *The Diameter Computing Algorithm on a completely overlapping network has a running time of O(n) where n is the number of the distinct points in the set P.*

Proof. In parallel algorithm, running time is divided into communication time T^{comm} and computation time T^{comp}. For simplicity, assume that one step in communication is equal to one step in computation. There are four phases in our algorithm.

Phase 1 (Communication): Each processor sends its own point *myPoint* to the other processors (lines 2-3). Since this sending is done in parallel, the time of the longest communication path dominates the whole communication.

$$T_1^{comm} = 3n - 1$$

Phase 2 (Computation): Each processor computes the Euclidean distances between its own point *myPoint* and the other points *point* that receives from the other processors. By comparing, the maximum distance is eventually kept in *max*, and any pair of points corresponding to the maximum distance is also kept in the set *S*. (lines 6-12).

$$T_1^{comp} = n - 1$$

Phase 3 (Communication): Each processor sends a variable *twoItems* consisting of the set *S* and the maximum distance *max* between its own point and the other points to the other processors (lines 14-15) for finding other pairs of points that have the distance greater than or equal to *max*. For simplicity, assuming that time of sending one item and two items are the same, we therefore have

$$T_2^{comm} = 3n - 1$$

Phase 4 (Computation): Each processor checks for whether the distance that receives from the other processors *max_dist* is greater than or equal to the maximum distance *max* that it keeps (lines 19-24). There are in the worst case *n*-1 times to check. Therefore, we have

$$T_2^{comp} = n - 1$$

Hence, the total time complexity T_{total} is

$$T_{total} = T_1^{comm} + T_2^{comm} + T_1^{comp} + T_2^{comp} = O(n). \square$$

IV. CONCLUSION

In this paper we have presented an efficient algorithm called *Diameter Computing Algorithm* for computing the diameter of a finite set of *n* points in any dimension *d* on a completely overlapping network. Our algorithm not only gives the diameter of the point set but also outputs the set of pair(s) of points that represent(s) the diameter. In addition, this algorithm works in O(*n*) time. In the 2 and 3 dimensions, our algorithm has a speed up of O(log *n*) over the fastest sequential algorithm of this problem.

A theoretical network CON is an extension of Wilkinson's model. One may ask about practicality of our theoretical CON network. Even though we are not engineers (and, therefore, admittedly, are probably not a good judge on this matter!), we believe that CON can be implemented cost-effectively since it is similar to Wilkinson's experimental networks that are known to be cheaper than most parallel machines.

Throughout this paper we have only discussed the case in which all processors are fine-grained. However, like the multiple bus network with overlapping connectivity model, the concept of our theoretical network can also be applied to coarse-grained processors with larger memory. This is the case particularly worth attention because it can be applied to existing, widely-used local area networks. Fig. 4 shows an example of embedding a 16-node CON into a 8-node CON. This is certainly our further research.

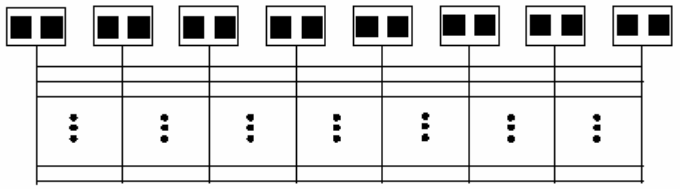

Figure 4. 16-node CON embedded in a 8-node CON

ACKNOWLEDGMENT

The authors would like to thank Assistant Professor Dr. Sanpawat Kantabutra for his suggestions and significant comments on this paper.

Classification Using Semi-Lazy Learned First Order Rules

Sarawut Lueangampol, Sukree Sinthupinyo

Thammasat University THAILAND
woon115@gmail.com, sukree@cs.tu.ac.th

Two major problems of ILP learning are: very long learning process that takes very long time and unclassifiable examples in multi-class problems. Some previous works have been done using weighted partial rules which can solve the latter problem. These works can improve the accuracy of ILP on classifying multi-class data but they need to completely train ILP classifier. So that they still take long training process. Hence, this paper proposes a new method of ILP learning by using semi-lazy learning concept. The semi-lazy learned rules are created from incomplete learning of ILP in order to reduce learning time. The obtained rules are shorter and more general, so that they can cover data easier. These rules are used with some weighting information to classify unseen examples.

I. INTRODUCTION

Inductive Logic programming (ILP) is a well known machine learning that has been applied to many real world applications. The concept of ILP is to search for the best rules that cover only positive examples but not cover negative examples by using additional background knowledge. However limitations of ILP are (1) its training process takes very long time and depends on the size of background knowledge and examples; (2) ILP will give the poor accurate rules if the training set contains noisy data. Some works using the idea of partial rules have been proposed. Reference [1] and [2], the partial rules are some parts of rule obtained from the completely trained ILP rules. These partial rules are shorter and more general than the original ones. So that they can cover examples easier than the original. The covering information is then weighted by using Backpropagation Neural Networks. The weighted partial rules method shows that it can give the better result than the original rules, especially on multi-class datasets.

The weighted partial rules method needs the complete training process of ILP. This training process may take very long time. Hence, in this paper, we shorten the training process and use the idea that the rules which are not completely trained may be useful.

In machine learning studies, there are two kinds of learning, i.e. *eager* and *lazy learning*. The *eager learning* is a kind of learning in which the training examples are used to construct the hypotheses as soon as they appear to the learners. While in the *lazy learning*, the training examples are not used until we actually want to classify new examples.

As described above, we will use the rules which are not completely trained. Thus we are located at some point between eager and lazy learning. So that the kind of rules proposed in this research is called *semi-lazy learned rules.* Our proposed method can solve the problem of the weighted partial rules in which the partial rules may take very long time to be accomplished. We instead use the incompletely trained rules, so that the time spent on the training process of ILP can be reduced.

[10] Thus, another algorithm must be applied to attack this new problem. In this research, we select the Backpropagation Neural Network to assign weights to each semi-lazy learned rule and then they are combined with the weights from the networks to classify new examples.

After we obtain the incompletely trained rules or our semi-lazy learned rules, the problem is now transformed into the problem of using many shorter rules to classify new examples, like the field of using the mined association rules in classification problems.

II. RELATED WORKS

A. Inductive Logic Programming

The data components that used for ILP learning are Background knowledge, positive and negative examples.

ILP's search strategy is aimed to find the hypotheses that cover only the positive examples but not the negatives. The result would be more than one hypothesis described in the form of first order which can be use to explain the examples effecia.

Equation of ILP learning condition

$$\forall e \text{ in } E^{+} \; ((B \wedge H) \models e). \quad (1)$$

$$\forall e \text{ in } E^{-} \; ((B \wedge H) \not\models e). \quad (2)$$

One disadvantage of ILP is that the learning process takes very long time. This is caused by that the searching process of ILP try to find the best hypothesis in a large hypothesis space.

Another disadvantage of ILP learning is that the hypotheses or the rules are often too specific. When we apply these too specific rules to classify an example, the likelihood of the situation that the example is not covered by any rule may arise. This disadvantage can cause a class selection problem when we use ILP's rules to classify the examples. Because the ordinary ILP method have no information to help ILP when no rule from the rule set can be applied to the example.

For example, below is a rule from complete ILP training on

Finite-element dataset in the third fold of five-fold cross validation experiments

```
    mesh(A, 8) :- neighbour_xy_l(B, A),
neighbour_xy_l(C, B),neighbour_zx_r(C, D),
    neighbour_xy_r(A, E),not_loaded(C),
neighbour_xy_r(B, A),neighbour_yz_r(B, F),
        fixed(E),half_circuit(A).
```

According to the rule example, we have found that it covers only nine examples from 43 examples of class8. This means that in case of having only one rule for learning, then the use of ILP in classification problems may have some incorrect classification because there are 34 examples are not covered.

B. Weighted Partial Rules

A problem of ILP learning is that the rules which are the result from training process may not cover some examples or may undecidedly cover examples. Weighted Partial Rules [2] are a set of some part of rules which are weighted by using some machine learning algorithms. This method is used to attack the problem in which the class of an example cannot be determined. Unclassifiable examples are categorized into two groups; the examples which are not covered by any rule and the examples which are covered by multiple rules from different classes. This method is based on the idea when the original rules cannot exactly match the examples, some part of rules may match such examples. The partial rules are extracted from the original rules. Most of them are shorter and more general than the original rules. Hence, in case of the examples which are not covered by any original rule, the partial rules may cover these examples. By this reason, we can now have some coverage information to classify them. The coverage information can also be used in case of the examples which are covered by multiple rules from different classes. The more important partial rules which are represented in the form of the higher weight assigned to those partial rules should have more influence on the decision. The weight is given by machine learning algorithm, i.e. Backpropagation Neural Network, Winow based algorithm, or probability in Naïve Bayes algorithm. However the weighted partial rule method needs the complete process of rules learning by ILP. The problem of long time learning process is still remained.

Reference [3] studied the method that combines ILP's rules learned from multi-relational data mining. Main problem mentioned in the research is how to combine the rules from ILP to construct an accurate classifier. ILP system can still give some useful rules and each rule will show the relation to each parts of sample even though there are some errors and missing data in relational database. The research presented process of selection and combination of the rule. Using voting and Bayesian classifier to find the rule that can classify data. The research is similar to the works presented before in the way that the whole rule cannot fit to an example, but some parts of rule can apply to the example. The difference of this research from the others is that it does not have the completed rules from which the partial rules are extracted but it chooses many specific rules to be combined using voting method and Bayesian classifier. By using this way the result is more accurate.

C. Lazy Learning

Lazy learning is a class of learning techniques that spend small or on learning effort on training process and delay the computation to the classification time. There are some lazy learning concepts applied to other machine learning algorithms such as Instance Base Learning, Bayesian and Decision Tree.

Reference [7] presented the Lazy Learning of Bayesian rules. The proposed method is aimed to reduce the attribute inter-dependence problem by generating a most appropriate rule with a conjunction of attribute-value pairs as its antecedent. Hence, the local naïve Bayesian classifier is built by some part of training examples.

Reference [9] proposed the Lazy Decision tree which creates decision rules at the classification time. The procedure of LazyDT is first selecting a subset of training examples and then performing majority vote. The LazyDT differs from the common lazy algorithms which are based on the nearest-neighbor algorithm.

III. SEMI-LAZY RULES LEARNING

As mentioned in the previous section, some part of rules may be useful for selecting the class of an example. We attack the problem of particularly long training process of ILP, also Weighted Partial Rules, by trying to stop the process before it completes. The incompletely learned rules are used with the weights from a Neural Network to classify the examples. We can see that our incomplete learned rules are located at some point between the complete learned rules in eager learning style and the empty set of rules in lazy learning style. Thus we call our rules as *semi-lazy learned rules.*

Steps of using the semi-lazy learned rules to classify examples are:

1) Generate the semi-lazy rules.

This is the first step to generate the semi-lazy rules from background knowledge, positive and negative examples. This research is implemented with Aleph using a searching mode for inducing association rules by "WARMR" algorithm [11]. This mode will generate all possible rules that cover the specific numbers of positive examples. We use the negative examples as well as the positive examples to guide the learner to construct the rules for both classes. The process to generate the semi-lazy rules compared with the process to generate the partial rules is shown in Figure 1a and 1b.

Figure 1a and 1b show the difference between the creations of the partial rules (Figure 1a) and the process of the semi-lazy learned rules (Figure 1b).

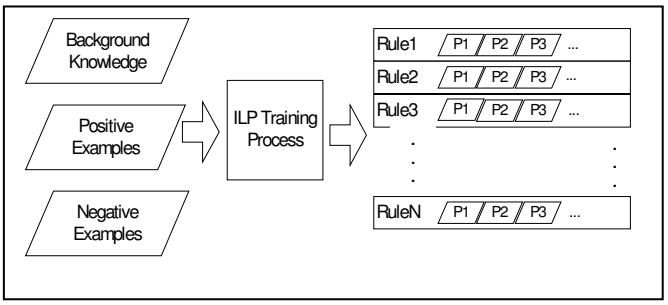

Figure 1a. Complete ILP Learning Step

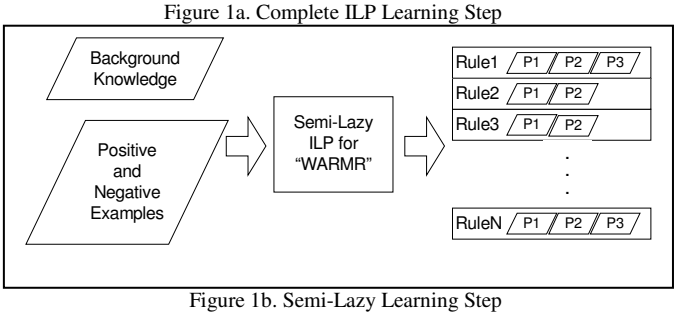

Figure 1b. Semi-Lazy Learning Step

2) Select the Rules.

We can see that our semi-lazy rules which come from the learning method presented in step 1 are different from the partial rules which come from the complete learning process. The partial rules are extracted from the obtained rules after the training process is completed. Hence the number of the partial rules is limited by the number of the original rules. The number of the semi-lazy learned rules is not bound by any number because they are constructed from the induction of the association rules which is often enormous. The number of the rules from the ordinary ILP, the partial rules, and the semi-lazy rules are shown in Table I.

Table I

Show the length of the number of the rules from each method

Dataset	Average amount of Rule after Training			
	ILP	Partial Rule	Semi-lazy	Selected Semi-lazy
Mesh	77-85	700-1200	4000-5223	270-350
Mutagenesis	7-12	65-92	850-920	35-52
Casinogenesis	28-35	305-436	3670-4280	75-103

The table shows that the number of the semi-lazy rules is much greater than the number of the rules from other methods. This huge number of the semi-lazy rules could cause the problem in classification. Thus they need to be filtered.

In order to select the influence rules which have ability for selecting the class of examples. Two methods separated by type of the problem are used, two-class and multi-class problems. In two-class problem, for each example, we choose the covering rule with maximum and minimum coverage on entire training set. The maximum coverage rule is most general rule which describes many examples while the minimum coverage rule is most specific rule which describes only that example. In multi-class problem, two more conditions are added. The maximum and minimum coverage rules of each class are selected. The reason of choosing the rules with maximum coverage of each class is that they are the best rules that describe that class. While the minimum coverage rules of each class are the rules which are very specific to that class. The step of selecting the rules shows in Figure 2b.

These selected semi-lazy rules will be used to determine the input vector of the Backpropagation neural network in next process.

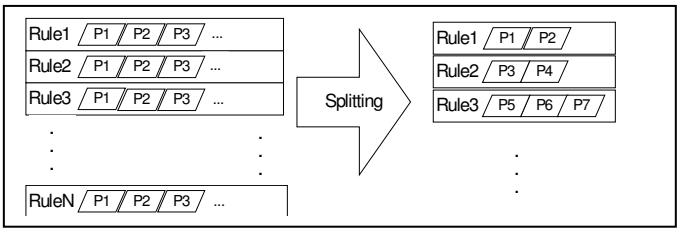

Figure 2a. Step of splitting general rules to partial rules

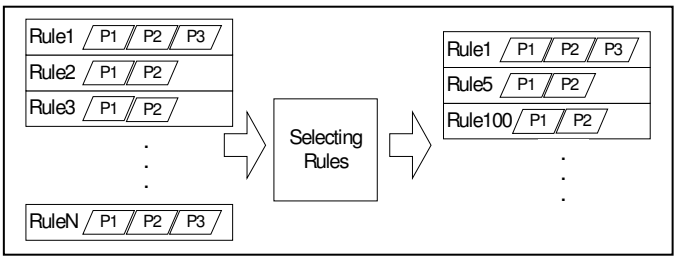

Figure 2b. Step of selecting semi-lazy rules to train neural network

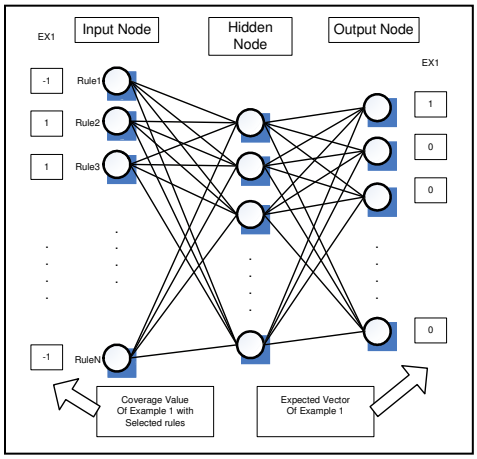
3) Construct a Neural Network.

After obtaining the semi-lazy rules, the covering information of them on each example is used as the input value for each input node of the Backpropagation neural network. If the rule corresponding to each input node covers the example, the input value of that input node is set to '1' otherwise is set to '-1'.

Our network contains three layers, namely *input*, *hidden*, and *output* layer. The number of input nodes is equal to the number of the semi-lazy rules while the number of hidden nodes is simply equal to the number of input nodes. Output nodes represent the class of examples. So that he number of output nodes is equal to the number of the class of examples. The structure of our network is shown in Figure 3.

Figure 3. Show structure of Backpropagation Neural Network.



IV. EXPERIMENTAL RESULTS

We conducted the experiments on three data sets, namely Finite Element Mesh Design (FEM), Mutagenecity of molecules (MUTA), and Carcinogenesis (CARCIO).

As mentioned earlier, we said that the partial rules and our rules (semi-lazy rules) are more general. To show the coverage of each kind of rules, we select some rules obtained from each kind and illustrate their coverage in Table II.

A. *ILP with Majority Vote Classification*

Classical ILP rules alone cannot classify multi-class data well. An example which is not covered by any rule or is covered by the rules from different classes cannot be classified. To fairly compare ILP to our method, we use the Majority vote method in such cases. The example which is not covered by any rule is classified as the class with the highest number of training examples. On the other hand, the example which is covered by the rules from different classes is classified as the class having higher number of training examples.

Table II

Show partial rules' coverage comparing with the original rule's coverage.

Partial No.	Rule contents	Covered /All examples
*	mesh(A, 8) :-neighbour_xy_l(B, A), neighbour_xy_l(C, B), neighbour_zx_r(C, D), neighbour_xy_r(A, E),not_loaded(C), neighbour_xy_r(B, A), neighbour_yz_r(B, F), fixed(E),half_circuit(A).	9/43
1	mesh(A, _) :-neighbour_xy_l(B, A), neighbour_xy_l(C, B).	31/43
2	mesh(A, _) :-neighbour_xy_l(B, A), neighbour_xy_l(C, B), not_loaded(C).	23/43
3	mesh(A, _) :-neighbour_xy_r(B, A), neighbour_xy_l(C, B).	31/43
4	mesh(A, _) :-neighbour_xy_r(B, A), neighbour_yz_r(B, C).	17/43

B. *Experimental Results*

We implemented a semi-lazy learning based on the method explained in the previous section. In the following experiments, we ran five-fold cross validation and averaged the results in all experiments. The experimental results are shown in Table III.

Tables III

Show accuracy and training time of experimental result.

Dataset	ILP		Weighted Partial Rules		Semi-Lazy Rules	
	Accuracy	Time	Accuracy	Time	Accuracy	Time
Mesh	52.13±3.01	12673	56.7±2.6**	14673	62.20±2.28***	7832
Muta	79.20±3.5	1507	84.65±4.2**	1880	87.78±3.61**	990
Carcio	46.86±3.88	3710	55.24±5.51**	4130	57.22±6.77**	1630

*, **, *** AND **** DENOTE THE SIGNIFICANT LEVEL UNDER .10, AT .10, AT .05, AND .01, RESPECTIVELY. Training time in second.

The results show that the accuracy of semi-lazy rules is better than the Weighted Partial rules and ordinary ILP on all datasets. Moreover the learning time of Weighted Partial Rule and ILP are more than semi-lazy rule, as shown in the table.

V. CONCLUSION

Using the complete ILP learning to learn rules for classifying examples is a cause of two problems. The complete ILP learning is a particular long time process that gives some specific rules as results. These specific rules lead to the other problem, especially in the multi-class problems, in which an example may not be covered by any rule or may be covered by multiple rules from different classes. In this paper, we have proposed an improvement of ILP learning which combine semi-lazy learning with Backpropagation Neural Network. The experimental results show that our method can reduce the learning time and yield better results. The semi-lazy learning method can avoid full searching for the best rule so that it can reduce learning time. The results of semi-lazy learning are not specific rules, hence they can easily cover examples and give another covering information which cannot be obtained from the complete rules.

Object-Oriented Design for Thai Herbal Taxonomy

Surangkana Rawungyot
IEEE Conference Publishing
School of Information and Communication Technology
Naresuan University, Phayao, Thailand.

***Abstract*-This paper represents the model of classification algorithms for medicinal plants taxonomy and systematic classification system (MPTSCS) with object-oriented design method. The core of this design is a use case driven and class diagram with the unified modeling language (UML). Our approach to optimization of declarative data store and queries in object-oriented design that allows to exploit the specification semantic characteristic of data types occurring in science application similar to botany data. This model can implement to an intelligent application for medicinal plants taxonomy classification and retrieval in web-based application. This approach provides a UML model of an application for the MPTSCS in a large medicinal plant database, that are collected, retrieved and expected a classification for those data. The proposed models concretely classify the medicinal plants taxonomy possible. Also, this method proved by implement with object-oriented programming and botanists testing that results are sufficient. Those methods were implemented phase, which produced via web-based application, thus achieving greater portability for botanist and other users. Thai herbal database especially presented in only Thai version. In order to testify the model, both instance of the model and its implementation in a simulation are shown. In the future, this research will be implementing other models for other plants and using an image processing to find other contents for high performance in this field.**

I . INTRODUCTION

There are millions of different kinds of plants in the world. Therefore, the botanists intended to survey several plants in the natural and collected with dry or fresh process for study. The problems were many special names for one plant, that non standard name and they have a lot of name in another location. So the scientist thought of an order system for classifying a lot of plants and assigned name for plants. Botanist was invented to binomial system, that specific plant name laws or taxonomy system, used sophisticate and experience [1-2]. This paper is developing the application for Thai herbs which are especially some flower plants (angiosperms)[1][3]. The raw data, input to this system, are the common plant characteristic. They were received by survey in the forest or observation from their plant, such as shown in Fig1. In addition, the input data came from plant with dry process, that example shown in Fig2.

Figure.1: Characteristic of plants in natural.

Figure.2: Examples of plants with dry process.

After that, there were compared with type specimens from plants database system. The more you give details, the more you earn actually metadata of plant from plant databases. Therefore, each user can get coarse details, a family level, or fine details, a genus or species, which are dependent on information from them. The details are attribute for instance scientific name, morphology, anatomy, medicinal and photograph of their plants. In other words, the algorithm for plant classification was used to modifying theory of a dichotomous key [1-2]. In summary, this process was shown in Fig3, which is descriptive of over all process in this approach.

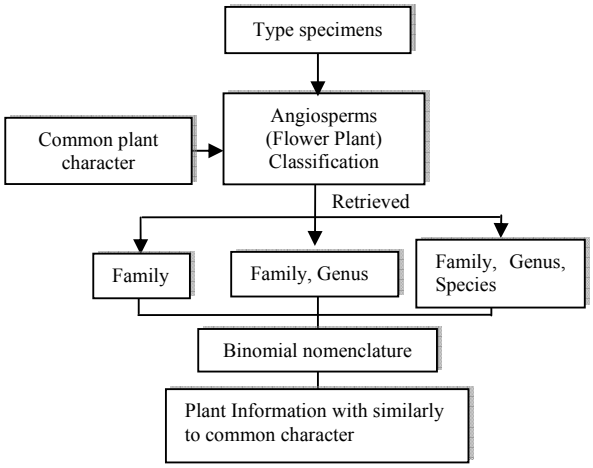

Figure.3: Examples of plants with dry process.

This paper was organized in the following way. Section 2 briefly presents the basic concept of classification in botany system. Section 3 reviews the concept of the object-oriented design. Section 4 discusses the analysis method of medicinal plant taxonomy classification with UML, and finally, section 5 gives conclusion and trends to the future of this paper.

II. CLASSIFICATION OF BOTANY SYSTEM

Plants were classified in several different ways, and further away from observation in the forest [1-3]. Also, there are more difficult for classification, because this field must be special to identify a particular plant. Classification of plants is starting from the highest category, which is class. After that, plants are classified as follows [3]. Each group has the characteristics of the level above it, but that has some distinguishing features. The further down the scale you go, the more minor the differences become, until you end up with a classification which applies to only one plant. Firstly, we distinguish plants which produce flowers (Angiosperms) or which don't produce plant flowers (Gymnosperms).In this paper is classified only the former. Secondly, several plants are separate to Dicotyledonae subclass, that is two leaves, or Monocotyledonae subclass, that is one seed leaf. After that, a group of related plant families, classified in the order in which they are thought to have developed their differences from a common ancestor. There are six Superorders in the Dicotyledonae(Magnoliidae, Hamamelidae, Caryophyllidae, Dilleniidae, Rosidae, Aateridae), and four Superorders in the Monocotyledonae(Alismatidae, Commenlinidae, Areciae, Liliidae). The names of the Superorders end in -idea. Later, each Superorder is further divided into several Orders. The names of the Orders end in –ales. Each Order is divided into Families. These are plants with many botanical features in common, and is the highest classification normally used. At this level, the similarity between plants is often easily recognizable by the layman. Modern botanical classification assigns a type plant to each Family, which has the particular characteristics which separate this group of plants from others, and names the Family after these plants. The names of the Families end in –aceae. Afterwards, the family may be further divided into a number of sub-families, which group together plants with in the Family that have some significantly botanical differences. Next, Genus is the part of the plant name, the normal name that you give a plant such as Papaver(poppy), Aquilegia(Columbine), and so on. The plants in a Genus are often easily recognizable as belonging to the same group. The name of the Genus should be written with a capital letter. Finally, Species is the level that defines an individual plant. Often, the name will describe some aspect of the plant for example, the color of the flowers, size or shape of the leaves, or it may be named after the place where it was found. Together, the Genus and Species name refer to only one plant, and they are used to identify that particular plant. Sometimes, the species is divided into sub-species that contain plants not quite so distinct that they are classified as Varieties. However, this paper can classify at the species, after that it can show about all attribute in Fig.5 for each plants, that similarly to input criteria and to retrieve plant data.

III. OBJECT-ORIENTED DESIGN

Nowadays, the software developments are including a dealing complex social process. Many software systems are embedded in an abstract, that are difficult to design overall these requirement with antiquate software design, program size grows large. Programming technologies are also change to support real-word and complexity system. Those programs must be designed to work perfectly in many areas, and business functionality is not the only one function but also many core functions in the system. Of course a well-designed architecture benefits any program, and not just the largest ones. Another consideration of structure is enable code reuse, that the design time is the simplest time to structure an application of modules or components. Eventually, enterprises build up a directory of component models, each representation are implemented and stored in a directory of code modules. When another application needs the same procedures, the designer can quickly import its module from the directory. At implementing time, the programmer can quickly import the code module into the program. So modelling, that is the designing of software applications before coding, is an essential part of the large software, and helpful to another size project as well. A model shows the analogous role in software development those blueprints or other plans. Using a model, those responsible for software development project's success can make sure the business functionality which is complete and correct, end-user needs are met, and program support business requirements before implements code and rebuild that more expensive and more difficult to perform. The models are visualizing your view, user requirement, specific program, and check again before you code of program.

Object-oriented concept is induced the unified modelling language (UML)[5-6], that has capable in mention above. UML defines a set of basic diagrams that provide multiple perspectives such as structural/static and behavioural/dynamic of system under analysis or development. UML diagram include use case diagrams, class diagrams, interaction (sequence and collaboration) diagrams, activity diagrams, state transition diagrams, deployment diagrams, etc. This paper only a subset of these diagrams will be addressed. The UML is a graphical language for visualizing, specifying, implementing, and documenting the artefacts of a software-intensive system. As such, the UML has found widespread use: it has been applied successfully to build systems for diverse tasks as information retrieval, accounting software, e-commerce, telecommunication and other information system. UML is primarily a description of a unified notation and semantics together with the definition of a metamodel. However, their application is certainly no easier than that of the old methods. Relationship between class, activity, collaboration, sequence, and state diagrams can become totally confusing to view. Hence, consistency and completeness of model can be considered only by appropriate software. Overall, the UML are more advantage than structure concept. First, manual modelling is out of the puzzle. Second, the class concept is used to work with units of data and operations. Third, object-oriented methods focus of model from the abstract problem and solution. The last, evolutionary development, a complex system is not built in one go and all complex systems in nature have developed step by step, each intermediate step had to stabilize first and prove its functional and survival capabilities. More information about UML can be found in [5].In addition,

many researches such as [7-8] were used UML concept to design their system, that results are very excellence performance. Therefore, this paper selected designing with UML for model medicinal plant taxonomy classification. These model are coding with object-oriented program for plant classify and in the same algorithm application. The third main diagram developed in the UML model for the representation of the different aspects of a MPTSCS development. These are use cases diagram, class diagram, and sequence diagrams. There are generated by using rational rose software in enterprise edition version 2002.

IV. The analysis method of medicinal plant taxonomy classification with UML

This approach is use case driven with the following steps : first, creating a use case diagram that specified the expectant user of a MPTSCS and their desired behaviour of using the system under preferable environments; second, modelling a class diagram that describes any internal objects that cooperated to support this system, which compound their attribute and their behaviour operated all entities; third, modelling some sequence diagram that show a series of messages exchanged by a selected set of object in a temporally limited situation, with an emphasis on the chronological course of events and the last, creating an activity diagram that presents how such behaviours proceed interactively to satisfy the expectations of all user. As mention above, these diagrams are UML based with desired extensions for the analysis of a MPTSCS.

A. Use case diagram

The use case diagram is compounded: the botanist is one actor, which can manipulate many Thai herbal features into a database. Everybody can be the botanist, if they must register to a botanist and pass a placement test in the system. This placement test is divided people become a botanist in this system, that has a lot of updatable people, so a large Thai herbal database was occurred. Another actor is other users, who can search, retrieve and classify the data from botany database system.

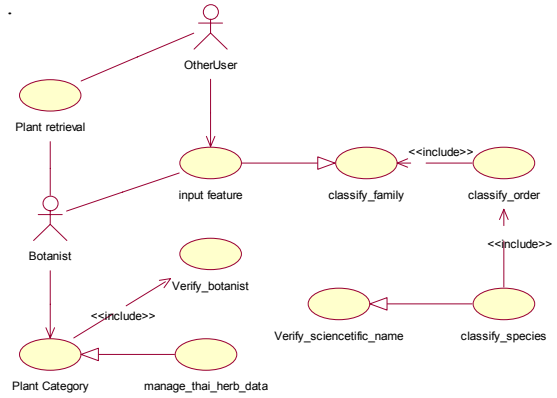

Figure.4: Use case diagram representation of the MPTSCS.

B. Class diagram

The class diagram composes of classes, which contains data and performs methods, and represents many relationships that indicate and resource sharing between classes. In this case, class represent real-word about plant classification system such as characteristic, plant morphology, medicinal properties, class in plant description, order of plant, family details, genius and species details of flower plant in Thai herbs. This model is a template for plant classification system. Classes composed of attributes and methods. Attributes are the data, which are input the databases. In addition, methods in that class are represent their functions that need for manipulate data, such as retrieve data from database, check characteristic of fruit data with specimen. This model can modify and reuse for similar to another system. Furthermore, the model used to implement by programming language. Fig.5 shows the structure of all class in MPTSCS and relationship between them

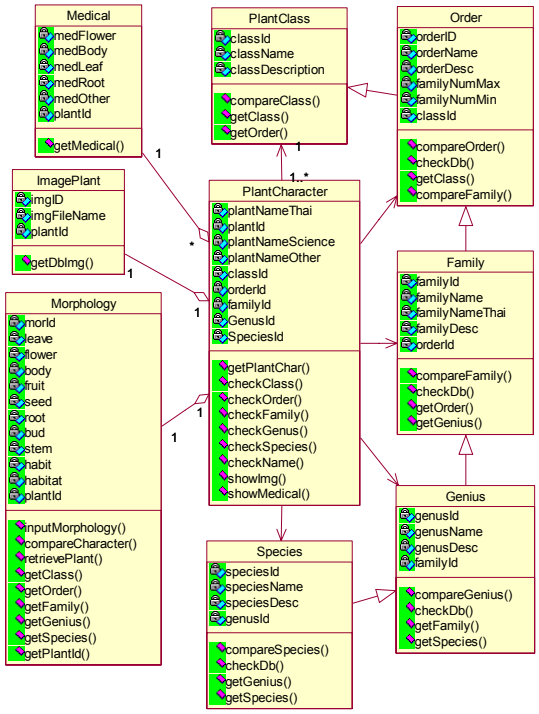

Figure.5: The attribute and method of each element involved in MPTSCS, class diagram generated by Rational Rose .

. C. Sequence diagram

Sequence diagrams were provided a dynamic high level representation of the system. They were captured and represented the interactions required to implement each use case that should have least one related sequence diagram. Fig. 6 depicts part of sequence diagrams from this approach, which illustrated a relationship between other user and MPTSCS. In this figure, relationship between PlantCharacter class and Morphology class is represented though the “input_feature”

use case. In this case, this use case requires that another use case such as classify_family use case.

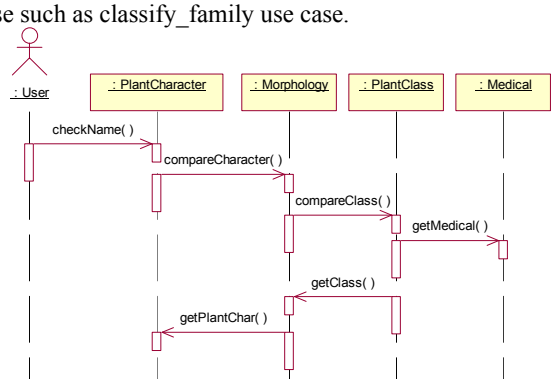

Figure.6: Sequence diagram illustrating a relationship between other users and MPTSCS.

D. Example for plants classification system

Figure.7: Capturing user interface for input all common plant characters via web browser.

Figure.8: Final process illustrating about all details similar to type specimen in MPTSCS.

In testify the UML model of MPTSCS, the application was implemented as part of a simulator. The simulator is used in some medicinal plants. Because Thai herb are a lot of species, this testify use some type of Thai herb for simulation. The simulators were depicted in Fig. 7 and Fig. 8. Fig.7 shows an input operator via web site. Fig. 8 shows an output process that shows classification in similar group from this system.

V. CONCLUSION AND THE FUTURE

This paper has presented a software development approach for MPTSCS that combines the use of the UML notation, so with this methodological approach for well-found methods. These are prepare lists of the variable plant data, which the program are find a matching record in plant database on the basis of the criteria outlined above. Not only, this data are very complexity but also this design needs some skilful botanist for classification. In addition, this paper can modify UML and mix Thai herbal botany knowledge with object-oriented technology together, as a result, this has developed to a worthy software application such a result from testify.

This approach leads to content-base retrieval concepts, which were described by text or looked for image content. Certainly, there have some mistake, which depend on attitude of everybody. In the order to control some error input process with human or some sight from person are sufficient. In the future, this application will have introduced an image processing [9-10], that help to retrieve automatic content from botany data such as shape of leaf. As a result, the plant data can usually find a match for each of these records very simplify and very actual plant classification system.

ACKNOWLEDGMENT

This research was partially supported by school of information and communication technology in Naresuan University at Phayao province, Thailand. Furthermore, The author is grateful to A.Den Keasan for his helpful guidance in plant system and my staffs for providing computing facilities and agreeable environment. In addition, the author thanks to the forest herbarium officers and the botanical garden organization ministry of natural resources and environment officers for a lot of information.

***Abstract*-As to enable a variety of the Internet users to easily achieve and share virus description, a convenient platform and well defined general terms are required. In this paper, various virus techniques, behaviors and damages have been analyzed to design the virus metaschema. We defined a set of general terms to represent virus description words for several conflict terms. This could help people to easily understand and make it comfortable to exchange to the public.**

I. INTRODUCTION

At the moment, the outbreak of virus has spread increasingly than ever while virus information source or description of each virus limited only in the websites of antivirus companies or organizations. Description of each virus has been provided as individual without distinct data exchange or sharing with other company or organization.

In this paper, analytical study has been done on technique and behavior of the viruses in order to design the structure of database by using NIAM model which is easy to be applied by illustrated presentation. This metadata presentation is provided with simple description and definition for easy access and meant to publicize this knowledge to anyone interests in virus, for better understanding and gain more viruses data exchange among people, communities & organization.

II. THE STUDY OF VIRUSES

Computer virus [1] is a type of computer program designed to rapidly replicate itself into targeted computer's files without user notice or permission. But virus unable to replicate itself across the other computer except that the user manages himself as a carrier, for instance, virus can be distributed only when infected user attaches file or document via email. Exchanging diskette, CD-ROM and Flash drive with virus infected are the other ways that allow virus to spread into other computers. That's it, the virus keep replicate itself over and over again.

Computer virus can be divided into two categories. Based on infected environment or infected methods [2]. In this paper, we have designed the concept virus metadata which is mainly concern on infected environment type.

Most viruses can be found in one of the following environments:

- **File**
- **Boot sector**
- **Macro command**
- **Script host**

A. Virus behavior

Among the various types of virus we confront with, there are always common traits which can be divided into three phases as following:

Installation phase: The phase that virus writer intends to install virus code into user's computer.

Infection phase: The phase after virus installation, virus will spread itself into targeted file as it designed by writer.

Damaged phase: This phase is meant to cause damage to user directly from virus or its side effect. The damage also includes the effect that occurred during the infection phase.

B. Virus technique

We can categorize virus technique as following [3, 4, 5]:

- **Stealth:** Stealth virus can conceal their presence from antivirus program. It can also inhibit in computer without user's awareness.
- **Polymorphic or Encrypted:** This type of virus got many appearances in order to hide their signature by scrambling virus body to avoid a detection of antivirus programs. Moreover its encrypted virus body always be changed.
- **Metamorphic:** This technique is similar to polymorphic but it has additional part which calls "Mutation Engine" which can change both of decryption routine and encryption virus body.
- **Memory Resident:** Viruses use this technique to load itself in to computer memory and to infect the next loaded program file.
- **Multipartite Viruses:** This virus infects both in file and boot sector. It can also spread itself across infected program file to boot sector.
- **Overwriting Viruses:** This virus type replaces itself to a target file.
- **Companion Viruses:** This virus is similar to overwriting virus, moreover it rename the original file to the new one. For instance PROGRAM.EXE to PROGRAM.EXD, when computer run PROGRAM.EXE virus code will activate first and execute original afterwards.
- **Prepending Viruses:** These viruses write itself to the beginning of the file.

- **Appending Viruses**: These viruses write itself to the end of the file.

C. Damages of viruses

In this paper, we define damage as an action caused by virus means harm that occurs to user no matter what it came from virus writer's intention or side effect. Damages occurred to user can categorized as following:

- **Interface damaged:** Annoying user's interface such as display monitor, mouse, speaker etc. For example, virus distorts displayed font on user monitor.
- **Data damaged:** Damage to user's documents or files by erasing or modifying user's data, for example, some virus searched text in user's document and replaced it with the virus text.
- **System file damaged:** Damage to operational system, boot sector and CMOS, for example, when virus erases or modifies system file of the operational system or boot sector of hard disk or CMOS. So that user could not run computer as usual.
- **Accessible damaged:** Virus may changes or create password access mode that's used to access a file or document. So user cannot open document or file.
- **Program damaged:** Damage to programs, virus would erase or hide significant menu, sometimes virus make program unable to run normally.
- **Security damaged:** Damage to security system, virus would erase antivirus program files or modify security menu to allow virus intrusion.
- **Overall data damaged:** Damage to all storage data, virus would erase or destroy all data in the computer, for example, virus may using command such as Format C:/, DEL *.* etc.
- **Performance damaged:** Damage which is caused by existence of virus in computer memory which mean computer has wasted its resource. This category includes computer halt, shutdown or restart itself unexpected.

III. NIAM CONCEPTUAL SCHEMA MODEL

After we have analyzed the detail of viruses' behaviors, viruses' techniques and viruses' damages from various information sources. We could design a computer virus conceptual schema as shown in Figure 1. The schema was designed on purpose that virus description has to cover all important data that useful for user and represent it in the way that is easy to understand.

According to our design, virus description has been grouped into two groups, first group is mandatory data to user such as virus name, OS, technique of virus, infected environment of virus, virus's routine, damage of virus and virus infected file type. The second group consists of supplementary data such as alias name of virus, in the wild, risk rate, reporter's name, reporting date and virus's message.

NIAM conceptual schema in Figure 1. could be mapped by optimal algorithm to relational schema as shown in Figure 2.

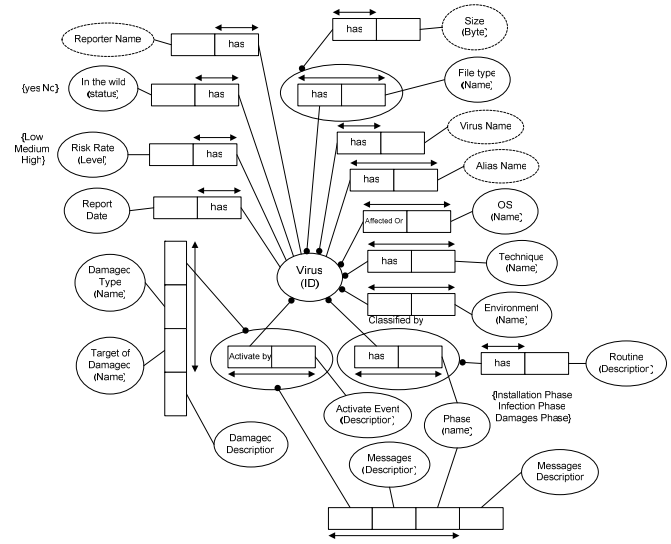

Figure 1. NIAM conceptual schema model of computer virus

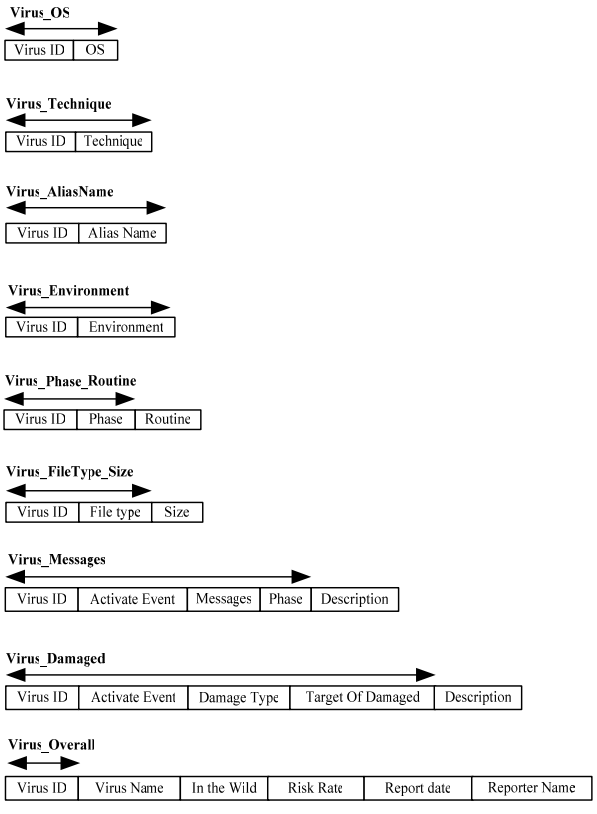

Figure 2. Corresponding relational computer virus database schemas mapped from Figure 1.

TABLE 1

Computer virus metadata

Entity \ Label name	Description	Example
Virus (ID)	Identity of virus	ID0001
Virus Name	Name of virus	Jerusalem
Alias Name	Virus alias name	Israel
OS (Name)	Operation System	Windows XP
Technique (Name)	Virus technique	Stealth
Environment (Name)	Type of virus	File virus
Phase (Name)	Phase of virus procedure	Installation
Activate Event (Description)	Event that activate virus.	Friday 13th, July 18th.
Messages (Description)	Messages that virus display to user.	"!Hola yo soy Ruperto y….."
Damaged Type (Name)	Virus damaged type.	Interface Damaged
Target of Damaged (Name)	Target of virus damage.	Monitor, Keyboards
Damaged description	Description of virus damaged.	"The systems slow down…"
Messages Description	Messages description.	"The messa..."
Report date	Date of reporting	13/10/2006
Risk Rate (Level)	Risk rate of virus.	Low.
In the wild (Status)	Show that virus is in the wild or not.	Yes, No.
Routine (Description)	Virus routine.	"Virus infec..."
File Type (Name)	Target file that virus intend to infect.	.COM .EXE
Size (Byte)	Size of virus.	1,080 bytes.
Reporter name (Name)	Name of description reporter	"MR. Smith", "MR. Neo".

Table 1 is virus metadata that describes entities name, descriptions and examples of corresponding label of NIAM schema computer viruses.

IV. EXPERIMENT

As to prove the consistency of the designed schema, we tried to populate existing data of viruses from various information sources as following:

- F-Secure Corporation [6]
- Sophos Plc [7]
- Trend Micro Incorporated [8]
- Symantec Corporation [9]

Because of limitation in this paper, we could show only some parts of some tables that are populated by existing data of Jerusalem virus. Table 2-9 is created in order to show that each virus information sources is concerning on different set of virus description attributes.

TABLE 2

Example of data in Virus_Overall table from F-Secure Corporation

Virus_ID	Virus_Name	Risk_Rate	In_the_wild	
ID0001	Jerusalem	-	-	

("-" = Not mention to.)

TABLE 3

Example of data in Virus_Overall table from Sophos Plc

Virus_ID	Virus_Name	Risk_Rate	In_the_wild	
ID0001	Jerusalem	-	-	

("-" = Not mention to.)

TABLE 4

Example of data in Virus_Overall table from Trend Micro Incorporated

Virus_ID	Virus_Name	Risk_Rate	In_the_wild	
ID0001	Jerusalem	Low	Yes	

TABLE 5

Example of data in Virus_Overall table from Symantec Corporation

Virus_ID	Virus_Name	Risk_Rate	In_the_wild	
ID0001	Jerusalem.1808	Low	Yes	

(Jerusalem.1808 in Symantec Corporation is similar to Jerusalem on other virus information source.)

TABLE 6

Example of data in Virus_Phase_Routine table from F-Secure Corporation

Virus_ID	Phase	Routine
ID0001	Installation	-
ID0001	Infection	Virus infects .exe over and over.
ID0001	Damaged	When virus is activates on Friday 13 th, it deleting programs that run on that day. Thirty minutes after an infected program is run virus will slows the computer down and make a part of the screen scroll up two lines. Virus continues infects the same file over and over in order to wastes computer resource.

("-" = Not mention to.)

TABLE 7

Example of data in Virus_Phase_Routine table from Sophos Plc

Virus_ID	Phase	Routine
ID0001	Installation	-
ID0001	Infection	Virus infected exe file over and over again and increased they size. But .com files it infected only once
ID0001	Damaged	After infected thirty minutes, virus scrolled screen up two lines, then it slows the system down. On Friday 13th it deletes every program run.

("-" = Not mention to.)

TABLE 8

Example of data in Virus_Phase_Routine table from Trend Micro

Virus_ID	Phase	Routine
ID0001	Installation	When user run infected file virus load itself in memory
ID0001	Infection	Virus stay in memory then infect program files as they are accessed
ID0001	Damaged	Virus increased infected files in order to wastes computer resource. Thirty minutes after an infected program is run virus will slows the computer down and will delete any program started on Friday the 13th of any year.

TABLE 9

Example of data in Virus_Phase_Routine table from Symantec Corporation

Virus_ID	Phase	Routine
ID0001	Installation	-
ID0001	Infection	-
ID0001	Damaged	Virus active every Friday 13th, it deletes any running program. Thirty minutes after first deletion, the computer slows down and the screen scrolls up two lines.

("-" = Not mention to.)

Each information sources got their technical terms that might be incommon and this may difficult for users to understand. As to solve this problem, we have to choose the most popular terms or defined more meaningful names to be used as general virus technical terms. The well defined general terms will be stored in Technical to general terms mapping table as shown Table 10.

TABLE 10

Technical to general terms mapping table

Entity\Company	F	S	T	Sy
OS	Platform	Affected Operating Systems	Platform	Systems Affected
Damaged	-	-	-	Damage
File Type	-	-	-	Target Of Infection
Alias Name	Alias	Aliases	Aliases	Also Known As
Reporter name	-	-	-	Writeup By
In the wild	-	-	In the Wild	Wild
Risk rate	-	-	Overall Risk Rating	Risk Level

F= F-Secure Corporation, S= Sophos Plc, T= Trend Micro Incorporated, Sy= Symantec Corporation

V. RESULT

After we have populated existing data of Jerusalem virus from various information sources into virus metadata tables. We found that each virus information source describes viruses in arbitrary way, some provides sufficient details and some doesn't. Table 11 is created to show what kind of mandatory virus description data that we found in each virus information source.

Table 11 shows that Trend Micro Incorporated reveals virus description covers almost all mandatory data except for OS information. Whereas Symantec Corporation is less mention on mandatory data which is required on each virus description such as virus's technique, infected environment of virus and routine process.

TABLE 11

Mandatory virus description table

Entity\Company	F	S	T	Sy	A
Virus Name	Yes	Yes	Yes	Yes	Yes
OS	No	No	No	Yes	Yes
Technique	Yes	No	Yes	No	Yes
Environment	No	No	Yes	No	Yes
Damaged description	Yes	Yes	Yes	Yes	Yes
Routine*	No	No	Yes	No	Yes
File type	Yes	Yes	Yes	Yes	Yes

F= F-Secure Corporation, S= Sophos Plc, T= Trend Micro Incorporated, Sy= Symantec Corporation, A= Our metadata, Routine* = Description has to covers all phase of the routine process.

VI. CONCLUSION

In this paper, we present metadata for computer viruses that and the well defined general virus technical terms for easily understand. The content of technical to general terms mapping table is intended to solve the conflict terms problems of various information sources. Furthermore this metadata can be used as exchangeable format among interested people or viruses' community.

Consensus of Decision Trees

Suwimon Thawornchaoensukho, Sukree Sinthupinyo
Department of Computer Science, Faculty of Science and Technology,
Thammasat University THAILAND
suwimon_t@yahoo.com, sukree@cs.tu.ac.th

***Abstract*- This paper proposes a novel method which employs the idea of using differently weighted pieces of knowledge from individual learner in ensemble of decision trees. Ordinary ensemble methods use the class decided from each learner to collaboratively determine the class of an unseen example. On the other hand, our method, called Consensus of Decision Trees (CDT),uses newly defined *support values* of leaf nodes to identify theclass of the example. Experimental results using the CDT method on ten data sets selected from the UCI repository show an improvement over classical ensemble methods.**

I. INTRODUCTION

Decision Tree Learning [1] is one of classical machine learning methods. It is a well-known algorithm which is used in many classification problems. Many approaches have been proposed in order to improve the accuracy of the decision trees. One method which is often employed to improve the accuracy is to use more than one decision tree in ensemble. Popular ensemble methods are Bagging [3] and Boosting [5], both of which can increase the accuracy of the decision tree method.

The ensemble of classifier approach commonly focuses on methods of using multiple decision trees rather than using single decision tree. The ordinary ensemble method can be done as follows: training examples are first divided into a number of training subsets; the decision tree learning algorithm is then applied to each subset to construct the trees; finally, the results from each tree are collaboratively used to classify unseen examples by some simple voting schemes. In this paper, we thus present a new voting method which employs the idea of consensus theory to assign the different level of importance to each learned tree. Our method can determine the level of importance in the form of weight of each leaf node.

This paper is organized as follows. In the next part, we review the current ensemble methods as well as works related to methods on the consensus theory. We then present our methodology, followed by an experiment. Finally, we discuss the experimental results and conclude our work.

II. RELATED WORKS

In this part, we describe the general idea of ensemble methods which will be used to construct the decision trees and the idea of consensus method from which we will utilize the concept to combine the results from the trees.

A. Ensemble of Classifiers

In this paper, we focus on the ensemble of decision tree learning algorithms. Two popular decision tree ensemble methods which have been investigated for long time are Bagging and Boosting. Both share the idea of using several classifiers to classify an unseen example but different in each learner's training examples organizing. We can see in more detail from below.

Bagging [3] is a bootstrapping method [4] which randomly selects the training examples from the original training set and collects them in several subsets. So that, by using this method, one training example could be stored in multiple subsets or could be left out from being collected in any subset. The number of training example in each subset is equal to the number of the examples in the original training set. After the learning process of each decision tree, all trees are assigned the same weight. To classify an unseen example, a predicted class was determined by a plurality weight voting of all trees.

In the other popular ensemble method, Boosting [5], the trees are trained by using an ordered list of training sets. Each training set is constructed based on the performance of the previous tree. In other words, the Boosting algorithm attempts to construct new classifiers that can better predict the class of examples based on the current ensemble's performance. The organization of training set starts by randomly selecting training examples for the first tree. For the subsequent trees, the training examples are obtained from the previous trees based on weights of the training examples, which indicate the performance of the trees. There are two popular forms of Boosting, Arcing-x4 [6] and AdaBoost [5]. The Arcing-x4 (*A*daptively *R*esample and *C*ombine) chooses n examples from the original training set to construct the next classifier, where n is the size of the original training set. In the Arcing-x4 algorithm, the training examples are selected according to the probability each training example will be selected; whereas, in the Bagging algorithm, the probability each training example to be selected is all equal. We can see that in Arcing-x4, the probability of an example being selected is based on the number of misclassified examples from the previous classifier. This probability will increase if the number of misclassified examples rises.

The other popular method of the Boosting algorithm which we mention in this paper is AdaBoost method (came from Adaptive Boosting) [5].which consist of two forms of example selection. The first form is based on the probability of training examples being selected. In the second form, all examples are

used but they are assigned different weights so that the highly weighted examples can be selected more often.

Both Arcing-x4 and AdaBoost set the probability of each example to *1/n*. After recalculating the probabilities of training examples of each trained classifier, the AdaBoost determines the class of an example from the classifier.

$C_1,\ldots,C_k$ (where C_i is the i^{th} decision tree) using weighted vote. The algorithm calculates the weight of C_k from $log(B_k)$ where B_k is $(1- E_k)/E_k$ and E_k is sum of the probabilities of misclassified examples of the current classifier C_k. So that, the summation probabilities of the example to be selected of all examples is equal to one. On the other hand, the Arcing-x4 method computes the probability of the $(k+1)th$ decision tree as follow. Let p is probability, $p(k+1)(n) = (1+m(n)4)/ \Sigma(1+m(n)4)$, and $m(n)$ is the number of misclassifying classifier in $C_1 ,\ldots,C_k$ of case n.

B. Consensus methods

We can see from the previous section that the problem arises when we use multiple learners in ensemble. In Bagging and Boosting methods, when learners decide on different classes, we must use some simple voting method. However, in social science studies, when voters have different answers, *consensus* is used.

In this paper, we employ the idea of consensus to help the ensemble in making decisions, especially when examples are classified differently by multiple learners. Hence, we describe the concept and methods of reaching consensus in this section and explain how to utilize the idea of consensus in ensemble in the next section.

Concept of consensus is *"the group continues deliberation until all members of group find an acceptable solution"* [7]. Generally, the consensus theoretic method is applied either in statistical manner or mathematical manner. The statistical approach of consensus, which applied to multi-source data, such as forest map, radar data, and slope of topology, is a probabilistic method based on Bayesian decision theory. The study of this method is called the Consensus Theory. French [8] proposed three situations where the concluded opinion might be needed.

(1) The expert problem: A decision maker which is outside the group asks for advice from the group of experts or data sources.

(2) The group decision problem: The group may be jointly responsible for a decision.

(3) The text book problem: Members of the group might propose their opinions to one another at some time in the future.

Jon and Kolbeinn [9] and Jon and Philip [10] were interested in the expert problem. They used information from each data source to make decision outside the group of experts and used weighting as the mechanism to separate data sources. Jon and Kolbeinn [9] proposed two selected weight structures. The first structure is based on the idea of classical consensus theory which assigns weights to each data source but not to each group of data sources. While the other structure assigns the weights to both the data sources and the groups of data sources. Jon and Philip [10] suggested weight assessment methods as follows:

a) Equal weights. The decision maker does not have the knowledge on whether one example is more reliable than another. Therefore, all examples are equal weighted, $w_i = 1/n$; $i = 1,2,3,\ldots,n$

b) Weight proportional to ranking. The decision maker can rank each example. The weights are then assigned according to the rank. The ranking starts from 1 to n where n is the best assessment.

c) Weight proportional to a self-rating. The decision maker assigns weights to sources proportionally to the self-rating given by the sources themselves.

d) Weights based on some comparison of previously assessed distributions with actual outcomes. This weight uses *scoring rule* function which is applied using the method described in Jon and Kolbeinn [9]. The scoring rule, which can be thought in the sense of assessor to give his maximum expected score, is proposed to lead the assessor to reveal his knowledge

Mathematical approach of consensus is a form of arbitration. The expert systems provide the input and output in the first round of decision making. Keung-chi and Bruce [11] proposed the Multi-expert system (MKBs) which uses multiple experts to solve a single problem. After experts have their own opinions, all opinions are combined using the procedure below:

a) Assess the probability of each hypothesis

b) Assess the credibility of each probability, and then each expert system creates its own weight from the source

c) Create a combination rule from the probabilities and weights given by the expert systems

d) Give the final result to the user.

III. METHODOLOGY

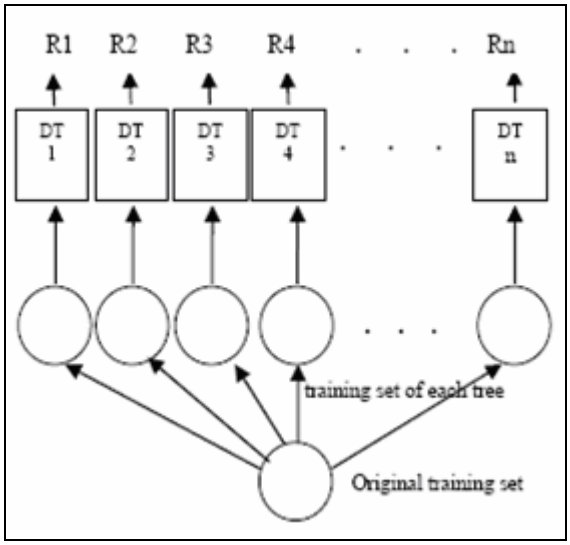
In this paper, we integrate the idea of consensus theory into decision tree learning and propose an alternative method of ensemble learning. We name this new approach *Consensus of Decision Trees (CDT)* with the methodology described as follows.

CDT consists of two main processes: 1) learning of each tree and 2) determining the class of the example.

A. The learning of each tree

The training set of each tree is generated by using bootstrapping method, similar to the Bagging algorithm [3]. In this method, n examples are randomly selected from the original training set. The selection process is repeated n times, resulting in n subsets, each containing n examples. With this process, an example may be selected to multiple subsets or may not be selected to any subset at all. Each subset is then assigned one-to-one to a decision tree as the training set (Figure 1).

Figure 1
The learning of each tree; DTn is the nth decision tree; Rn is the class decided by the nth decision tree



After all trees are trained, we determine a *Support Value* for each leaf in the trees, described in more detail in the next section.

B. Determining the class of the example

After all trees are trained, in order to classify a new example, we apply that example to all n trees. Thus, we will get a total of *n* answers each of which is denoted as R_n as shown in Figure 1. Unlike the classical ensemble method where the class of an example is determined by simple voting of answers from the trees, our method does not consider the answered class from the tree. Albeit, we determine the class of the example from a function of *Support value* of the leaves.

The *Support value* comes from the idea that when learners give different answers, the learner with higher confidence degree should have more influence in voting. And this confidence value should be different in each answer of the same tree.

We utilize the idea of the text book problem of French [8] to make the decision in stead of the simple voting method. Leaf nodes of the tree are similar to the member of the group in the text book problem. Each leaf node has its own answer with some confidence degree which is represented in the form of the *Support value.*

Hence, the compromising method is that the learner with less confidence or less support value should have less weight in voting.

After we present the concept of *Support value*, we can now explain how to determine this value.

First, the leaves in the trees are assigned *Support Value* which is initialized as 1. Then, the support values are adjusted using the entire original training set, each example of which is applied to all trees. The class determined by the algorithm shown in Figure 3 is selected as the class of the example. In case of wrong prediction, the *Support value* of leaf node in the tree which answers the wrong class is decreased by one while the *Support value* of the leaf node with correct answer is increased by one.

The detail of the algorithm of determining the class of the example and the algorithm of adjusting the *Support value* are shown in Figure 2 and 3, respectively.

Figure 2
Algorithm for the classifier

To classify an example *e,* we use the following procedure:

- Let P be the problem which an example is classified into class $V=\{v_1,v_2,\ldots,v_n\}$.
- $R_1,R_2,\ldots,R_m$ are the answer of decision tree $T_1,T_2,\ldots,T_m$, respectively.
- s_{iv_k} is the support value of node i which answers class v_k
- Let $L=\{l_1,l_2,\ldots,l_m\}$ is a set of leaf nodes which match the example *e*

The final result (v_{voted}) constructed by consensus method can be determined from:

$$v_{voted}=\underset{v_j\in V}{argmax}\sum_{i=1}^{m}s_{iv_j}$$

Figure 3
Algorithm for determining the Support Value

The method of determining support values of decision trees:

Let c be *Support value* of leaf node *i* and E be training set of examples

Initialize all s_{iv_k} to 1

For each learning example $e\in E$ which is class v

Classify the example e by using the approach shown in Figure 2

IF e is incorrectly classify

For each tree T_k whose answer is v_k

Increase support value s_{iv_k} of the leaf node in T_k of which node i is the answer, if $v_k=v_t$

Decrease support value s_{iv_k} of the leaf node in T_k of which node i is the answer, if $v_k\neq v_t$

V. EXPERIMENTS

To evaluate the accuracy of our method, the results were compared to results obtained from the C4.5 [2], the Bagging [3] and the Boosting [5] algorithm. In this experiment, we used the WEKA [13] tool to test the C4.5, the Bagging and the Boosting method. We constructed ten trees in ensemble style in Bagging and Boosting, similarly to our method.

The data sets come from the UCI [12] data set repository. These data sets are benchmark in machine learning studies. Our selected data sets are *balance, balloons, car, contact-lenses, mushroom, dermatology, soybean, hepatitis, Pittsburgh bridge,* and *breast cancer*. The results shown in Table I were averaged from 10- fold cross validation.

VI. CONCLUSION

We have presented the new voting method which can be used in ensemble learning of decision trees. Our method is different from classical ensemble methods such as Bagging and Boosting method in which the class of an example comes from combining of the result from each tree. The simple voting method of each tree given equal weight is used in both algorithms. On the other hand, we propose a different method in which each tree is given those unequal weights. The weights of each tree are not only unequal to another tree but also unequal to another leaf in the same tree. The experimental results also show the improvement of our method over the combining method used in classical ensemble algorithm. From our method, we obtained more accuracy than other methods run in this experiment.

Inductive Logic Programming or ILP is aimed to construct rules which explain positive examples and exclude negative example. The learning process of ILP often takes very long time, especially in large datasets. Since the search space of the clause grows exponentially. Many works have been done using the idea of parallel learning and multiple learners to reduce the learning time. Mostly, the methodology of such methods is selecting the rules rather than combining them. There is no real combination of the rules. This paper thus proposes a new multi-learner method which can better combine results from several learners. Differently from other researches, the knowledge learned from individual learner will be used to improve the learned rules as well as to create the new rules. The results of our experiment show an improvement over other rules combining methods.

I. INTRODUCTION

Inductive Logic Programming (ILP) is a well-known machine learning algorithm. It has been used in many areas of either machine learning or data mining. ILP has advantages that background knowledge can be included and output is represented in the form of first-order rules. This makes ILP rich in expressiveness and comprehensiveness.

However, to apply the ILP algorithm to real world datasets it may take very long time to search for the rules which explain positive examples, but not negative examples, especially for the large datasets. Many approaches have been done to reduce the time spent on constructing complete and correct rules, e.g. parallel processing and multi-learner. Both employ the idea of dividing training set into smaller groups and construct the rules of each group. Finally, the rules from each dataset are selected to explain the positive examples. By using this approach, we can reduce the time for constructing the rules. Since the rules are constructed from learning in the smaller dataset, they may not cover the positive examples which are not included in their training set or they may cover the negative examples which are not included in their training set. Consequently, simply combining all rules from each group may decrease the correctness of the rule set.

This paper proposes the method which can be used to reduce the time for constructing the rules and maintain the correctness of the rule set. Our method employs multi- learner scheme by splitting the dataset into a number of smaller datasets. Then, each smaller dataset will be used as training examples for ILP algorithm to find the set of rules. All rules are then combined by selecting the set of rules from the best learner evaluated on its own training set and the clauses from other learner is finally used to improve the selected rule set. By using our method, the obtained rules are more accurate and the set of rules will better cover the entire dataset as well.

II. RELATED WORKS

A. *Inductive Logic Programming*

The basic idea of ILP consists of four parts. First, a set of positive examples which are represented the target concept, denoted as E^+. Second, a set of negative examples which are not belong to the desired concept denote as E^-. Third, a set of Horn clauses which provides background knowledge of the domain denoted as B. and the last past is the logic program representing the learned hypothesis and denoted as H.

B. *Learning Inductive Logic Programming with multi-learner*

Learning of ILP is aimed to create the rules from the background knowledge, positive and negative examples. These rules must describe the concept or pattern commonly found in the positive examples, but not the negative examples. Since the learning process of ILP takes very long time. Many researches have been done by using the idea of the multi-learner and parallel processing to solve this problem. In addition, there are some researches about the rules combining and examples selecting to get the better results. The detail is described as follows:

Reference [4] studied and compared their approach which learned by using Inductive Logic Programming in the form of parallel processing to find the best solution. They compared and evaluated three methods on the memory usage and memory type (shared memory or distributed memory) to learned the rules with the shortest processing time. The best method in their research is shown below.

Algorithm A is used to construct the rules from training set T which is divided into $\{T_1, T_2, ..., T_n\}$. The hypothesis H is obtained from applying algorithm A to T_i where $\forall i \in 1...n$. The final hypothesis can be constructed by $\cup_{i=1}^{n} H_i$ from each hypothesis H_i obtained from applying the algorithm A to T_i. By using this method, it is easy to get the final rules.

Reference [5] proposed the method which applies an ensemble method, namely Bagging, to Inductive Logic Programming. They compared two data selection methods, i.e. randomly select from dataset and select as in Bagging

selection. After that, they used Aleph [9] to construct the rules for each selected examples. The experimental results show that the simple random method is more accurate than the ensemble with Bagging selection. Because some examples in the Bagging selection are not in included in the training set, the learned rules are less complete.

Prati and Flach proposed a rule selection algorithm called ROCCER [6] which selects classification rules from a larger set of rules obtained from the rules found by Apriori [12]. Their approach relies on using ROC analysis to select rules instead of using a classical covering algorithm. A ROC graph is a plot of the fraction of misclassified positive examples (fpr) on the x axis against the fraction of correctly classified positive examples (tpr) on the y axis. A threshold-based classifier can obtain several pairs of point (fpr_i, tpr_i) by varying the threshold. If we trace a line connecting those points, we obtain a curve in the ROC space which represents the behavior of the classifier over all possible choices of their respective threshold. In a rule learning context, Furnkranz and Flach [10] showed that the rules learned by using a set covering approach can be seen as tracing of a curve in ROC space. The basic idea of ROCCER is to insert the rule into the rules list only if the insertion leads to a point outside the current ROC convex hull (the current ROC convex hull is the upper convex hull of the rules that are already in the rule list). Otherwise the rules are discarded.

Comparison with rules induction algorithms showed that ROCCER tends to produce considerably smaller rules set with compatible area under the ROC Curve (AUC). However, computational time is more expensive than other algorithms. In the worst case, the complexity is $O(n^2)$, where n is the number of rules used as the input.

Cohen and Singer proposed a rule learner called, SLIPPER [7] which uses confidence-rated boosting to learn an ensemble of rules. For the concept of SLIPPER, the rule-builder begins by randomly splitting the dataset into two disjoint subsets, i.e. GrowSet and PruneSet. The split is constrained so that the total weight of examples in GrowSet is about 2/3. The rule-builder then invokes the GrowRule routine. The GrowRule begins with empty conjunction of conditions and considers adding to this conjunction any condition~ which has the maximal values for Z_t on GrowSet where Z_t is an objective function to select the good rule. This process is repeated until the rule covers no negative examples from GrowSet, or no further improvement. However, this rule is often too specific and overfit the training data thus the resulting rule is immediately pruned using the PruneRule routine. PruneRule considers deleting any final sequence of conditions from the rule. Each sequence of deletions defines a new rule whose goodness is evaluated on PruneSet. Moreover, it is possible for a weak-leaner to generate the same rule several times. Therefore, after the last round of boosting, the final strong-hypothesis is compressed by removing duplicate rules. Experimentally, SLIPPER scales no worse than $O(n \log n)$, where n is the number of examples.

Reference [8] proposed the method to reduce the error in example data before taking it to be learned by filtering the data. There are two ways of filtering data, by giving the score and by weighting using boosting method. The principle of giving score is to divide the examples into *n* groups equally. Then, the examples are learned *n* times and each time of learning will skip one group. After that, the examples in the skipped dataset are tested for the correctness then the learned rules are given the score according to the correctness on each dataset. This approach is called cross-validated committees filter.

To weight the examples by Boosting method, the concept is that if the dataset with high error rate is learned, it has likelihood to be highly weighted. This helps us to find the high error rate dataset. Experimental results showed that the given score by their proposed methods can better reduce the error rate than weighting method of Boosting approach.

III. KNOWLEDGE EXCHANGEABLE ILP LEARNERS

Earlier in previous section, we demonstrated many works have been proposed, but none of them has paid special attention on the learned rules from each learner. Hence, this paper proposes the method which can integrate the learned rules from different learners. Our proposed method is called Knowledge Exchangeable ILP Learners (KEIL).

The ILP learners are fed by training sets which have the same distribution as the original training set. After each learner learns its own hypotheses, it exchanges its hypotheses with other learner's.

Before we explain the procedure of knowledge exchanging between the learners, we must define the basic element of the hypotheses which are represented in the form of first-order rules as follows:

Definition 1: Literal chain is the set of literals $\{l_1, l_2, ..., l_n\}$ in the body of a rule.The input variables of literal l_j must be the output of literal l_i with $i > j$ and in the last literal l_n , there must be no output variable occurring in other literals in the rule which are not included in this chain.

The idea of the literal chain is close to the idea of open chain and closed chain proposed in [11] but our definition is looser. For more details about the literal chains please refer [11]. To illustrate the concept of literal chain, we show an example of the literal chains in Fig. 1.

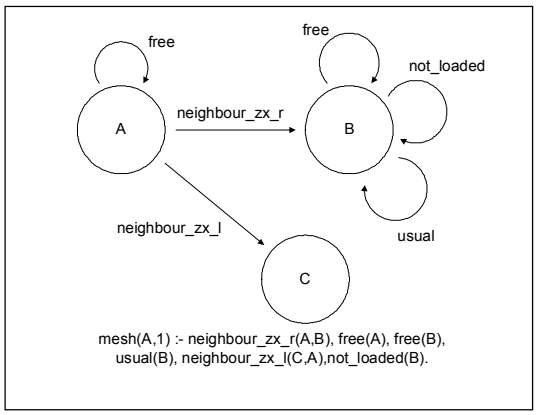

Fig. 1. An example of literal chain.

After defining the definition of literal chain, we can explain learning procedure as follows:

- Randomly divide the training set E which consists of positive examples and negative examples into $E_1, E_2, ..., E_n$.
- Use the learners $L_1, L_2, ..., L_n$ to create the hypotheses set $H_1, H_2, ..., H_n$ from $E_1, E_2, ..., E_n$, respectively. Each hypotheses set must obey the condition $H_i \cup B \models E_i^+$ and $H_i \cup B \not\models E_i^-$ where B denotes the background knowledge.
- Select hypotheses set H_i which is most accurate on its own training set E_i to be the base hypotheses set. Then adjust the hypotheses set H_i by
    - For each positive example e^+ in E_i which is not covered by H_i.
        - Insert a hypothesis h from H_j where $i \neq j$ and $\{h\} \cup B \models e^+$ into H_i. If $\{h\} \cup B \models E_k^-$ where $k \neq j$, it is required to adjust h to be more specific by adding one or more literal chains having common structure with h from H_k to h as h' whose accuracy is higher than the accuracy of h on training set E.
    - For each positive example e^+ in E_j which is not covered by H_i.
        - Insert a hypothesis h fro H_j where $i \neq j$ and $\{h\} \cup B \models e^+$ into H_i. If $\{h\} \cup B \models E_k^-$ where $k \neq j$, it is required to specialize h by adding one or more literal chains having common structure with h from H_k to h as h' whose accuracy is higher than the accuracy of h on learning dataset E.
- Use the modified hypotheses set H_i to classify test examples.

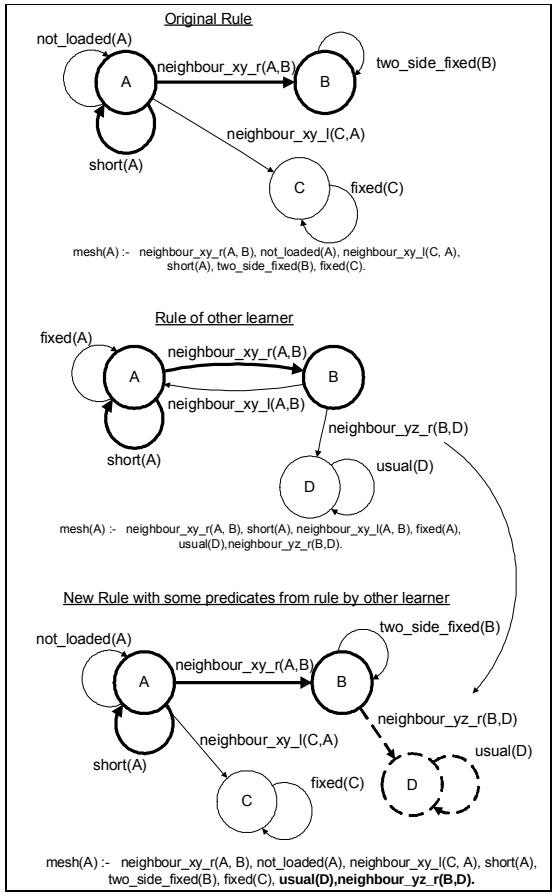

Fig. 2. Example of rule adjustment by adding literal chains from other learners

Fig. 2 illustrates how to improve the accuracy of the hypotheses set discovered by the best learner. The original hypothesis is represented in the form of first-order rule. From the figure, we assume that the original rule is too general (It means that this original rule covers some negative examples of other learners' training set), therefore we want to specialize this rule. The literal chain from the middle graph has some common structures so that we can combine these two chains. The result of combination is shown in the bottom graph. Furthermore, an example of the entire process is shown in Fig. 3.

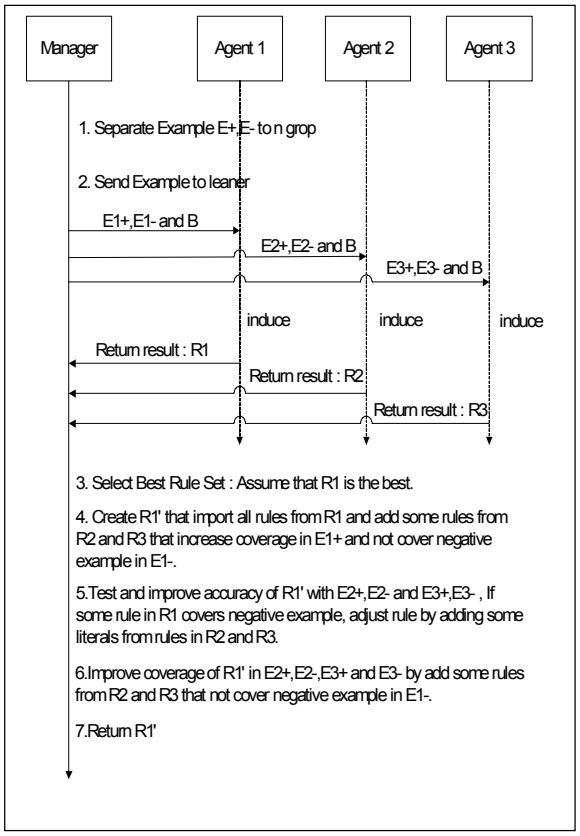

Fig. 3. shows learning process with separated dataset and how to combine result from each learner

IV. Experimental Results

We ran the experiments on three benchmarks, namely Mutagenesis, Carcinogenesis and finding the number of Finite-Element Mesh. In the last dataset, the original problem is to find the number of finite element in given structures. This problem is multi-class and it is too complicated to handle examples in multi-class fashion. We hence relax this problem by transforming it into two two-class problems which are distinguishing class one from the others (Mesh1) and distinguishing class two from the others (Mesh2).We compared our method (KEIL) to two other simple rules combining methods, i.e. All Rules (AR) and Best Learner (BL), by running 5-fold cross validation. The ILP learner used in this experiment was Aleph [9]. The results with statistical significance tested by the one-tail paired t-test are shown in Table 1.

We can see from the table that our method performed well on all datasets and better than two simple rule combining methods compared in our experiment.

V. Summary

This paper has illustrated the way to use multi-learner to collaboratively construct the hypotheses by Inductive Logic Programming algorithm. Each learner creates the different hypotheses from disjoint training sets. By using this training scheme, the learner cannot see the others' training sets. We thus propose the idea of Knowledge Exchangeable ILP Learners which can import the knowledge represented in the form of the rules from other learners. To evaluate the efficiency of our method on combining rules, we conducted experiments by comparing to two simple rules combining methods, i.e. AR and BL. The results showed that our method can better combine the rules and obtain the higher accuracy than the other methods.

***Abstract*— Complex data sets are often unmanageable unless they can be subdivided and simplified in an intelligent manner. *Clustering* is a technique that is used in data mining and scientific analysis for partitioning a data set into groups of similar or nearby items. *Hierarchical clustering* is an important and well-studied clustering method involving both top-down and bottom-up subdivisions of data. In this paper we address the parallel complexity of bottom-up hierarchical clustering. We describe a sequential algorithm for bottom-up hierarchical clustering. We then define a natural decision problem based on this algorithm, and add this** HIERARCHICAL CLUSTERING PROBLEM **(HCP) to the list of *CC*-complete problems, thereby showing that HCP is one of the computationally most-difficult problems in the** COMPARATOR CIRCUIT VALUE PROBLEM **(CCVP) class. This class contains a variety of interesting problems, and now for the first time a problem from data mining as well.**

I. INTRODUCTION

Clustering is a division of data into groups of 'similar' objects, where each group is given a more-compact representation. When researchers represent data by using fewer clusters, they necessarily lose certain finer details, but achieve a simplification of sorts. Researchers use clusters to model very large data sets. It is worth presenting an example of some clusters to get an intuitive feel for this topic. Figure 1 shows a set of points in the plane which have been partitioned into four clusters. All points within the same cluster are somewhat closer or more similar to points in their own cluster than they are to points in the other clusters.

Clustering has its roots in mathematics, statistics, and numerical analysis; clustering is the subject of active research in several fields including pattern recognition and machine learning. In particular, clustering is a useful tool in data mining, where immense data sets which are difficult to store and to manipulate are involved. In this paper we study the parallel complexity of the (bottom-up) *hierarchical clustering problem*. This problem is one of the most-popular ones in the clustering literature, and in what follows we review some of the related work.

Hierarchical clustering builds a *tree of clusters*. Sibling clusters in this tree partition the points associated with their parent, thereby producing a further refinement of the data. From the opposite viewpoint, parents remove structure from the representation of the data by grouping together the data corresponding to their children. This approach permits one to explore data using various levels of granularity. There are two widely studied methods for hierarchical clustering: *bottom-up* and *top-down* [9], [11]. As the name suggests, a bottom-up approach starts with single-point clusters and then recursively merges two or more of the most-'appropriate' clusters. A top-down approach starts with one large cluster consisting of all of the data points and then recursively splits the most-'appropriate' cluster. In each of these two clustering methods, the process continues until a desired stopping condition is met. The stopping conditions can be one of several things such as a required number of clusters or a bound on the diameter of the 'largest' cluster.

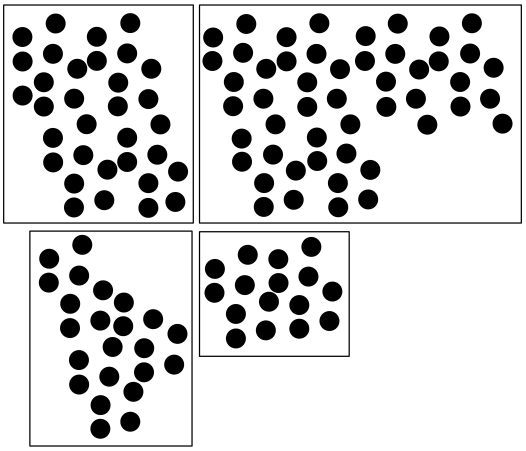

Fig. 1. A set of points partitioned into four clusters.

A variety of sequential versions of hierarchical clustering methods have been studied. We now mention a few of them. Guha et al. introduced the bottom-up hierarchical clustering algorithm CURE. Empirical evidence indicates this algorithm is good for clusters having arbitrary shapes and/or *outliers*, that is, points which do not fit into any appropriate cluster [8]. Another bottom-up hierarchical clustering algorithm called CHAMELEON was introduced by Karypis et al.; their algorithm relies heavily on graph partitioning [10]. Boley introduced the PRINCIPAL DIRECTION DIVISIVE PARTITIONING ALGORITHM; his algorithm is a top-down hierarchical approach for clustering document collections [2]. Steinbach et al. proposed another top-down hierarchical approach called

HIERARCHICAL DIVISIVE BISECTING k-MEANS [18].

A number of papers have also been written on the topic of parallel hierarchical clustering for various models of computing. When there are n input points, Olson described $O(n)$-time algorithms for hierarchical clustering using various linkage metrics on an n-processor Concurrent-Read Concurrent-Write Parallel Random Access Machine (CRCW PRAM). He also gave $O(n \log n)$-time algorithms for these metrics on butterfly networks and trees, where $n/\log n$ processors were required [15]. Li and Fang presented a single-link hierarchical clustering algorithm with an $O(n \log n)$ running time on a Simultaneous Instruction Multiple Data (SIMD) hypercube multiprocessor having *mn* processors, where n is the number of points and m is the number of dimensions [13]. In another paper by Li, he gave $O(n^2)$-time parallel algorithms on an n-processor SIMD shuffle-exchange network for n-point hierarchical clustering and cluster-validity computation [12]. When there are n input points, an $O(\log^2 n)$-time algorithm was given by Tsai et al. that uses an n^3-processor array with a reconfigurable-bus system [19]. Wu et al. discussed an $O(\log n)$-time hierarchical clustering algorithm which uses n^3 processors on a model with reconfigurable optical buses, where there are n points [20]. Let c denote the number of partitioned cells. Dash et al. provided an $O((n^2 \log n/c)/p)$-time parallel hierarchical clustering algorithm on a shared-memory multiprocessor architecture that uses p processors [5]. More recently, Rajasekaran presented an $O(\log n)$-time randomized hierarchical clustering algorithm which uses $n^2/\log n$ processors on the CRCW PRAM [16].

The outline of this paper is as follows: §II covers preliminaries and notation; §III describes a bottom-up sequential algorithm for hierarchical clustering; in §IV we state our main results; and §V contains conclusions and open problems.

II. NOTATION AND PRELIMINARIES

Let $\mathbb{N} = \{1, 2, 3, \ldots\}$ denote the set of natural numbers. Let $\mathbb{R}$ denote the set of real numbers, $\mathbb{R}^+$ the positive real numbers, and $\mathbb{R}^d$ the d-fold Cartesian product of $\mathbb{R}$. Let x and y denote two distinct points. When we choose two points from a set, we always assume that the points are distinct. We use $d(x, y)$ to denote the distance between x and y with respect to a distance measure d. If $x, y \in S$, we subscript the notation with S to $d_S(x, y)$ to denote the distance between x and y in S with respect to the distance measure d. Let S and T be sets of points. We use the notation $d_{\min}(S, T)$ ($d_{\max}(S, T)$) to denote the minimum (respectively, maximum) distance between *any* pair of points, where one point comes from S and the other point comes from T.

We are interested in relating the complexity of hierarchical clustering to that of a problem involving Boolean circuits containing a special type of gate. A *comparator* gate has two output wires and outputs the minimum of its two inputs on its first output wire and outputs the maximum of its two inputs on its second output wire. Furthermore, comparator gates are restricted so that each output has fanout at most one. We next define an important problem in complexity theory that is based on the comparator gate, and shortly define an entire complexity class based on this problem.

COMPARATOR CIRCUIT VALUE PROBLEM (CCVP)
GIVEN: An encoding $\overline{\alpha}$ of a Boolean circuit α composed of comparator gates, inputs $x_1, \ldots, x_n$, and a designated output y.
PROBLEM: Is output y of α TRUE on input $x_1, \ldots, x_n$?

We discuss a number of fundamental complexity classes in this work. Let *P* denote the class of all languages decidable in polynomial time. Let *NC* denote the class of all languages decidable in poly-logarithmic time using a polynomial number of processors on a PRAM. Let *CC* denote the class of all problems that are *NC* many-one reducible to CCVP (see Mayr and Subramanian [14]). We will use the notation $\leq_m^{NC}$ to denote *NC* many-one reducibility. For more background the reader is referred to Greenlaw, Hoover, and Ruzzo [6].

The *P*-complete problems are believed to be inherently sequential. Problems that are *CC*-complete are considered unlikely to be *P*-complete, but no fast parallel algorithms are known for them, with the exception of some $\sqrt{n}(\log n)^{O(1)}$ time algorithms that use $\sqrt{n}$ processors. So far, there are only nine known *CC*-complete problems, and they include CCVP plus the following: STABLE MARRIAGE PROBLEM, and LEXICOGRAPHICALLY FIRST MAXIMAL MATCHING PROBLEM, among others. It is known that $CC \subseteq P$, but *NC* and *CC* are incomparable using the subset relation. We should point out that if a problem is *CC*-complete, then that problem is very unlikely to have an *NC* algorithm. When we prove the equivalence of the HCP and the CCVP in §IV, we demonstrate that hierarchical clustering of this type is unlikely to have a feasible highly parallel algorithm. This result shows that the HCP is *CC*-complete.

III. BOTTOM-UP HIERARCHICAL CLUSTERING ALGORITHM

We describe the bottom-up hierarchical clustering algorithm. As input, the algorithm takes a set of points, a distance function, and the desired number of clusters k. The algorithm first pairs up all points starting with the two closest ones, then the next remaining two closest ones, and so on, until all points are paired. Next the sets of points X and Y minimizing $d_{\min}(X, Y)$ over all remaining sets are merged, until only k sets remain.

SEQUENTIAL (BOTTOM-UP) HIERARCHICAL CLUSTERING ALGORITHM

{ Input: A set S of points $p_1, \ldots, p_n$ in $\mathbb{R}^d$, where n is even, a distance function $d_S : S \times S \mapsto \mathbb{R}^+$, a distance bound B, and $k \leq n/2 \in \mathbb{N}$. }
{ Output: A partition of S into k groups. }
begin
  $S \leftarrow \{ p_1, \ldots, p_n \}$;
  for $i \leftarrow 1$ to $n/2$ do
    $C_i \leftarrow \emptyset$;

```
  // initialize leftover
  leftover ← n/2 + 1;
  T ← ∅;
{ Comment: First-phase. }
  for i ← 1 to n/2 do {
    choose x, y ∈ S such that d_S(x, y) is a
      minimum;
    if d_S(x, y) > B then {
      let T be the set of singleton sets of all
        remaining points including x and y;
      leftover ← i;
      break;
    }
    C_i ← { x, y };
    S ← S − C_i;
  } // end of for loop
  partition-set ← { C_1, ..., C_(leftover − 1) }
    ∪ T;
  number-partitions ← ( leftover − 1 )
    + |T|;
{ Comment: Second-phase. }
  while (number-partitions > k) do {
    choose C_a and C_b so that d_min(C_a, C_b)
      is a minimum over partition-set;
    partition-set ← partition-set ∪
      { C_a ∪ C_b } − { C_a } − { C_b };
    number-partitions−−;
  }
  output partition-set;
end.
```

The algorithm operates in a bottom-up fashion. Without loss of generality, we have assumed that the number of input points is even. Depending on the distribution of the initial points, the algorithm may, for example, form $k-1$ clusters having two points and one cluster containing the remaining points. If, for example, the points are distributed uniformly in the Cartesian plane and d_S is the Euclidean distance, then the clusters are expected to be balanced in terms of size. Note that there are no restrictions placed on the distance function d_S. For technical reasons in the first-phase of the algorithm we only cluster points whose distance is less than or equal to B. This version of the hierarchical clustering algorithm is equivalent to the standard version if B is greater than $d_{\max}(S,S)$. The algorithm clearly operates in polynomial time. In §IV we will focus on the complexity of the first-half of this algorithm.

IV. The Complexity of Hierarchical Clustering

A. Decision Problems

We begin here by defining a natural decision problem based on the Sequential (Bottom-Up) Hierarchical Clustering Algorithm.

> Hierarchical Clustering Problem (HCP)
> Given: A set S of n points in $\mathbb{R}^d$, a distance function $d_S : S \times S \mapsto \mathbb{N}$, number of clusters $k \leq n/2 \in \mathbb{N}$, a distance bound B, and two points $x, y \in S$.
> Problem: Are x and y with $d_S(x,y) \leq B$ in the same cluster C after the first-phase of the Sequential (Bottom-Up) Hierarchical Clustering Algorithm?

Note that in the definition of the HCP there are no restrictions placed on the properties that the distance function must satisfy. Obviously, this version of the problem easily reduces to the version of the problem where the weights come from $\mathbb{R}^+$. When we define distance functions, we are not concerned with the distance between a point and itself. The k specified in the instance of the problem refers to the number of clusters to be formed. Observe that the definition also requires that x and y be no further apart than the distance bound B.

In the statement of the HCP we were careful about the restrictions placed on the distance function since the complexity of the Distance Geometry Problem (*DGP*) is interesting in and of itself [1]. That is, given $n, d \in \mathbb{N}$ and $n(n-1)/2$ distances $d_{ij} \in \mathbb{R}$, where $1 \leq i, j \leq n$, and zeros on the diagonal, can it be determined whether or not there are n points $x_1, \ldots, x_n \in \mathbb{R}^d$ such that using the Euclidean distance between points, we have $|x_i - x_j| = d_{ij}$ for $1 \leq i, j \leq n$? The DGP can be solved sequentially in $O(n^{d+3})$ time (Personal Communication, Geir Agnarsson, 2006). We needed to define the HCP, so that the DGP's complexity did not dominate the complexity of the problem that we were really interested in studying.

We define the Lexicographically First Maximal Matching Problem (LFMMP), which we need in the proofs of Theorems 4.1, 4.2, and 4.3, as follows:

> Given: An undirected graph $G = (V, E)$ with an ordering from 1 to $|E|$ on its edges plus a distinguished edge $e \in E$.
> Problem: Is e in the lexicographically first maximal matching of G?

B. Main Theorems

Here we state our main results. Proofs may be found in our full paper [7]; most details are omitted here due to space limitations.

Theorem 4.1: The Hierarchical Clustering Problem is NC many-one reducible to the Lexicographically First Maximal Matching Problem, that is, HCP $\leq_m^{NC}$ LFMMP.

The next theorem shows that the HCP is *CC*-hard.

Theorem 4.2: The Lexicographically First Maximal Matching Problem is NC many-one reducible to the Hierarchical Clustering Problem, that is, LFMMP $\leq_m^{NC}$ HCP.

Proof: We perform an *NC* many-one reduction from the LFMMP to the HCP. Let $G = (V = \{1, \ldots, n\}, E)$, $\phi : E \mapsto \{1, \ldots, |E|\}$ be an ordering on E, and $e = \{u, v\} \in E$ be an instance of the LFMMP. From this instance of the LFMMP, we construct an instance of the HCP, that is, a set S of n points $p_1, \ldots, p_n$ in $\mathbb{R}^d$, a distance function $d_S : S \times S \mapsto \mathbb{N}$, the number of clusters $k \leq n/2 \in \mathbb{N}$, a distance bound B, and

two points $x, y \in S$. We now describe the reduction, which we will call f.

Let $S = \{1, \ldots, n, n+1, \ldots, 2n\}$. The first n points in S represent the vertices in V. The second n points are needed to balance out the clusters; call these values V', that is, $V' = \{n+1, \ldots, 2n\}$. We define the distance function between each pair of points in S as follows:

$$\begin{aligned} d_S(x,y) &= \phi(\{x,y\}) && \text{if } \{x,y\} \in E \\ &= 2|E| && \text{if } x \in V \text{ and } y \in V' \text{ or vice versa} \\ &= 3|E| && \text{if } x \in V', y \in V', \text{ and } x \neq y \\ &= 4|E| && \text{if } x \leq n, y \leq n, x \neq y, \\ & && \quad \text{and } \{x,y\} \notin E \end{aligned}$$

We let $B = |E|$, $k = n$, and choose u and v as our two points. It is clear that f is an *NC* many-one reduction. We next examine the correctness of f.

We claim that edge $e = \{u, v\}$ is in the lexicographically first maximal matching M of G if and only if the pair of points u and v is clustered in the first-phase of the SEQUENTIAL (BOTTOM-UP) HIERARCHICAL CLUSTERING ALGORITHM. We prove an even stronger result by showing that edge $\{u, v\}$ is the t-th edge added to the lexicographically first maximal independent set in G if and only if the set of points u and v with $d_S(u, v) \leq B$ is the t-th set of points clustered in the first-phase of the algorithm. We prove this result by induction on t.

By the values of the distances assigned by the reduction f, the base case holds since $e = \{u, v\}$ with $\phi(e) = 1$ is the first edge added to the matching if and only if $d_S(u, v) = 1 \leq B$ is the minimum distance between any pair of points in S which is if and only if u and v are put in the same cluster in the first step of the first-phase of the algorithm.

The remaining details of the proof may be found in [7] and are omitted here due to space limitations.

■

We combine Theorems 4.1 and 4.2 to obtain our main result.

Theorem 4.3: The HIERARCHICAL CLUSTERING PROBLEM is CC-complete.

Theorem 4.3 expands the list of *CC*-complete problems and places the very first clustering/data mining problem into this category. We should point out that the Euclidean version of the HCP in which the distance function is the Euclidean distance function is in *CC*. The Euclidean HCP is, of course, a special case of the HCP. It is an open problem whether or not the Euclidean HCP is *CC*-complete.

The results in this section show that it is very unlikely that there is an *NC* algorithm for the HCP. We have focused on the first-phase of the SEQUENTIAL (BOTTOM-UP) HIERARCHICAL CLUSTERING ALGORITHM. Notice that the first-phase of this algorithm can be reduced to the second-phase of the algorithm by considering each point as a singleton set, setting `number-partitions` equal to $n/2 + 1$, and taking k equal to 1. It is not clear how to reduce the second-phase of the algorithm, involving potentially large sets of points, to the singleton sets considered in the first-phase of the algorithm. These remarks indicate that there is the possibility for a decision problem based on the overall SEQUENTIAL (BOTTOM-UP) HIERARCHICAL CLUSTERING ALGORITHM to be more complex than the HCP.

V. CONCLUSIONS AND OPEN PROBLEMS

We have shown that a natural decision problem based on bottom-up hierarchical clustering is *CC*-complete, while in contrast in our full paper [7], we showed that top-down hierarchical clustering is in *NC*. It is an interesting open problem as to whether or not the Euclidean HCP is *CC*-complete. Knowing the complexity of the second-phase of the SEQUENTIAL (BOTTOM-UP) HIERARCHICAL CLUSTERING ALGORITHM would be very interesting since this result would shed additional light on the complexity of hierarchical clustering itself. Adding new problems to the class of *CC*-complete problems would also be of interest.

***Abstract*— Clustering elements defined in schemas has been recognized for reducing the number of element-to-element comparisons and hence improving the schema matching performance. A cluster of elements is typically identified by a *metadata* in which it is dominant in the match operation to further determine the match of its element members. The effectiveness of schema matching thus relies on the quality of metadata. To the best of our knowledge, the metadata created by previous approaches is dependent on either the predefined concepts which prohibits an automatic metadata creation, or inefficient inputs that results in poor metadata. In this paper, we propose a novel metadata development based on element labels using a linguistic technique. Specifically, the metadata is linguistically related to its element members. In this work, we have defined three metadata creation algorithms, namely *distinct-based* (DM), *synonym-based* (SM) and *relation-based* (RM) metadata creation algorithms. Our experiments showed that a metadata can be automatically created without predefined concepts (rules) and be a potential representative of its element members as shown by their similarity distances. In addition, RM provided a better metadata with respect to the number of tokens than SM and DM do.**

Keywords: Schema matching, Similarity distance, Difference distance, Cluster Metadata

I. INTRODUCTION

Schema matching [2], [5] has been recognized in several database application domains such as schema integration, data warehouse, e-commerce and semantic query processing. Its fundamental operation is *match* which takes two schemas as input and produces a mapping between elements of the two schemas that correspond semantically to each other. The *match* operation [1] is typically done in a pairwise fashion in which all possible pairs of elements are compared, resulting in unreasonably large tasks especially since most pairs do not represent the same information. To efficiently reduce the number of element-to-element comparisons, elements should be clustered into categories where each category is identified by *metadata*. The category metadata, instead of its element members, is in turn used in the process of match operation to further determine the match of its element members.

Today, some approaches ranging from element-based to content-based heuristics have been proposed in the literature [1], [2] to achieve this. In the absence of data instances (or content), Cupid [2] clusters elements and defines metadata based on either data types or concepts of tokens encapsulated in element names. Here, only all possible pairs of elements, e_s and e_t, in compatible categories of two schemas, S_s and S_t, are compared to find the matching pairs where compatible categories are determined by comparing all tokens in two given categories. While this approach provides appropriate metadata, the metadata itself is heavily dependent on concepts predefined by experts, prohibiting an automatic metadata creation or resulting in poor metadata with nonexistence of concepts. In addition, the application of metadata is totally discarded in the match operation. SemInt [1] trains neural networks to classify elements according to element specifications (i.e. type, length and value constraint) and data values (i.e. patterns and statistics). Each category is represented by *weight-based* metadata. The match between the source element (e_s) and weight-based metadata (the representative of target elements e_t) implies that e_s potentially matches with all e_t. While this approach infers element relationships unrecognized by programmers, it is limited to numeric convertible inputs (i.e. data type, key and value constraint), making it inapplicable for element names which contains the useful information. In addition, metadata based solely on such inputs is inefficient as they encapsulate either syntactic or ambiguous semantic information.

While these approaches take steps into the right direction, each approach individually is limited to the *quality* of metadata produced. To address the previous drawbacks, in this paper, we propose a novel metadata development based on element names (or labels) using a linguistic technique. Specifically, the metadata is linguistically related to its element members. In this work, we have defined three metadata creation algorithms, namely *distinct-based* (DM), *synonym-based* (SM) and *relation-based* (RM) metadata creation algorithms. Our experiments showed that a metadata can be automatically created without predefined concepts (rules) and be a potential representative of its element members as shown by their similarity distances. In addition, RM provided a better metadata with respect to the number of tokens than SM and DM do.

Roadmap: The rest of this paper is organized as follows: Section II describes three metadata creation methods. Experimental evaluation is given in Section III. We conclude in Section IV.

II. METHODOLOGY FOR METADATA CREATION

In this work, we consider metadata as a representative of a group of element labels (not data contents) defined in a

schema. For example, the metadata *address* refers to *street*, *city*, *state* and *zipcode* elements. To create such metadata, we have defined three methods, namely *distinct-based* (DM), *synonym-based* (SM) and *relation-based* (RM) metadata creation methods, in which the latter method is an extension to the former method. Specifically, each method creates a new metadata $M^{'}$ based on a current metadata M and an element label L to be added into a cluster. Details of each method are provided in the following sections. For simplicity, let T_M a set of normalized tokens t_m in M, T_L a set of normalized tokens t_l in L, and $T_M^{'}$ a set of normalized tokens $t_m^{'}$ in $M^{'}$.

A. Method DM: Distinct-based Metadata Creation

Definition 1: $T_M^{'} = T_M \cup T_L$

Description: A distinct-based metadata is simply a collection of *lexically different* tokens defined in T_M and T_L.

The algorithm *createDM* is shown in Figure 1. Here, *createDM* receives T_M and L as input and produces $T_M^{'}$ as output. Specifically, the label L is firstly normalized via the method *normalize()* which has similar process as defined by [5]. The method *normalize()* returns a set of normalized tokens as output wherein these tokens in turn are distinctly combined with T_M.

```
Set createDM(Set T_M, String L) {
  T_L = normalize(L);
  if T_M = ∅ then
    T_M = T_L;
  else
    T_M = T_M ∪ T_L;
  return T_M;
}
```

Fig. 1. createDM Algorithm.

Consider Table I that shows two metadata created based on: (1) the current metadata {*street,state*} and label *country*; and (2) the current metadata {*street,state*} and label *city*. With the method DM, in the first example, the new metadata {*street,state,country*} is created by combining all tokens defined in the current metadata and label. Similarly, in the second example, the new metadata {*street,state,city*} is created.

B. Method SM: Synonym-based Metadata Creation

Definition 2: $T_M^{'} = (T_M \cup T_L)$ - S

where $S = \{t_l \mid t_l \in T_L$ and t_l is synonym to $t_m \in T_M)\}$

Description: A synonym-based metadata is a collection of tokens defined in T_M and T_L where such tokens must be *lexically different* and are not *synonym* to each other. In particular, it is an extension to a distinct-based metadata with the exception that one of two lexically different but synonym tokens, t_m and t_l, is removed to reduce the number of tokens in metadata.

The algorithm *createSM*, an extension to algorithm *createDM*, is shown in Figure 2. Here, all possible token pairs, t_m and t_l, are linguistically compared via the method *lSim*(). Based on this match result, the new metadata is defined as a combination of (i) a set of t_m extracted from identical and synonym token pairs whose matches are the value of 1; and (ii) all the rest tokens via the method *addDistinct*() shown in Figure 3.

```
Set createSM(Set T_M, String L) {
  Set T_L = normalize(L);
  if T_M = ∅ then
    T_M = T_L;
  else {
    String[] arrayT_M = set2Array(T_M);
    String[] arrayT_L = set2Array(T_L);
    Double[][] similarity = lSim(T_M, T_L);
    // find synonym pairs
    Set synPairs = findPairs(similarity, 1);
    T_M = ∅;
    for each (i,j) ∈ synPairs {
      T_M = T_M ∪ arrayT_M[i];
    }
    T_M = addDistinct(T_M, arrayT_M, synPairs, 1);
    T_M = addDistinct(T_M, arrayT_L, synPairs, 2);
  }
  return T_M;
}
```

Fig. 2. createSM Algorithm.

```
Set addDistinct(Set T_M, String[] arrayT, Set pairs,
                Boolean opt) {
  set takenIdx = ∅;
  for each (i,j) ∈ pairs {
    if opt == 1 then
      takenIdx = takenIdx ∪ i;
    else
      takenIdx = takenIdx ∪ j;
  }
  set notTakenIdx = ∅;
  for i=0 to i < length(arrayT) {
    if i ∉ takenIdx
      notTakenIdx = notTakenIdx ∪ i;
  }
  for each idx ∈ notTakenIdx {
    T_M = T_M ∪ arrayT[idx];
  }
  return T_M;
}
```

Fig. 3. addDistinct Algorithm.

Again, consider Table I with the method SM. In the first example, the new metadata {*street,state*} remains the same as *country* is synonym to *state*. In the second example, the new metadata {*street,state,city*} is created as there is no identical or synonym taken pairs.

C. Method RM: Relation-based Metadata Creation

Definition 3: $T_M^{'} = ((T_M \cup T_L)$ - S - $R) \cup A$

where $S = \{t_l \mid t_l \in T_L$ and t_l is synonym to $t_m \in T_M\}$, $R = \{t_m, t_l \mid t_l \in T_L, t_m \in T_M$ and t_l is related $t_m\}$ and $A = \{t \mid t$ is the nearest ancestor of t_m and t_l where t_m is related to $t_l\}$

Description: A relation-based metadata is a collection of tokens defined in T_M and T_L where such tokens must be *lexically different* and are not *related*. Two tokens, t_m and t_l, are related if their match is above threshold. In particular, it is an extension to a synonym-based metadata with the exception that two lexically different but related tokens, t_m and t_l, are replaced with their nearest ancestor.

The algorithm *createRM*, an extension to algorithm *createSM*, is shown in Figure 4. Specifically, all possible token

EXAMPLE OF LINGUISTIC SIMILARITY

	street	state	DM method	SM method	RM method
Example 1: country	0.60	1.00	street_state_country	street_state	street_state
Example 2: city	0.74	0.89	street_state_city	street_state_city	street_region

pairs, t_m and t_l, are linguistically compared via the method *lSim*(). Based on this match result, the current metadata is defined as a combination of (i) a set of t_m extracted from identical or synonym token pairs; (ii) a set of nearest ancestors of token pairs whose matches are above threshold. The nearest ancestor is discovered by the method *findAncestor*(); and (iii) all the rest tokens via the method *addDistinct*() shown in Figure 3.

```
Set createHM(Set T_M, String L, Double threshold) {
  Set T_L = normalize(L);
  if T_M = ∅ then
    T_M = T_L;
  else {
    String[] arrayT_M = set2Array(T_M);
    String[] arrayT_L = set2Array(T_L);
    Double[][] similarity = lSim(T_M, T_L);
    // find synonym pairs
    Set synPairs = findPairs(similarity, 1);
    T_M = ∅;
    for each (i,j) ∈ synPairs {
      T_M = T_M ∪ arrayT_M[i];
    }
    // find related pairs
    Set relPairs = findPairs(similarity, threshold);
    for each (i,j) ∈ relPairs {
      String parent = findAncestor(arrayT_M, arrayT_L);
      T_M = T_M ∪ parent;
    }
    Set pairs = synPairs ∪ relPairs;
    T_M = addDistinct(T_M, arrayT_M, pairs, 1);
    T_M = addDistinct(T_M, arrayT_L, pairs, 2);
  }
  return T_M;
}
```

Fig. 4. createRM Algorithm.

Again, consider Table I with the the method RM. In the first example, the new metadata {*street*,*state*} is created in a similar manner to the method SM. In the second example, the new metadata {*street*,*region*} is created wherein *region* is the nearest ancestor of two related tokens, *state* and *city*.

III. PRELIMINARY EXPERIMENTAL EVALUATION

The **L**abel-based **M**etadata **C**reation system , LMC, is developed on the basis of three metadata creation algorithms defined in Section II. The goal of the LMC system is to improve the quality of metadata – a representative for a set of corresponding elements. A series of experiments were conducted to evaluate the potential benefits of the LMC system. In particular, the experiments were designed to test the following hypotheses:

Hypothesis 1: RM method provides a better metadata than DM and SM methods do with respect to the number of tokens.

Hypothesis 2: RM method has traded off the slight similarity distance for better metadata.

A. Experimental Setup

Figure 5 illustrates the overall architecture of LMC system[1]. The LMC system together with three metadata creation algorithms, *createDM*, *createSM* and *createRM*, are implemented by Java (SDK 2.0) and deployed on a standalone PC IV 3.2 GHz with 1 GB RAM running Microsoft Windows XP. LMC takes an element label and the current metadata as input, and returns the newly created metadata, that is defined based on the selected metadata creation algorithm, as output. Specifically, LMC invokes the *similarity* module that exists in WordNet::Similarity [4] through the method *lSim*() defined in Section II. The similarity module is used for measuring the linguistic similarity between two tokens. In the experiments, we use the wup measurement [6]. The WordNet::Similarity in turn connects to WordNet Dictionary [3] and WordNet QueryData to facilitate its tasks.

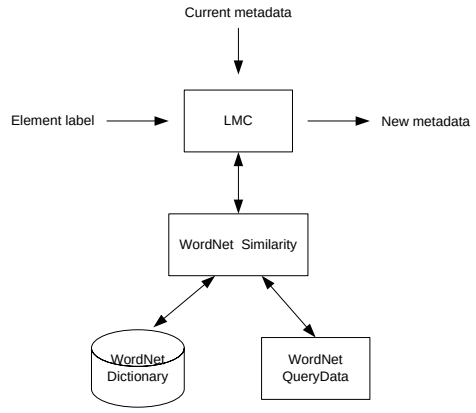

Fig. 5. The Overall Architecture of LMC.

A set of 9 element labels used for the experiments consists of *street*, *city*, *state*, *zip*, *district*, *region*, *address*, *province* and *country* wherein they are labeled with $l1$ - $l9$, respectively. In the experiments, the metadata for these elements must be created as they refer to the *address* concept and are hence related.

B. Effect of Algorithms on Metadata

The first set of experiments measured the *compactness* of metadata produced for 9 element labels by different algorithms – DM, SM and RM as well as the First-based Metadata creation algorithm (FM) that considers the first label added in a cluster as metadata. Here, the compactness of metadata was determined by the number of tokens encapsulated in metadata

[1]We assume that there is a system, responsible for clustering elements and connecting to our LMC for the corresponding metadata.

itself. Particularly, the few number of tokens indicates the few number of token comparisons and hence the better metadata. The initial metadata was set to null.

Figure 6 shows the number of tokens in the metadata produced by different algorithms while adding each of labels (from $l1$ to $l9$) in a cluster. The x-axis has the number of labels in a cluster and the y-axis is the number of metadata tokens. Here, FM performed the best with a constant of 1 token for each newly created metadata as expected. RM created fair metadata with 3 tokens. DM and SM performed the worst, providing an increasing number of tokens in metadata while accepting new element labels into a group. Their final metadata contained 9 and 7 tokens, respectively.

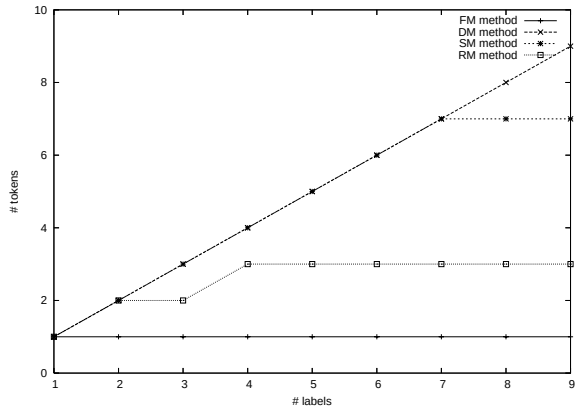

Fig. 6. The Number of Tokens in Metadata Produced by Different Methods.

C. Effect of linguistic similarity distance on LMC algorithm

The second set of experiments measured the *fitness* of metadata produced for 9 element labels by different algorithms – DM, SM, RM and FM. Here, the fitness of metadata was determined by the difference distance (compliment to similarity distance) between metadata and each individual label. Particularly, the less difference distance, the better fitness of metadata as a cluster representative.

Figures 7 shows the final metadata together with the difference distance average of metadata and all element labels as well as each individual difference distance with each label. Here, the difference distance with the value of 0 indicates that the label is either identical or synonym to the metadata, while the rest values varied by the relation of metadata and labels. In Figures 7, DM performed the best with the difference distance average of 0.22 and the individual difference distance below 0.37. SM provided the average as well as individual difference distance of 0.23 and below 0.30, respectively. RM provided an average difference distance of 0.26 as well as an individual distance below 0.34. FM performed the worst with the average of 0.33 and the individual up to 0.53.

IV. Conclusion

In this paper, we propose a novel metadata development based on element labels using the *wup* method, a linguistic similarity measurement. Particularly, a metadata, that is

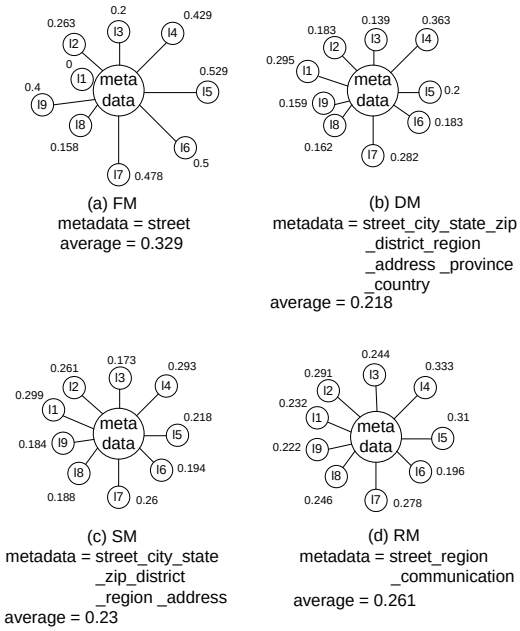

Fig. 7. The Final Metadata Produced by Different Algorithms together with The Average and Individual Difference Distances.

linguistically related to its corresponding elements, can be created using *distinct-based* (DM), *synonym-based* (SM) or *relation-based* (RM) metadata creation method. Our experiments showed that RM provided a better metadata with respect to the number of tokens than SM and DM do. However, RM has traded off the *slight* similarity distance between metadata and labels for better metadata. In addition, a metadata can be automatically created without predefined concepts (rules). While a metadata can be a potential cluster representative, the metadata itself may not be meaningful to human.

Future work focuses on (i) an extensive evaluation of our approach using information from different domains; (ii) an evaluation with existing approaches; and (iii) the application of metadata in schema matching.

***Abstract*-This paper proposes *RNET system* which has been developed for the collection, analysis, and visualization of Thailand's IT researcher network. The system employs Semantic Web technologies for semantically representing and manipulating researcher profiles as well as their publication collections, which are automatically and periodically retrieved from an online citation database. Such information is gathered by means of a constructed crawler and then extracted using HTMLParser. In addition, as it is founded on *RDF(S)* and *OWL* ontology language, the study extends *FOAF* (*Friend of a Friend*) schema into *RNET* vocabulary in order to semantically describe researcher profiles together with their publication details. Managing, querying and reasoning with RDF(S) and OWL data are carried out by employing *Sesame server*. Moreover, in order to enable a graphical visualization, an analysis of the researcher networks, as well as the associations among research topics and the collaborations among research institutes, *JUNG* (*Java Universal Network/Graph*) programming toolkit is adopted. Furthermore, with an emphasis on ease of use and installation, RNET system is implemented as a Web application using JAVA applets, JavaServer Pages (JSP) and JAVA servlet technologies.**

I. INTRODUCTION

Since IT is a huge research discipline, the network of IT researchers is often messy and difficult to analyze. Thus, finding answers to the following questions, for instance, is a challenging and demanding task: "Who are the experts in the Semantic Web and ontology research area in Thailand and how can they be contacted?", "Which research institutes or organizations have active collaborations with NECTEC?".

A search engine is a productive tool for resolving these questions. However, information extraction and collection by humans is tedious work, thus all electronic information on the WWW should be automatically extracted and analyzed.

This paper proposes and develops a *Semantic Web* [1] application, namely *RNET* (available online for public access at http://ict.shinawatra.ac.th/projects/rnet), which can automatically collect researcher information and publication details from an online database on the WWW. Moreover, in order to enable machine-processable semantics of the extracted information and also to allow semantic data interchange, such information is encoded in an RDF/OWL [2] metadata format and stored in an RDF/OWL database. An RDF/OWL inference engine can then reason about this semantic-enabled data, and thus derive certain implicit information. For visualization purposes, a user can browse and search for an expert in a certain area using graph and network data models. All of these functional requirements are well founded by Semantic Web and open-source technologies.

The organization of this paper is as follows: Section 2 describes the proposed system architecture and discusses the employed techniques and tools. Section 3 presents the system implementation in detail. Finally, the conclusion and direction for future research are presented.

II. SYSTEM ARCHITECTURE

RNET system is designed using a 2-tier architecture that simply demonstrates a client-to-server relationship, and can be divided into three layers: *(i) data collection*, *(ii) data analysis*, and *(iii) information visualization*, as shown in Fig.1.

A. Data Collection Layer

The system extracts researcher's publication information from an online publication database using a *crawler* [3] and a *parser* [4]. RNET ontology is developed to semantically describe such extracted data.

1) Crawler: This component browses the WWW in a systematic manner. It traverses a distributed network by following the hypertext links from a specified Web page to other pages.

2) Parser: This service is used for extracting the desired information contained in a web page. The function of a parser can be classified into two parts: *extraction* and *transformation*. The first process extracts data from text, links or other resources, while the latter transforms input data into a data structure.

3) RNET Ontology: In order to allow both machine-readable and human-representation of the extracted researcher profiles and their publications, RNET employs and extends *FOAF* (*Friend of a Friend*) [5] into RNET ontology as depicted in Fig 2.

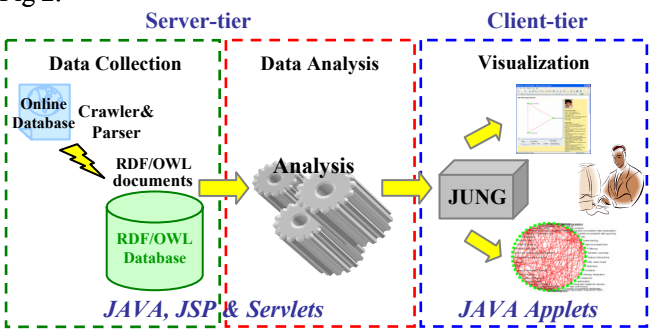

Figure 1. System Architecture of RNET.

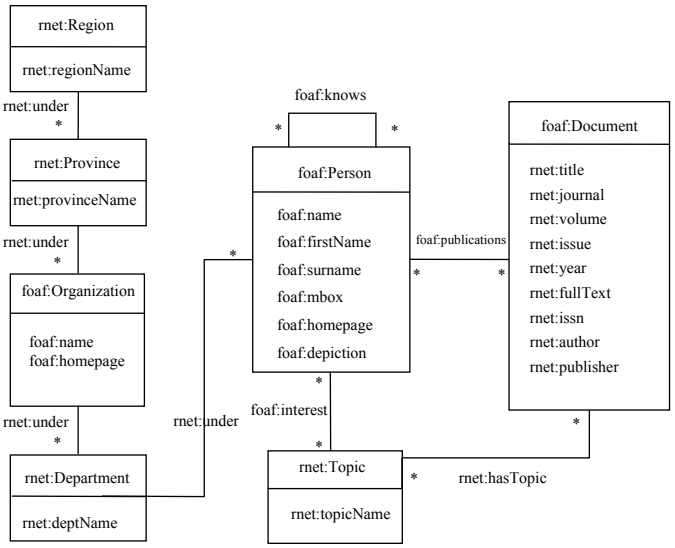

Figure 2. RNET Ontology.

In brief, FOAF is an RDF/OWL schema defining relationships between people and various attributes such as name, gender and interest. Similarly, RNET employs RDF/OWL to express relevant information about researchers including departments, organizations, provinces and regions, as well as topics of interests.

B. Data Analysis Layer

This layer obtains the RDF/OWL documents conforming to RNET ontology and generated by the Data Collection Layer, and then stores them in a database. It requires an RDF/OWL inference engine for the data analysis task as well as for the derivation of implicit information.

C. Information Visualization Layer

This layer provides graphical user interface with RNET system, which allows users to graphically explore not only IT researcher profiles and their networks, but also publication details and research topics, as well as collaboration among organizations. Such exploration and visualization can be part of a sociological study, a collaboration network investigation, and an analysis on active research topic trends.

III. SYSTEM IMPLEMENTATION

With an emphasis on ease of use and installation, RNET system is designed to be implemented as a Web application using merely standard and widely used Web technologies.

This section elaborates the implementation of the three system components corresponding to the three layers of RNET's architecture, that is: *(i) data collection*, *(ii) data analysis*, and *(iii) information visualization*.

A. Data Collection

Initially, researcher information consisting of name, email, homepage, image, and affiliation are predefined using the developed RNET ontology and stored in *Sesame* [6] – an open-source RDF/OWL database. For each of these researchers, RNET dynamically collects his/her publication details from *the Guide* [7], ACM's citation database providing a bibliographic collection from major publishers in computing with over 945,000 entries. This data collection task is accomplished by constructing an HTML crawler to automatically search and traverse the Guide's HTML result pages which indicates the specified researcher's publications. *HTMLParser* [8] is then employed to extract the desired information such as author names, title, source, year, ISBN, full text resource, publisher, and keywords. Finally, an RNET document describing a researcher's personal information and publication details and conforming to the developed RNET ontology is generated and stored in the Sesame database server. Fig. 3 illustrates an example of a generated document.

Note that apart from the Guide, other online citation databases such as *CiteSeer* [9] and *DBLP Bibliography* [10] can also be used and extracted from in the same manner.

Figure 3. RDF document using RNET Ontology.

B. Data Analysis

With a goal to enable users to explore certain knowledge about researcher networks, association of research areas and collaboration among research institutes, this component formalizes certain important axioms in order to derive implicit and hidden knowledge which is useful for analysis in the following important aspects:

1) Researcher Network Analysis: Using the collected research publication details, this analysis employs the discovered co-author relationship for the formulation of a researcher network. In other words, when a group of researchers co-author a particular paper together, one can imply that they know each other. Thus, RNET can illustrate this collaboration among them in terms of a researcher network. Fig. 4 formalizes this axiom.

2) Topic Interest Analysis: This analysis uses the axiom of Fig. 5 to derive the research topics that interest a particular researcher. Note that for the sake of simplicity and demonstration, it assumes that if a researcher has at least one publication in a certain topic, he/she is interested in that topic. However, in practice this can be implemented by specifying a threshold, where this interest relationship between a researcher and a topic can be derived only if the number of publications in that particular topic is higher than the specified threshold.

3) Organization Network Analysis: This analysis discovers the collaboration among organizations or institutes using the axiom of Fig.6. When a group of researchers from various organizations knows each other, it implies that there is some degree of collaboration between this set of organizations.

C. Information Visualization

In order to represent certain knowledge derived from the Data Analysis part, RNET provides a user-friendly interface which allows a user to explore graphical visualization. The user interface is a JAVA Web application based on the client-server model.

Description	If Publication A is co-authored by Person X and Person Y Then Person X knows Person Y.
Axiom	(foaf:Person:X foaf:puclications foaf:Document:A) AND (foaf:Person:Y foaf:puclications foaf:Document:A) => (foaf:Person:X foaf:knows foaf:Person:Y)

Figure 4. Axiom for researcher network analysis.

Description	If Person X publishes Publication A and Publication A has T as its keyword or topic Then Person X has an interest in Topic T.
Axiom	(foaf:Person:X foaf:puclications foaf:Document:A) AND (foaf:Document:A rnet:hasTopic rnet:Topic:T) => (foaf:Person:X foaf:interest rnet:Topic:T)

Figure 5. Axiom for topic interest analysis.

Description	If Person X knows Person Y and Person X under Organization A and Person Y under Organization B Then Organization A collaborates with Organization B.
Axiom	(foaf:Person:X foaf:knows foaf:Person:Y) AND (foaf:Person:X rnet:under foaf:Organization:A) AND (foaf:Person:Y rnet:under foaf:Organization:B) => (foaf:Organization:A rnet:collaborate foaf:Organization:B)

Figure 6. Axiom for organization network analysis.

The client-side employs Java Applets to create the interaction part embedded in HTML pages for users browsing. On the server-side, a Java Server Page (JSP) and servlets are used to create the system applications that hide the complexity of services.

The application exploits a variety of Semantic Web technologies to provide various network models such as the researcher networks, the associations among research areas, and the collaborations among research institutes. Once the user has submitted a search by specifying a keyword such as a researcher name, a topic interest or an organization name, the system returns a summary page of the selected domain to demonstrate a network model, which includes additional details as well as links to related information.

In order to represent a network model, the system employs the service of *JUNG* (*JAVA Universal Network/Graph*) [11] programming toolkit, a JAVA based software library developed for data manipulation, analysis, and visualization as a graph. The graph consists of vertices and edges. Vertices represent entities that are researcher, topic or organization. Edges connected to vertices represent relationships among the entities that the vertices represent.

The Web interface, as shown in Fig. 7, allows users to visualize knowledge in three domain areas including *(i) researcher network, (ii) topic interest network, and (iii) organization network*.

1) Researcher Network: This graph shows the collaboration among researchers with summarized profile information. The page's sidebar additionally gives a list of links to topics of interests and publication details. Fig. 8 illustrates such example of a researcher network.

2) Topic Interest Network: Fig. 9 depicts the associations among research topics. In brief, a relation between topics is discovered using co-occurrence analysis, i.e., if two particular topics co-occur in the same publication, they appear to have a certain relation with each other. Therefore, if they co-occur for more than a particular threshold value, their relation is considered to be significant, and hence illustrated by the visualized graph. Apart from this, the page's sidebar also provides links to researchers who are interested in such topic, as well as a list of related research topics.

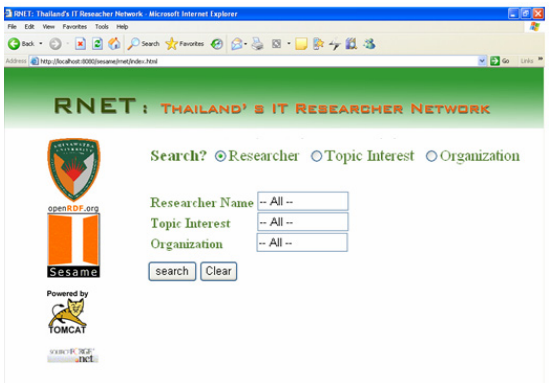

Figure 7. User Interface of RNET.

3) Organization Network: The system demonstrates collaboration networks between organizations in a graph model with all the researchers who work at certain organizations as shown in Fig. 10. This collaboration is defined from a group of researchers that know each other. Moreover, the system can show an organization network from a regional perspective.

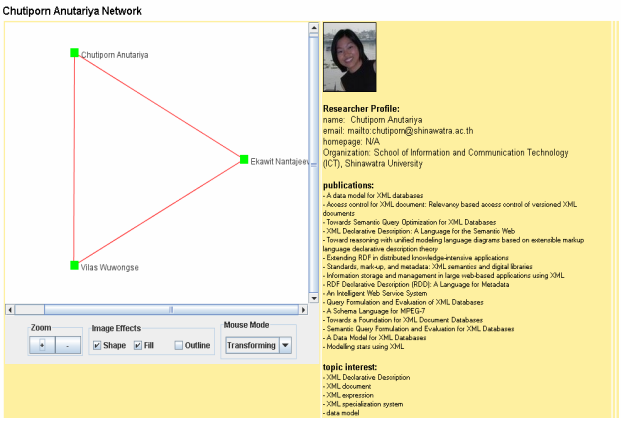

Figure 8. Example of researcher network.

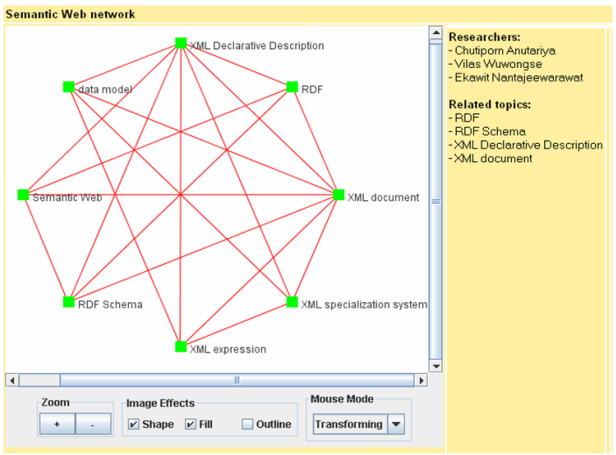

Figure 9. Example of topic interest network.

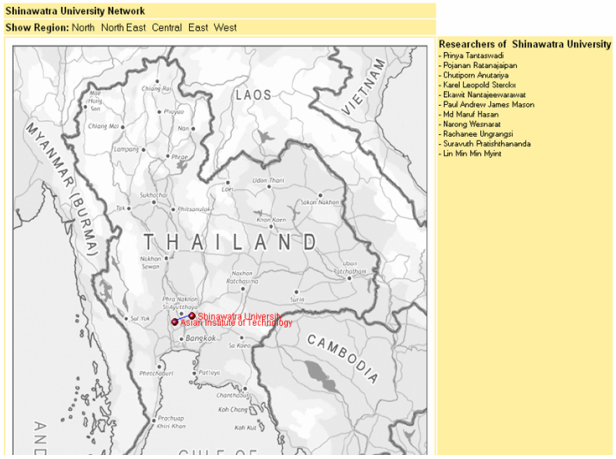

Figure 10. Example of organization network.

IV. Conclusions

The developed RNET system employs various methodologies for collection, analysis and visualization. It automatically gathers researcher's publication details from an online citation database using an implemented crawler and parser. The extracted data is represented in an RDF/OWL document using RNET Ontology and then stored in a database server. In addition, an RDF/OWL inference engine is adopted for deriving hidden and implicit data which are useful for collaboration network study and research topic analysis. The Web application is implemented using JAVA technologies to provide a Web interface, which allows visitors to explore researcher networks and the associations among research areas, as well as the collaborations among research organizations. In addition, the system also provides additional details and a list of links to related information.

Future works include various enhancements to RNET system, which are as follows: to dynamically extract researcher information from various online databases, collect more publication data with a diversity of researcher profiles from various organizations in Thailand, and extend RNET ontological schema for collecting more useful data.

Moreover, in the visualization process, some additional statistical values such as degree of centrality, betweenness, and closeness could be calculated and shown together with the visualized network in order to provide more insight into the network analysis. In a graph model, an edge could depict the strength of association among researchers by using weighted edges or colored edges. Furthermore, an optimal threshold has to be calculated to demonstrate an appropriate research area network.

Abstract **- Mining association rules is being actively studied for transaction databases, but extension to text applications is relatively novel. Most of the previous studies implement an Apriori-like approach, which requires multiple passes over the database to find all frequent itemsets. However, for some type of databases such as the bibliographic database where the data are very sparse, the Apriori algorithm becomes very costly. In this paper, we propose a new algorithm called Object-Oriented Association Rule Mining (OOARM), which uses a special object-oriented data structure that holds all relevant information. The algorithm can find all frequent itemsets from a single scan through the database. Performance studies show that it is faster than the Apriori algorithm. All rules that involve a certain itemset can be generated in real time. That, in turn, opens new opportunities to organize and explore relationships in large text data sets.**

I. Introduction

Association rule algorithms were originally used for analysis of transaction data in the retail industry (market basket analysis). Agrawal et al. [1] introduced what he called the "Apriori" algorithm to analyze these data. Analyzing association rules in transaction databases has been demonstrated to be useful and technically feasible in several application areas such as retail sales [2, 3, 4]. Association rule mining (ARM) can help answer the following questions: How can the sale of a specific item be increased? What is the impact if a certain item is discontinued? Is the sale of items on shelf A related to the sale of items on shelf B?

In this paper, we propose a new algorithm for mining association rules in bibliographic databases toward the objective of enhancing research and development (R&D) management. Bibliographic databases such as INSPEC and EI Compendex contain information and abstracts of journal articles and conference papers from several thousand sources. The information provided from such databases is well structured into distinct fields such as title, author, affiliation, keywords, and abstract. This is different from the unstructured text obtained from the Internet or other full text databases (e.g., TREC).

Analyzing association rules between fields in bibliographic database can help R&D managers profile "who's doing what" on some particular research topics, for example, one can identify that 73% of the articles written by Lizhu Zhou published in PAKDD-99 Proceedings focus on Database theory, while 27% discuss about set theory.

Moreover, mining association rules within a field such as keywords can be used for building a concept hierarchy [5] or a thesaurus. In this paper, we are interested in mining association rules in bibliographic data. The word frequency distribution of a bibliographic database is very different from the item frequency distribution of a sales transaction database. Transaction data typically have a limited number of different items, but a very large number of transactions. The ratio of items/transactions therefore is typically << 1. A typical dataset for a basket analysis might have 1,000 items and more than 100,000 transactions. In contrast, the frequency of keywords often does not reach 1% of the total number of records and is usually much lower. The number of different keywords though can be relatively high. The typical ratio of items/transaction therefore is approximately 1 or larger. These differences make the existing Apriori-like algorithms ineffective in mining association rules for text databases. As a result, a new algorithm and data structure is proposed.

II. Association Rule Mining

The general statement of the association rule mining problem is as follows: Let $I = \{i_1, i_2 \ldots, i_m\}$ be a set of literals, called items. Let D be a set of transactions, where each transaction T is a set of items such that $T \subseteq I$. An association rule r is an implication of the form $X \Rightarrow Y$, where $X \subset I$, $Y \subset I$ and $X \cap Y = \varnothing$. The association rule $X \Rightarrow Y$ holds in the database D with *confidence* c if c% of transactions in D that contain X also contain Y. The rule $X \Rightarrow Y$ has *support* s if s% of transactions in D contain $X \cup Y$.

Association Rule Mining is the process of generating all association rules that have support and confidence greater than the user-specified minimum support (called *minsup*) and

minimum confidence (called *minconf*) respectively. Association rule mining is a two-step process:

1. Find all frequent itemsets. This is to find each set of items (called *itemsets*) that have a co-occurrence rate above the *minsup*. An itemset with at least the *minsup* is called a *frequent* itemset. The size of an itemset represents the number of items contained in the itemset, and an itemset containing k items will be called a *k*-itemset

2. Generate association rules from the frequent itemsets. For every frequent itemset *f*, find all non-empty subsets of *f*. For every such subset *a*, generate a rule of the form $a \Rightarrow (f - a)$, if the ratio of support *(f–a)* to support *(a)* is at least *minconf*.

A. Classic Apriori Algorithm

The literature has proposed various algorithms for discovering association rules. Most of the previous studies [2, 6, 7, 8] implement an *Apriori*-like approach, i.e., they require multiple passes over the database. The main idea of the *Apriori*-like approaches is to iteratively generate the set of *candidate itemsets* (potential *frequent itemsets*) of length *(k+1)* from the set of *frequent itemsets* of length *k* (for $k \geq 1$), and count their supports (occurrence frequencies) in the database. However, because the size of the database can be very large, it is very costly to scan the database repeatedly to count support for candidate itemsets. To reduce the combinatorial search space, all algorithms exploit the following property: if any length *k* itemset is not frequent in the database, its length *(k+1)* extension itemsets can never be frequent.

In situations with a large number of itemsets or very low minimum support thresholds, the Apriori algorithm suffers from the following costs:

• It is not reasonable to repeatedly scan the database and count supports for candidate itemsets.

• It is expensive to count the occurrences of a huge number of candidate itemsets, when only a small fraction is likely to be frequent.

To overcome these problems, we propose a new fast algorithm to generate all frequent itemsets for sparse text datasets.

III. OBJECT-ORIENTED DATA STRUCTURE FOR TEXT ASSOCIATION MINING

A. Justification for New Algorithm

The existing algorithms were developed especially for the Market Basket Data Analysis. The transaction data typically have a limited number of different items, but a potentially very large number of transactions. For the new domain of Association Rule Mining in bibliographic databases, these algorithms are not very efficient. Since the number of keywords can be relatively high, the number of 2-itemsets and larger itemsets can be also very high, depending on the minimum support that was set. The traditional Apriori-like algorithms will generate a very large number of potential candidates for which the support has to be determined. This means scanning over the database and counting the occurrences.

In order to overcome these difficulties, a special object-oriented data structure is implemented. It is specifically designed for itemsets with low support. The new data structure and algorithm has several advantages. It allows easy access and better organization of data as well as fast generation of frequent itemsets with low support and their association rules. A comparison of the performance between the proposed algorithm and the Apriori-like algorithm is presented later. The data structure can also be used for more complex tools such as graphical representation, since it contains all information needed.

B. Object-Oriented Association Rule Mining (OOARM) Algorithm

The following notation is used: Let L_k be the set of frequent *k*-itemsets (those with minimum support). Let T_k be the temporary set of itemsets used to create the new k-itemsets. The itemsets in L_k and T_k will be ordered lexicographically. Furthermore *i.records* will be used for the set of record references where itemset *i* is present, *r.itemsets* will be used for the set of itemsets associated with record *r*, *minsup* represents the minimum support. The OOARM algorithm works as follows:

1. Scan in data from file and store 1-itemsets in L_1.
2. **forall** itemsets $i \in L_1$ **do begin**
   if(|*i.records*| < *minsup*)
   delete *i* from L_1
   k=2
3. **while**($L_{k-1} > 0$)
   forall itemsets $i \in L_{k-1}$ do begin
   $T_k = \varnothing$
   forall *records* $r \in$ *i.records* **do begin**
   forall *itemsets* $c \in$ *r.itemsets* **do begin**
   if(c>i) //check if c is lexico-
   add *c* to T_k //graphically larger than *i*
   end
   end //now T_k contains all itemsets that occur //together with *i*
   forall itemsets $c \in T_k$ **do begin**
   if(|*i.records* $\cap$ *c.records*| > *minsupp*)
   create new itemset *j* with items of *i* and *c*
   j.records = *i.records* $\cap$ *c.records*
   if(*j* is *k*-itemset)
   add *j* to L_k
   end
   end
   k++
   end while

Only at the beginning the algorithm reads from the database or file. After deleting the itemsets from L_1 that do not

have minimum support, there will be no further scanning of the database. The itemsets with $k>1$ are created based on the *(k-1)* itemsets. This is similar to most other algorithms. The generation of the candidates is however entirely different. The algorithm goes through the list L_{k-1} one by one to generate the candidates T_k . Starting with an itemset *i* from L_{k-1}, potential candidates for T_k are found by following the references from *i.records* and then going back to the itemsets from *r.itemsets* for all *r i.records*. The itemsets found this way are only added if they are lexicographically larger than *i*. The itemsets of T_k are then used to create the *k*-itemset candidates. This can be done because the itemset *i* and the itemsets in T_k both occur in at least one record together. Hence the *k*-itemset candidates will have at least support 1. If the intersection of *i.records* and *c.records*, where *c* is an itemset from T_k, has at least *minsup* records, a new itemset *j* is created with the items from *i* and *c*. It can happen that this new itemset has more than *k* items. If that is the case it will be discarded, else the new itemset is added to the set of frequent items L_k.

This algorithm relies heavily on set operations. The algorithm was implemented with the JAVA collections framework which provides good support for set operations. It can easily be seen that the algorithm is not suitable for very large transactional databases, where itemsets have high support. For a database with 100,000 records and an itemset that has 50% support, this itemset would have to keep record references to 50,000 of the records. If there is a large number of such itemsets, memory will quickly become insufficient. Nevertheless for the purpose of mining bibliographic data, the algorithm works very well. The number of record references of an itemset is typically in the range of 5-50.

C. Rule Generation

Another advantage of this data structure is that all rules related to a specific itemset can easily be obtained. With this new algorithm and data structure it is possible to directly generate the desired rules. Since the number of potential association rules can be very high, it might not be reasonable to generate all rules at once but only rules that are of interest. The data structure can hold all relevant information and allows quickly extracting all association rules of interest. The researcher can pick itemsets, i.e., keywords that are of interest, and generate all rules related to it.

The usual procedure of generating rules is to take a *k*-itemset, where $k \geq 2$ and generate all subsets. The subsets then are used to calculate the rules [9]. For instance, when looking at *{ABC}*, we have the subsets *{AB}*, *{BC}* and *{AC}*. If the support is known, we can easily calculate the confidence of the rules $AB \Rightarrow C$, $BC \Rightarrow A$, $AC \Rightarrow B$. However one might be interested in all the rules that involve *{AB}*. With traditional approaches this would involve looking up all itemsets that have *{AB}* as a subset.

Using the new data structure the rule generation is greatly simplified. Now it is possible to generate all rules with a certain itemsets as antecedent or consequent. Let *R* be the set of Rules with minimum confidence *minconf* having the itemset *x* as antecedent or consequent. The algorithm to generate all rules with itemsets *x* as antecedent or consequent is as follows:

```
R= ∅
  forall records r ∈ x.records do begin
    forall itemsets c r.itemsets do begin
      generate the rules: c ⇒ x , x ⇒ c
      add the rules with
      confidence ≥ min conf  to R
    end
  end
```

The algorithm to generate the rules with itemset *c* as antecedent and *x* as consequent is:

```
create new itemset j with items of c and x
j.records= c.records ∩ x.records
  if(|c.records ∩ x.records|<minsup)
    stop, rule does not have minimum
    support
  else
```

$$confidence = \frac{\left|c.records \cap x.records\right|}{\left|c.records\right|}$$

```
  end
```

The idea behind this algorithm is similar to the itemset generation. A rule can only exist if there is a record, which has both antecedent and consequent. The algorithm works similar to the previous one. In order to generate all rules that involve itemset x the algorithm iterates through all records and finds all other possible itemsets that occur together with x. Then all rules that have x as antecedent or consequent, are generated. Rules that do not have minimum support are discarded.

D. Runtime Comparison with Apriori Algorithm

We compared our OOARM with an Apriori-like algorithm based on pseudo code provided by [9]. The two algorithms were run for different supports on two different datasets retrieved from the *INSPEC*.

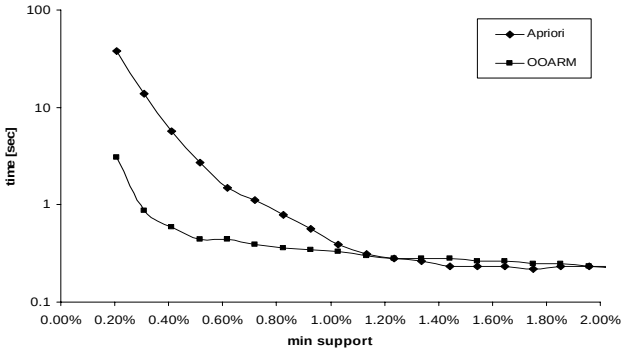

Figure 1. Runtime comparison for dataset with 971 records.

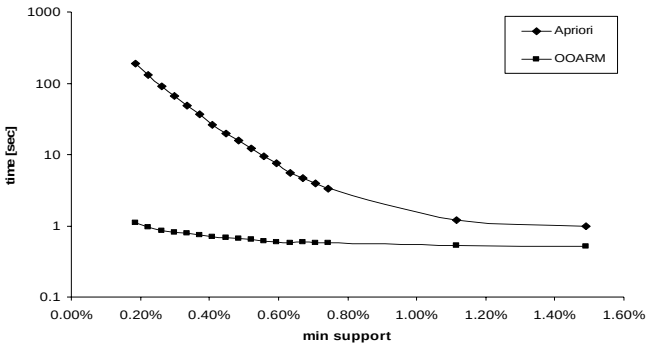

Figure 2. Runtime comparison for dataset with 2686 records.

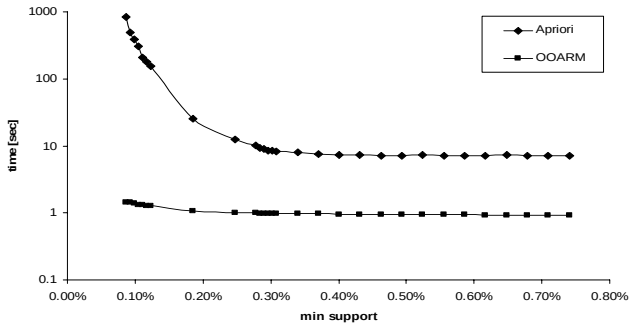

Figure 3. Runtime comparison for dataset with 16209 records.

The runtime of the OOARM algorithm is clearly smaller. For higher support values this advantage is decreasing. Note that the Y axis is in logarithmic scale. Also note the relative low support values that were used.

IV. Differences Between OOARM and Apriori Algorithm

The main difference is that for the proposed algorithm, after an initial scan, all data are held in main memory. The existing algorithms usually require several scans over the whole dataset in order to determine the support. This advantage is very substantial for itemsets with low support. However, for itemsets with high support, e.g., 20%, which can be found in retail data, the proposed algorithm requires more memory. For the domain of Association Rule Mining in bibliographic databases, this is usually not a problem, since the data are preprocessed and keywords that are too general and would have a very high support are usually not used. Keywords or phrases with very high support can also be removed easily, since their value in discovering new relations among terms is very limited.

V. Conclusion

This paper presents a new algorithm for mining association rules in bibliographic databases. The word frequency distribution of a bibliographic database makes the problem of mining association rules in text databases very different from the case of traditional sales transaction databases. Our single scan algorithm allows generating all itemsets very quickly. It is specially designed to work on itemsets with low support. The experimental results show that improvement in run time of up to 200 times can be realized compared to a traditional Apriori-like algorithm. This is due to the fact that during the candidate itemset generation the number of potential candidates is much smaller than with the traditional Apriori-algorithm.

However for higher support values the performance difference becomes smaller. Another advantage is that the data structure can hold all relevant information for association rule mining. This allows for a new way to generate rules. After the initial creation of all large itemsets, it is possible to obtain rules that involve a chosen itemset in real time. This includes all rules where the itemset is an antecedent or a consequent. The data structure can also be seen as a new way to organize and store itemsets in memory and access rules for ARM.

***Abstract*—By employment of the prominent *Semantic Web* technologies, recently emerging with a goal to facilitate well-defined mechanisms for representing machine-processable data, this paper enhances an ordinary *blog* system into *Semantic Blog* by enriching with semantic, machine-understandable metadata and ontology. This Semantic Blog system can be adopted as a tool in knowledge management, focusing primarily on the processes of creating, capturing, and disseminating (sharing) knowledge. In essence, it employs *RDF(S)* and *OWL* to model domain ontologies and to represent semantic-enabled blog entries, thus allowing further inference and semantic integration of blog systems. Moreover, intelligence or semantic search, which incorporates the use of ontology in order to enhance and improve a search quality, becomes possible. This can help encourage users and give a strong motivation for capturing, creating and publishing knowledge into the system.**

I. INTRODUCTION

Knowledge management (*KM*) [1] is commonly referred to processes and practices of acquiring, maintaining and managing knowledge such that it can be easily shared and reused across an organization. To accomplish this goal, there is a need to capture knowledge residing in organizational processes, members, and/or community of practices as well as to support a mechanism for precise knowledge retrieval.

Blog or *Weblog* is a recently emerging general-purpose tool for data exchange, information sharing as well as KM within organizations. It helps encourage ordinary users to publish and manage their own contents, hence becoming not only a content consumer but also a content producer. Key advantages of applying a blog system to KM come from its feature that allows employees, customers or business partners to easily and quickly annotate their work as well as to collaboratively share their experiences and expertise. Hence, its employment as part of a normal work environment can immediately facilitate knowledge creation and knowledge sharing. Each blog entry, containing any types of media, e.g., text, documents, images or videos, is therefore considered to be a knowledge resource created by an organizational member, and accompanied by its corresponding metadata, describing the title, author, posted date/time, description and categories. Thus, a metadata search which allows one to combine these various elements to express a more precise query, such as *to find entries posted in 2006 and contains the words "Semantic Web" in the tile*, is possible although this important feature is not explicitly provided by most blog systems. In general, the most common form of searching is merely a text-based one; for example, *finding entries about knowledge engineering* simply means *finding ones containing the word "knowledge engineering" in their contents*, which usually returns many non-relevant results. Therefore, intelligence or semantic-enabled search, which incorporates the use of metadata and ontology in order to enhance and improve a search quality, is increasingly demanded.

By employment of *Semantic Web* technologies [2], this paper develops a framework for *Semantic Blog* [3, 4] which extends the ordinary blogging paradigm with ontology mechanisms for modeling and representing semantic-enabled blog entries, thus enabling further inference and semantic integration of various blog systems. In particular, *OWL* (*Web Ontology Language*) [5] is employed to formalize domain conceptualization consisting of *concept taxonomy*, *axioms* and *constraints*. In addition, it can be employed to further define structure and semantics of each metadata element in order to allow a finer grained metadata search. Hence, besides annotating by a set of metadata, each blog can also be semantically related to particular concepts defined in the ontology, and thus further inference about blog entries become possible.

The remainder of this paper is organized as follows: Next section elaborates the proposed Semantic Blog framework and implementation details. Section 3 discusses its application as a tool for knowledge management and knowledge sharing. Finally, Section 4 concludes and outlines further research direction.

II. SEMANTIC BLOG SYSTEM DEVELOPMENT

This section develops a general-purpose Semantic Blog system to be used as a KM tool. First, details of the Semantic Blog framework are discussed, and followed by the implemented architecture.

A. Semantic Blog Framework

Semantic Blog [3, 4] extends the blogging paradigm with the possibility to add additional metadata to a blog entry. This metadata can cover a variety of aspects, ranging from information about the entry itself (e.g. entry's title, author, and relations to other communication sites) to metadata describing the topics mentioned in the entry.

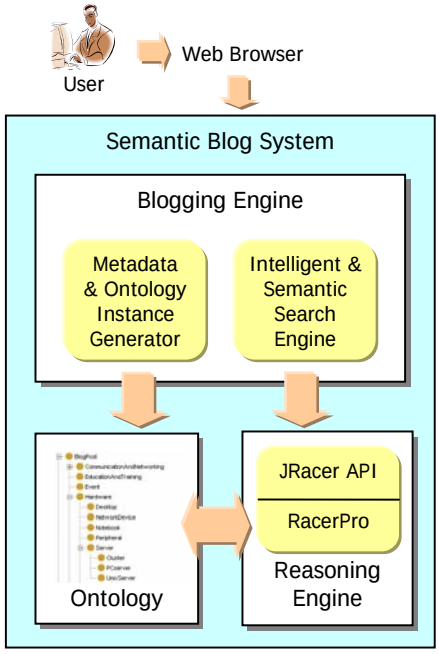

Figure 1. Semantic Blog system architecture.

Moreover, by means of the two prominent Semantic Web technologies: *Resource Description Framework* (*RDF*) [6] and *Web Ontology Language* (*OWL*) [5], which facilitate well-defined mechanisms for expressing machine-processable data in terms of *ontology* [7], each blog entry can be semantically associated with particular concepts defined in a given domain-specific ontology. Therefore, inferencing through a *concept taxonomy* (aka. *concept hierarchy*) becomes possible and thus, resulting in a capability for precise searches through the collection information.

B. Semantic Blog Implementation

Fig. 1 depicts the architecture of the developed Semantic Blog system, which consists of three important components: *domain-specific ontology*, *blogging engine* and *reasoning engine*.

1) Domain-Specific Ontology

Since ontology provides a basic infrastructure for the Semantic Blog, an *ontological schema* is first designed and constructed using OWL language and *Protégé* ontology editor [8] in order to allow semantic description and representation of knowledge in an organization. In particular, the developed ontological schema (aka. *vocabulary*) comprises important concepts such as BlogPost, Department, Member, and Position. Fig. 2, moreover, illustrates the relationships among these four concepts (using OWL's *object properties*). For instance, (i) a Member can blog a BlogPost and a BlogPost is blogged_by a Member, (ii) a Member holds a Position and affiliates_with a particular Department. Besides these object relationships, important *datatype properties* for each of these four concepts are also defined in the constructed ontology. For example, BlogPost also contains the properties title, date, link and

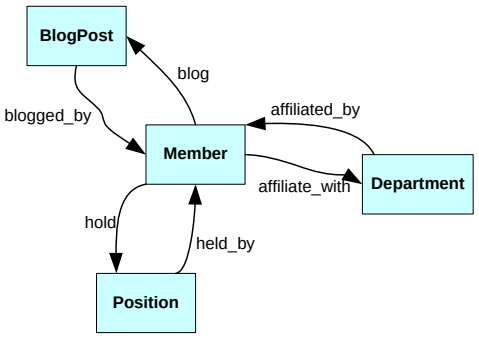

Figure 2. Semantic Blog's ontology: important concepts and relationships.

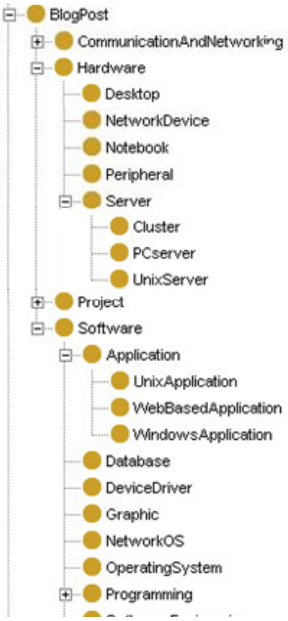

a) BlogPost concept taxonomy

b) Position concept taxonomy

c) Department concept taxonomy

Figure 3. Semantic Blog's ontology: concept taxonomy.

description, the values of which are simply textual data – rdf:literal or xsd:date; similarly, Member has the properties name, date_of_birth, email and contact-information.

Note that all of these four concepts can be further specialized to provide more precise concepts that meet the executing domain. As a sample case study of applying the developed ontology to describe knowledge in Information Technology (IT) department, the concept BlogPost can be

specialized into many IT related sub-concepts. Fig. 3-a shows the defined *concept taxonomy* (or *concept hierarchy*). In other words, it specifies that BlogPost can be classified into such categories as CommunicationAndNetworking, Hardware, Project, Software, etc. Each of these sub-concepts can also be further specialized into more specific concepts. For instance, Hardware is divided into Desktop, Notebook, Server, etc., while Server is divided into Cluster, PCServer, and UnixServer. In addition, as illustrated by Fig. 3-b, Position concept is also specialized into ManagementRelated and ITRelated, while the latter is further classified into Administration and SoftwareDeveloper, which is again specialized into ProjectManager, SystemAnalyst, etc. Department concept specialization can also be explained in a similar manner (see Fig. 3-c).

In summary, a domain-specific ontology defined using RDF/OWL language plays an important role in the system by providing explicit conceptualization of a shared understanding of a domain, and hence enabling certain inference facilities.

2) Blogging Engine

The developed system employs an open-source blog tool as an infrastructure. At present, there are several off-the-shelf blogging software publishing tools available. Since an ease of use is one of the significant features for a KM tool, the developed Semantic Blog system adopts Wordpress 2.0 (http://wordpress.org) built on PHP and MySQL, and runs on an Apache Web server. Moreover, in order to facilitate semantic capabilities, the system has been extended with two important features:

- *Metadata and Ontology Instance Generator:* This sub-component enriches each blog post with semantic, machine-readable metadata and also associates the post with an appropriate concept defined in the concept taxonomy. An ontological instance represented in terms of RDF/OWL syntax and conforming to the predefined ontological schema will then be generated and maintained by the system.
- *Intelligent and Semantic Search Engine:* This component is implemented in order to support not only simple text-based search, but also an intelligent and semantic one which allows combination of various metadata and ontology elements to express a more precise query. Moreover, it employs the defined domain ontology, and facilitates derivation of implicit information, and hence enabling a more accurate retrieval of relevant blog entries. For instance, a search for all blog posts categorized in Software category (or concept) will return not only those which are explicitly defined as Software's blog entries, but also those entries under all sub-concepts of Software. That is, the entries in the categories, Programming and Web Based Application will also be part of the results, provided that these two categories are sub-concepts of Software defined in the domain ontology.

3) Reasoning Engine

The Intelligent and Semantic Search Engine component described previously employs *RacerPro™* [9] and *JRacer API* [10], in order to support reasoning services over a given ontology. In particular, RacerPro is an OWL reasoner, which provides Java application programming interface via its JRacer API.

III. Semantic Blog Approach To Knowledge Management

This section discusses as a case study how to employ the developed system to support KM processes in an IT-related organization, such as a software-development company or an IT support department.

A. Knowledge Creation and Sharing

In principle, ordinary users can freely view or search the system, while subscribed users can additionally post blog contents, which could be in various forms such as texts, documents, pictures, audio and videos, and are considered as organizational knowledge resources. Thus, by supporting users with a friendly environment to convert their tacit knowledge into codified explicit knowledge, the system can encourage them to create and share more knowledge in terms of blog posts.

In order to connect each blog post with the predefined ontology and to enable inference searches, the user who enters such a post must specify the appropriate category defined in the ontology and associate it with the post; otherwise, as default it will be assigned to "Others" category. The system will then use this specified category together with other important semantic metadata, including posted date/time, link or URL of the post, title, description and author, to automatically generate an ontology instance in RDF/OWL. Fig. 4 illustrates an example of such an element, which describes a blog post categorized in Programming category, posted at 19:03 on 2006-02-16, by the user Administrator, with the title Alternative syntax for control structures.

B. Knowledge Retrieval and Reuse

By means of semantic-enabled and inference search features, users are well-equipped with a tool to precisely retrieve required knowledge. Besides the most common form of

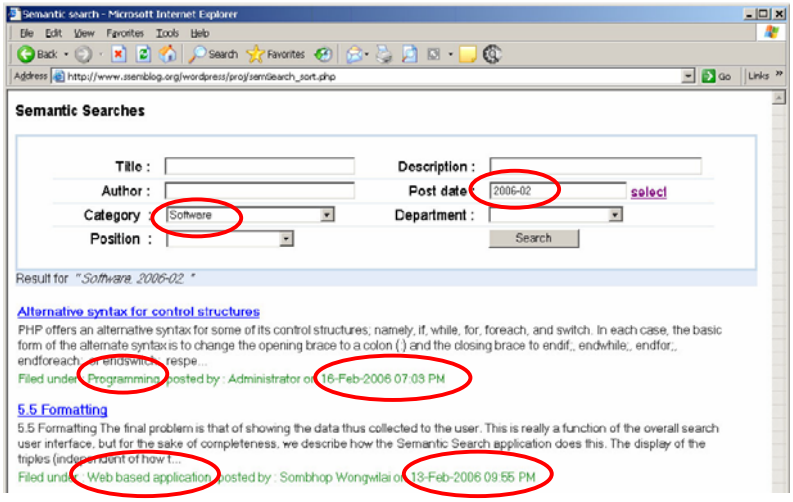

Figure 5. A sample semantic search result: a search for all blog posts created in February 2006 and categorized in Software category.

searching, which is merely text-based and usually returns many non-relevant results, the developed system supports also a semantic and intelligent search which allows combination of various ontology elements to express a more precise query. For instance:

- *To search for knowledge resources (i.e., blog posts) created in February 2006 and categorized in Software category*: Fig. 5 shows that this search will return all blog posts, which are created in the specified period, and categorized not only in the Software category, but also those in its subcategories, defined in the concept taxonomy of Fig. 3-a, such as Programming, WebBased Application, etc.
- *To find any resources in the category Hardware and created by a member working in the position of software developer*: Similar to the previous example, all blog posts returned by this search must belong to the Hardware category or any of its subcategories, defined in the concept taxonomy of Fig. 3-a, such as Desktop, NetworkDevice, etc. Moreover, the returned results must be created by those working as a SoftwareDeveloper, which includes ProjectManager, SystemAnalyst, etc. as depicted by Fig. 3-b.
- *To find knowledge resources posted by a member of IT Department*: As shown by Fig. 3-c, ITDepartment is further specialized into CustomerSupport and R-and-D-Division. Hence, this search then returns all resources posted by any members of these departments.
- *To find entries posted in 2006 and contains the words "Semantic Web" in the title.*

IV. Conclusions and Future Work

This paper has developed a Semantic Blog system and proposed its application as a tool for knowledge management, which can support users with a friendly environment to convert their tacit knowledge into codified explicit knowledge as well as to precisely retrieve required knowledge, and hence encouraging organizational members to reuse, recreate, and share in a cyclic fashion.

Future work includes an enhancement of the system by employment of efficient ontology mapping and integration techniques [11] in order to solve heterogeneity problems among semantically described data. This will allow various Semantic Blog systems using different ontologies to be easily integrated, and thus improving knowledge sharing and knowledge management processes.

In-Depth Analysis of the Quicksort's Efficiency based on the Threshold and Related Factors

R. Chaisricharoen and S. Suwatthanaphiset
School of Information Technology, Mae Fah Luang University
333 Moo 1, Thasud
Muang, Chiang Rai 57100 Thailand

***Abstract*-To increase efficiency, quicksort algorithm needs to be switched from its operation characteristic to another sorting algorithm that is more efficient than the quicksort for the small set of elements. The threshold, which is the size of a small-enough subset for swapping, is believed to be around 10 for almost 30 years. In this literature, the full factorial experiment is conducted to find out whether this magic number is obsolete or not. The factors are threshold, size of unsorted set, and performance of tested computer. The results provide strong evidences of outdated assumptions of threshold of 10 elements. In addition, there is no rule of thumb for the optimal value of threshold because it is significantly related to other factors. Furthermore, the regression model for roughly predicting the optimal threshold is estimated based on the experimental results with adjusted R^2 of 88.4%.**

I. INTRODUCTION

Since the introduction of computer systems, the sorting operation has occupied itself as a significant mechanism in various applications. For example, consider a set of numbers sorted sequentially in a computer's memory. It is usually easier to find a specified element of such a set if the numbers are maintained in sorted order. Unfortunately, there are a great number of methods that can be utilized to sort a file. The programmer must be aware of several interrelated and often conflicting efficiency considerations to make an intelligent choice about which sorting method is most appropriate to a particular problem.

In general, the complexity of the algorithm is determined by examining its O notation, which is a mathematical symbol to denote "the order of". For non-particular sorting, the complexity of provided sorting algorithms range from O(nlogn) to $O(n^2)$. Obviously, the sorting algorithms with O(nlogn) are more preferred than those of $O(n^2)$. However, there are many O(nlogn) sorting algorithms with various pros and cons. Among these algorithms, the quicksort, which was originally proposed by Hoare [1, 2] in 1962, is the excellent general-purpose sorting algorithm and has many descendants [3]. Based on the principle of divide and conquer, the quicksort provides the complexity of O(nlogn) only in average cases. Despite an occasional long execution time, quicksort is still the most favorable internal sorting method because it requires less hidden constant than other O(nlogn) sorting algorithms.

Based on its attractiveness, the efficiency of quicksort is frequently studied and improved. Usually, the improvements aim at the methods to partition the set equally [4, 5] because the appearance of unbalanced subsets can significantly deteriorate the performance of quicksort especially at the root level. Though the set is partitioned equally at every level, the quicksort still faces another fatal difficulty of inefficiency at small subset. Unfortunately, as its nature is recursive, quicksort will divide the set as long as its size is greater than one. To address this problem, Hoare suggests that the divided small subset should be sorted with other more efficient methods rather than let the quicksort handle it until the end [2]. Known of its reputation of good efficiency over small file, the insertion sort which has the complexity of $O(n^2)$ is utilized to help the quicksort handle the small subset effectively. For almost 30 years, the threshold, which is the size of a small-enough subset for swap algorithm, is believed to be around ten for best practice, which is supported by the precisely modeled formula and one-factor experiment [5]. As computer technology is rapidly growing, is this magic number proposed at almost 30 years ago still provide the optimum solutions for nowadays computing power? In addition, is there really a single threshold suitable for all sorting situations? In this literature, the full factorial experiment is conducted based on three factors; original size of unsorted set, threshold, and computer's performance. Furthermore, the estimation of the new optimal threshold for all or particulars situations is expected to be modeled if the previously defined is statistically proved obsolete.

II. STANDARD ALGORITHM

The original quicksort algorithm can be simply described using two procedure calls, *pivot* and *quicksort*, which are implemented as follows [6]:

```
procedure pivot(T[i..j]; var l)
    p ← T[i]
    k ← i; l ← j +1
    repeat k ← k +1 until T[k] > p or k ≥ j
    repeat l ← l -1 until T[l] ≤ p
    while k < l do
        swap T[k] and T[l]
        repeat k ← k +1 until T[k] > p
        repeat l ← l -1 until T[l] ≤ p
    swap T[i] and T[l]

procedure quicksort(T[i..j])
```

if $(j - i) < M$ **then** *insert*($T[i..j]$)
else
pivot($T[i..j]$,l)
quicksort($T[i..l - 1]$)
quicksort($T[l + 1..j]$)

The *pivot* procedure is for permuting the elements in array $T[i..j]$ and retures a value l such that , at the end, $i \le l \le j$, $T[k] \le p$ for all $i \le k < l$, $T[l] = p$, and $T[k] > p$ for all $l < k \le j$, where p is the initial value of $T[i]$. The *quicksort* procedure utilizes the *pivot* and determines when the size of subset is less than the threshold to switch the operation to inserting sort algorithm.

III. Design of Experiment

A. The Factors

The factors that are interesting are the threshold, size of unsorted set, and the computer's performance which is the score of the famous PCMark05 from FUTUREMARK corporation. The score is increased as the configuration of system becomes better. To aid in presentation, from now on, the threshold will be stated by "M" symbol, the size will be stated by "N" symbol and the performance of computer will be stated by "P" symbol.

B. The Response

As the quicksort algorithm has the complexity of O(nlogn), the response is the normalized coefficient defined by:

$$C_{N,M,P} = \frac{10^9 t_{N,M,P}}{N \log_2 N} \qquad (1)$$

The $t_{N,M,P}$ is overall time of quicksort algorithm for sorting a set of N elements using such M threshold on the PC with P score. For convenient, t_N is multiplied by 10^9 to prevent very small value.

C. The Design

To study on three main effects and interaction between factors, the experiment is designed to be 3-factor full factorial experiment. The test is run on each combination of factors three times (three replicates).

N factor is designed to have five levels, M factor is designed to have nine levels, and the number of different configuration of PCs is three. This yields a $5 \times 9 \times 3$ factorial design with the factor description in table I. With three replicates, there are 405 runs, which are assigned randomly.

TABLE I
FACTORS DESCRIPTION

Factor	Level value
N (10^6)	1 1.5 2 2.5 3
M	0 25 50 75 100 125 150 175 200
P	913 1538 2774

The unsorted set is a randomly assign unsigned integer array of size N based on uniform distribution to prevent the unbalance subset. Then, evaluate $t_{N,M,P}$ by the average time of three serial run and use it to calculate $C_{N,M,P}$ for one replicate.

IV. Results and Analysis

As the table is large and complex, the raw data of the experiment is not displayed. Before analyzing, data is checked for model adequacy for the normality and constant variance assumption.

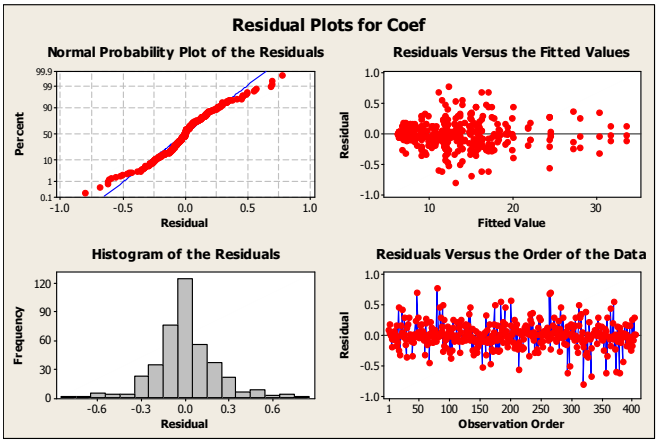

Figure 1. Residual Plots

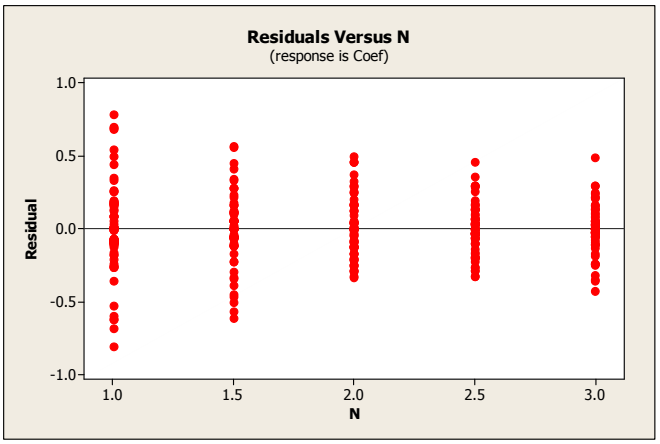

Figure 2. Residuals vs. N

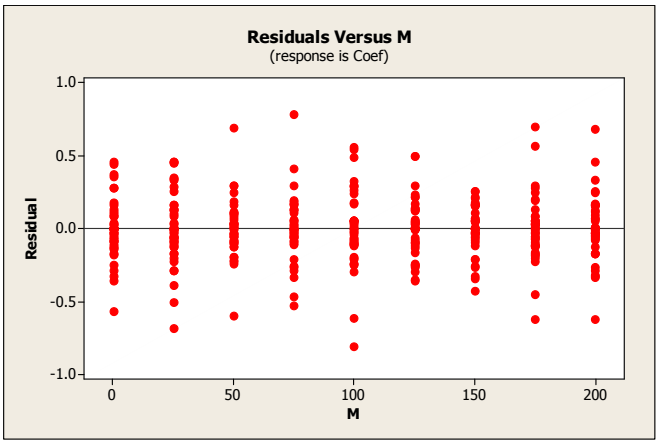

Figure 3. Residuals vs. M

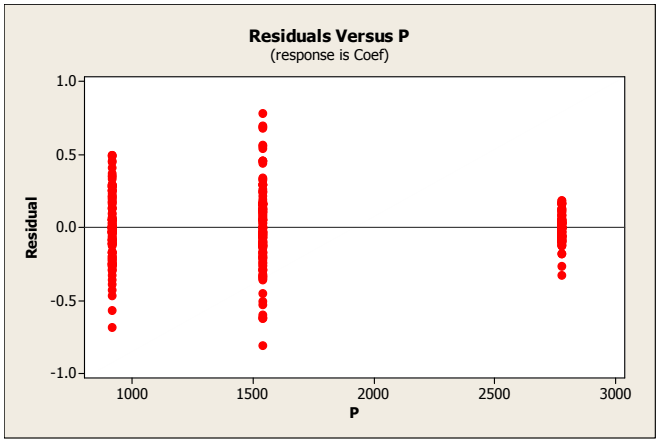

Figure 4. Residuals vs. P

From these graphs, there is no severe indication of any problems with the validity of normality and constant variance assumption.

To determine whether the factors affect the response or not, we use ANOVA tables with $\alpha = 0.05$.

Analysis of Variance for Coef, using Adjusted SS for Tests

Source	DF	Seq SS	Adj SS	Adj MS	F	P
N	4	55.81	55.81	13.95	213.06	0.000
M	8	3142.66	3142.66	392.83	5998.32	0.000
P	2	5965.65	5965.65	2982.82	45546.00	0.000
N*M	32	1458.84	1458.84	45.59	696.11	0.000
N*P	8	129.62	129.62	16.20	247.41	0.000
M*P	16	751.37	751.37	46.96	717.06	0.000
N*M*P	64	344.40	344.40	5.38	82.17	0.000
Error	270	17.68	17.68	0.07		
Total	404	11866.03				

S = 0.255911 R-Sq = 99.85% R-Sq(adj) = 99.78%

From ANOVA, there are strong indications of significant effects of N, M, and P on normalized coefficient. In addition, the interaction between N, M, and P are also significant. To analyze these effects and interaction intensely, main effects and interactions of the response are plotted separately.

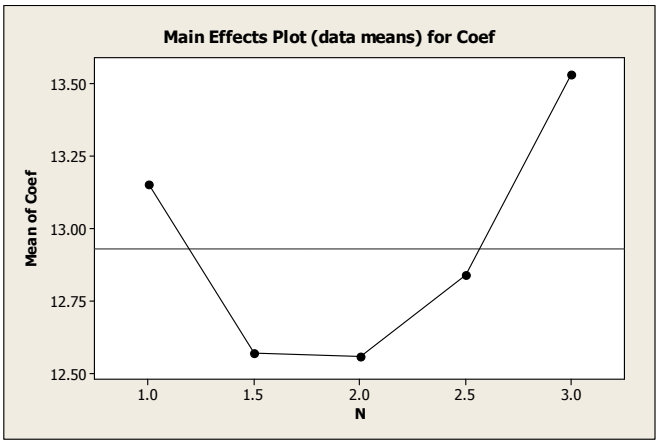

Figure 5. Main effect of N

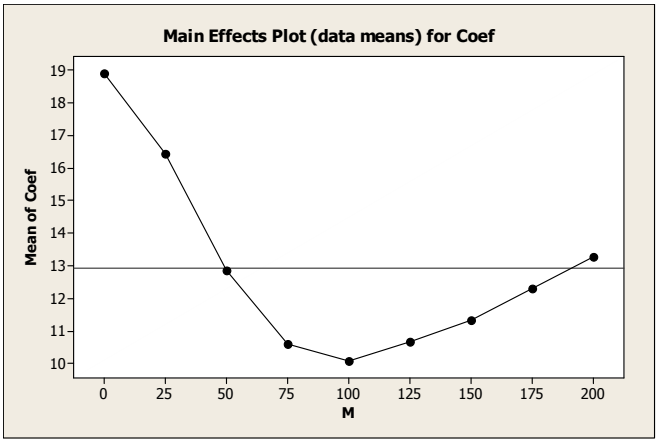

Figure 6. Main effect of M

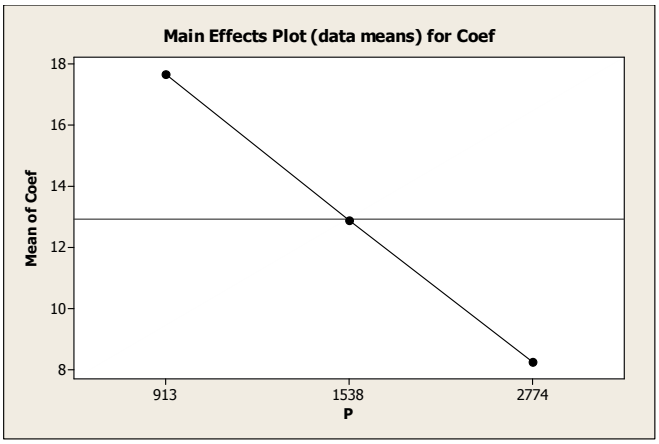

Figure 7. Main effect of P

These main effect plots show the effect of each factor on the normalized coefficient. Though the purpose is to keep it as small as possible, the conclusion of the most suitable threshold of 100 cannot be stated before the interaction plots are examined. However, these main effects plots show strong evidences that the optimal threshold will not be around 10.

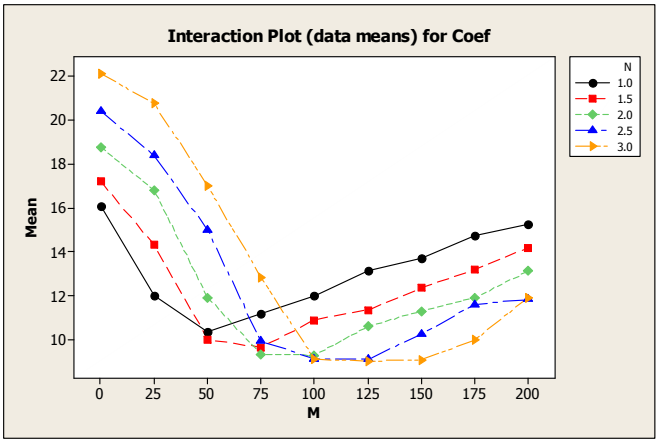

Figure 8. Interaction of N and M

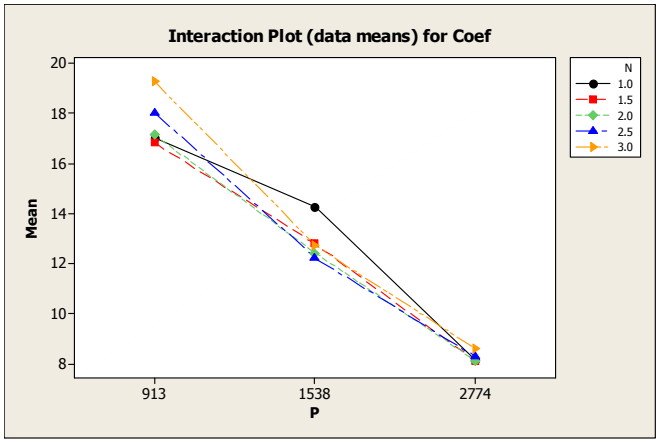

Figure 9. Interaction of N and P

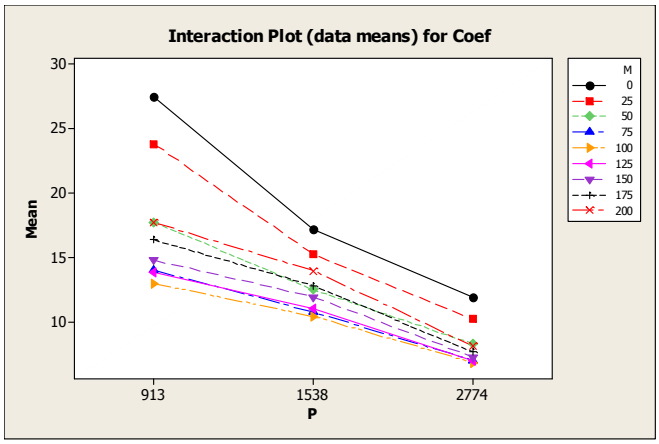

Figure 10. Interaction of M and P

Fig. 8 indicates that there is no one magic threshold that is suitable for all situations as optimal threshold tends to increase as size of unsorted set increases. Though their interactions are statistically significant, the interaction of the computer's performance with threshold and size are not to be seriously considered because the coefficient obtained at a better-performance computer is less than a lower one in all interactions.

To obtain a model for predicting the behavior of such a particular system, the regression analysis is carried out and results in (2) with adjusted R^2 of 88.4%.

$$C(N,M,P) = 22.7 + 4.73N - 0.0231M - 0.00922P - 0.0721NM - 0.00241NP - 0.000029MP + 0.000021NMP + 0.813N^2 + 0.000598M^2 + 0.000002P^2 \quad (2)$$

Substitute N and P of particular systems in (2) results in one variable formula *C(M)*. To estimate the suitable threshold for such systems, set an equation as in (3) and solve it to obtain such optimal threshold.

$$\frac{\partial C(M)}{\partial M} = 0 \quad (3)$$

V. Conclusion

The conducted experiment shows strong evidences, which lead to the proving that the assumption of one single threshold at around 10 is expired. As there is, no magic number suited for all situations, the threshold can be carefully estimated through the utilization of regression model. Nevertheless, as the size of unsorted set is increase, the optimal threshold is likely to be increase as well.

Acknowledgment

The authors would like to convey special thank to the FUTUREMARK corp. whom kindly provides the free evaluation copy of PCMark05.
