ECTI-CON 2007

Proceedings of the 2007 Electrical Engineering/Electronics, Computer, Telecommunications and Information Technology (ECTI) International Conference

Wednesday May 9 – Saturday May 12, 2007

Mae Fah Luang University, Chiang Rai, Thailand

Organized by

Electrical Engineering/Electronics, Computer, Telecommunications and Information Technology (ECTI) Association

ECTI-CON 2007

Proceedings of the 2007 Electrical Engineering/Electronics, Computer, Telecommunications and Information Technology (ECTI) International Conference

Wednesday, May 9 – Saturday May 12, 2007

Mae Fah Luang University, Chiang Rai, Thailand

Organized by

Electrical Engineering/Electronics, Computer, Telecommunications and Information Technology (ECTI) Association

Steering Committee
Sawasd Tantaratana, Chair (07)
Pansak Siriruchatapong (07)
Wanlop Surakampontorn (07)
Sinchai Kamolphiwong (07)
Weerapant Musigasarn (07)
Somsak Choomchuay (07)
Jun-ichi Takada (08)
Kazushi Nakano (08)
Saykhong Saynasine (08)
Athikom Roeksabutr (08)
Prabhas Chongsatitwattana (08)
Monai Krairiksh (08) Secretary

Technical Advisory Committee
Akinori Nishihara, (TIT, Japan)
Hara Shinji (U. of Tokyo, Japan)
Luigi Benedicenti, (U. of Regina, Canada)
Rolf H. Jansen (Aachen U., Germany)
Narong Yoothanom (SPU)

Local Advisory Committee
Vanchai Sirichana (MFLU)
Ted Tesprateep (MFLU)

General Chair
Wanlop Surakampontorn (KMITL)

Vice Chairs
Kosin Chamnongthai (KMUTT)
Jitkasem Ngamnil (MUT)
Apirat Siritaratiwai (KKU)

Technical Program Chair
Chaiwut Chat-uthai (KMITL)

Technical Program Co-Chairs
Tiparatana Wongcharoen (BU)
Songphol Kanjanachuchai (CU)
Itsda Boonyaroonate (KMUTT)
Vara Varavithya (KMITNB)
Apichan Kanjanavapastit (MUT)
Keattisak Sripimanwat (NECTEC)

Special Session Chairs
Chuwong Phongcharoenpanich (KMITL)
Raungrong Suleesathira (KMUTT)

Local Arrangement Chairs
Preecha Upayokin (MFLU)
Thongchai Yooyativong (MFLU)
Damrong Amorndechaphon (NU-PYO)
Werachate Khan-ngenn (KMITL)

Publication Chairs
Denchai Worasawate (KU)
Teratam Bunyagul (KMITNB)
Daranee Hormdee (KKU)

Publicity Chairs
Danai Torrungrueng (ASUT)
Phongsak Keeratiwintakorn (KMITNB)

Exhibition Chairs
Chalie Charoenlarpnopparut (SIIT)
Wanida Kan-argart (KKU)
Chiranut Sa-ngiamsak (KKU)

Finance Chairs
Banlue Srisuchinwong (SIIT)
Rujipan Sampanna (BU)

General Secretaries
Prayoot Akkaraekthalin (KMITNB)
Vutipong Areekul (KU)

Message from Chair of Steering Comittee

The first two ECTI-CON's were held in Pattaya, Cholburi. The Steering Committee then had a policy to reach out to researchers in all part s of Thailand. Consequently, the third ECTI-CON was held in Ubon Ratchatani last year. This year the fourth ECTI-CON is scheduled for Chiang Rai on the beautiful campus of Mae Fah Luang University.

Chiang Rai is the northernmost province of Thailand, which is located within the renowned Golden Triangle area where Myanmar, Laos, and Thailand converge, also known as the gateway to Myanmar, Laos, and Southern China. Chiang Rai has a lot of attractions including magnificent mountain sceneries, historic sites, and ethnic villages, as well as several hill tribes who maintain fascinating lifestyles. These are some reasons for choosing Chiang Rai as the venue of ECTI-CON this year. However, the main reason is to initiate a research gateway to this region and motivate researchers in this area to become more active in future ECTI-CON's.

On behalf of the Steering Committee of ECTI-CON, I would like to express my sincere gratitude to all of ECTI-CON 2007 organizing committee members and staff for their excellent work and to the authors from around the world for sharing their results by their presentations and discussions. It is hoped that the participants will enjoy not only the technical aspects of the conference, but also the banquet, food, and culture of northern Thailand. Next year, ECTI-CON will move its venue to Krabi, a beautiful province in the southern part of Thailand. I look forward to seeing all of you at ECTI-CON 2007 and again at ECTI-CON 2008 next year.

Sawasd Tantaratana
ECTI-CON 2007 Steering Committee Chair

Message from General Chair

On behave of the Organizing Committee; it is my great pleasure to cordially welcome all the participants to the 2007 Electrical/Electronics, Computer, Telecommunications, and Information Technology Conference (ECTI-CON 2007). This year the conference is the fourth annual conference in the series and is held in the northern part of Thailand, at Mae Fah Luang University, Chiang Rai province, on May 9-12, 2007. As one of the major activities of the ECTI Association, the ECTI-CON international conference aims annually to provide as a forum to bring together researchers to discuss and exchange of original works, new ideas and new recent advances in the areas.

The success of this conference is due to the sponsor from the National Electronics and Computer Technology Center (NECTEC) of Thailand, and the Western Digital Thailand. The technical collaborations are provided by the IEEE MTT/AP/ED Thailand Chapter, the IEEE CAS Thailand Chapter, the IEEE ComSoc Thailand Chapter, the IEEE LEOS Thailand Chapter and the IEEE Thailand Section. I also would like to express my sincere appreciation for the effort, hard work and significant contributions by the Organizing Committee members, especially the Vice Chair: Assoc. Prof. Dr. Kosin Chamnongthai, the General Secretaries: Assoc. Prof. Dr. Prayoot Akkaraekthalin and Assoc. Prof. Dr. Vuthipong Areekul, the Technical Program Chair: Assoc Prof. Dr. Chaiwut Chat-uthai. The valuable contributions from the authors that submitted technical papers for review, the technical program committee members, the speakers, and the session chairs and the attendees are also gratefully acknowledged.

As you can notice, the ECTI Association tends to organize the ECTI-CON conference at a new place each year. This means that some inconveniences may occur during the arranging of the conference. The Organizing Committee Members will do our best to solve and to make sure that you participate in the conference with pleasure. Finally, we do hope that you will find a good opportunity to meet, to exchange ideas and to make research contacts and collaboration, which are the objectives of the conference too.

Wanlop Surakampontorn
ECTI-CON 2007 General Chairman
President of the ECTI Association

Message from Technical Program Chair

We cordially welcome you to the 4th annual international conference ECTI-CON 2007 held during May 9-12, 2007 in Chiang Rai, farthest north province and intersection of three reigns (Thailand, Myanmar and Laos).

Following the successful conferences of ECTI-CON 2004, 2005 and 2006, ECTI-CON 2007 continuously aims to provide a forum for academic and industrial researchers in the area of Electrical Engineering, Electronics, Computer, Telecommunications and Information Technology to discuss and exchange up-to-date information. The conference received overwhelming response which is apparent from the over 400 papers submitted by researchers around the world. After a careful and rigorous review process, 318 quality papers from 12 countries were accepted. For the reason of topic diversity, this conference provides the presentations of regular papers into 66 sessions of ten parallel rooms. In addition, the invited papers of interesting issues will be also presented in 4 special sessions.

For the ECTI-CON 2007 opening ceremony, we honorably invite Prof. Dr. Akira Taguchi from the Musashi Institute of Technology, Japan, Prof. Dr. Shuzhi Sam Ge from the National University of Singapore, and Dr. Pansak Siriruchatapong, the director of National Electronics and Computer Technology Center (NECTEC), Thailand to be the keynote speakers. At the present, Prof. Akira Taguchi serves the chair of Nonlinear Signal and Image Processing Board (IEEE, EURASIP). Professor Shuzhi Sam Ge is the head of Social Robotics Lab, Interactive and Digital Media Institute, and the director of Edutainment Robotics Lab, Department of Electrical and Computer Engineering. Subsequently at conference banquet in the evening, the best paper awards which were judged by the executive referees will be presented to the authors.

The Organizing Committee and colleagues who have been working behind-the-scenes deserve special mention. In particular, I would like to single out the Technical Program Co-Chairs and Publicity Chairs for their hard work and sincerity. Finally, I would like to say thanks to all honorable keynote speakers, authors, reviewers, session chairpersons, participants and other people for their support, and wish all of you a successful and stimulating meeting and a pleasant stay in Mae Fah Luang University, home to the culture of Lanna.

Chaiwut Chat-uthai
ECTI-CON 2007 Technical Program Chair

List of Reviewers

We would like to express special thanks to the following individual and anonymous reviewers for their effort in the review process of ECTI-CON 2007:

Symposium Schedule at a Glance

Wednesday, May 9, 2007

14:30-17:00	Registration at Wangcome Hotel
18:00-22:00	Welcome Party at Wangcome Hotel

Thursday, May 10, 2007

07:30-08:30	Registration at Mae Fah Luang University
08:30-09:00	Open Ceremony
09:00-09:40	Keynote Speech: "*Where Thailand should go for ECTI Research in the next Decade: NECTEC Strategy*" by Dr. Pansak Siriruchatapong, National Electronics and Computer Technology Center (NECTEC), Thailand
09:40-10:20	Keynote Speech: "*Restoration of the Lost Information by Sampling and Quantization"* by Dr. Akira Taguchi, Musashi Institute of Technology, Japan
10:20-10:50	Coffee Break
10:50-12:10	Technical Sessions
12:10-13:00	Lunch Break
13:00-15:00	Technical Sessions
15:00-15:20	Coffee Break
15:20-17:00	Technical Sessions
17:15-17:55	Keynote Speech: "Social Robotics: Integrating Advances in Engineering and Computer Science" by Dr. Shuzhi Sam Ge, National University of Singapore, Singapore
18:30-22:00	Conference Banquet at Mae Fah Luang University

Friday, May 11, 2007

08:30-10:10	Technical Sessions
10:10-10:30	Coffee Break
10:30-12:10	Technical Sessions
12:10-13:00	Lunch Break
13:00-15:00	Technical Sessions
15:00-15:20	Coffee Break
15:20-17:00	Technical Sessions
17:00-18:00	Closing Ceremony

Where Thailand should go for ECTI Research in the next Decade: NECTEC Strategy

Dr. Pansak Siriruchatapong

Predicting and forecasting the technology and its impact is a dangerous business. But how the new technologies will emerge is quite clear. For whichever particular technology that can create impact in this near future, its evolution will most likely come from the converging of multiple technologies.

In the next decade, global issues will emphasize on health, energy, and environment. Technologies that will address them must be multidisciplinary and integrated. In the past decade, IT related technologies were major players on the emerging technology fields. IT had made impacts to humanity, putting us on the information explosion age. While IT reach-ability and impacts vary from region to region, undeniably, they are profound. Coming of age, IT will become a driver for convergence of others.

Among many, NBIC (Nano-Bio-Info-Cogno) has been often mentioned and expected to form a powerful convergence. How will it impact the world? Where will Thailand stand on this new land? Will it create new opportunities for us? Will it help solve some of our problems? What are the resources and infrastructure and strategies that will make us ready? These will be partially addressed.

NECTEC, as a member of NSTDA and a national research center specialized in Electronics, Computers, Telecommunication and IT, must prepare for this coming trend. We reformed our organization, and founded 3 new platform technology programs focusing in Sensor, Securities, and Knowledge Engineering. Our strategy will strongly emphasize working with alliances; create common research infrastructure, and sharing visions and intellects to put Thailand on world technology map.

Restoration of the Lost Information by Sampling and Quantization

Akira Taguchi

Department of Biomedical Engineering,
Musashi Institute of Technology
1-28-1 Tamazutsumi, Setagaya-ku, Tokyo 158-8557, Japan

I. INTRODUCTION

Digital image/video signals are obtained by sampling and quantization of analog signals. It is necessary for sampling to restrict its bandwidth. The resolution of amplitude of signals is restricted by quantization. The signal information is restricted by the Analog to Digital conversion [1]. In this paper, we introduce restoration of the lost information by sampling and quantization.

The restoration problem of the lost information by sampling is equal to the enlargement method of digital image. It is necessary to predict or estimate the unknown higher-frequency components that generate in the enlargement process. In general, enlargement of the digital image is also carried out by the interpolation. However, it is impossible for these methods to predict the unknown high-frequency components.

We have proposed two kinds of image enlargement methods with predicting the unknown high-frequency components. First method is based on the Laplacian pyramid representation [2]-[4],[6],[7]. In this method, we gave the procedures which, can be estimated the unknown high resolution Laplacian image of the arbitrary size. Another enlargement method is the interpolation with warping of the coordinate point and biasing of signal amplitude [8]. We introduce two methods in this paper.

The resolution of amplitude of signals corresponds to the bit-length of signals. The bit-length expansion technique is necessity for the high-quality display such as the liquid crystal display (LCD) and the plasma display. Moreover, bit-length expansion is also necessary for low-bit length images, which are observed the pseudo-contour. We have proposed a bit-length expansion technique from M gray levels to N=(3(M-1)+1) gray levels. This bit-length expansion method is also introduced in this paper.

II. THE RESTORATION OF THE LOST INFORMATION BY SAMPLING (1) - Image Enlargement Method based on Laplacian Pyramid Representation -

II-1. The Laplacian Pyramid Representation[9]

The Gaussian and Laplacian pyramid representations are described in [9]. The Gaussian pyramid consists of low-frequency components image sequences $\{G_0, G_1,..., G_N\}$. G_{n+1} is derived by

$$\overline{G}_{n+1} = W * G_n \tag{1}$$

$$G_{n+1} = DS(\overline{G}_{n+1}) \tag{2}$$

where $*$ shows the convolution operator. W is the Gaussian filter for image compression and $DS(\bullet)$ denotes the down sampling operation.

The Laplacian image L_n, which is consisted of high-frequency components, is calculated as

$$L_n = G_n - EXPAND(G_{n+1}) \tag{3}$$

$$EXPAND(G_{n+1}) = 4 \times (W * G^0{}_{n+1}) \tag{4}$$

$G^0{}_{n+1}$ is the image obtained by interpolating 0s (up-sampling) into G_{n+1}. The size is the same as G_n. The width of G_{n+1} is twice as G_n.

II-2. The Arbitrary Scale Enlargement Method Based on the Laplacian Pyramid Representation

We show an example of the Laplacian pyramid by using the one dimension step signal G_0 as Fig.1. From Fig.1, a position on the edge of the step signal is observed as ZCs in the same position in Laplacian component of each layer. However, the slope of the low layer Laplacian component in the neighborhood of ZCs is steeper than that of the high layer. Therefore, we can estimate the low layer (high resolution) Laplacian component L_n by making the slope near the ZCs of the high layer (low resolution) Laplacian component steeper. Thus, an unknown high-resolution Laplacian signal L_{-1} can be estimated by using the low resolution Laplacian signal L_0. Then, an unknown high-resolution signal G_{-1} is estimated as

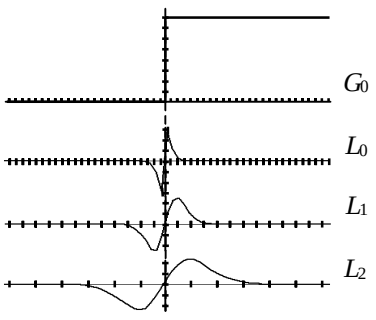

Fig.1 Laplacian pyramid of a step signal.

$$G_{-1} = L_{-1} + EXPAND(G_0) \tag{5}$$

In order to realize the arbitrary scale enlargement, we generalize the relation of the Eq.(5) as

$$G_r = L_r + (EXPAND)_r(G_0) \qquad (r < 0) \tag{6}$$

where G_r and L_r are non-integer layer of the Gaussian and Laplacian components respectively. The width of G_r image is the 2^{-r} times size of G_0 image.

II-3. The Arbitrary Scale Enlargement Method

We explain the arbitrary scale enlargement method according to the idea shown in II-2.

First, we denote how to calculate $(EXPAND)_r(G_0)$ (= $\tilde{G}_r$) of the Eq.(6). The $\tilde{G}_r$ can get from the interpolation of the Gaussian function $W(x)$.

$$W(x) = \frac{1}{2\sqrt{\rho\pi}} e^{-\frac{x^2}{\rho}} \qquad (\rho = 16/9\pi) \tag{7}$$

Then, the signal value $\tilde{g}_r(j)$ (j=1, 2, 3,..., ($M\times 2^{-r}$)) of the $\tilde{G}_r$ can be calculated from the signal value $g_0(i)$ (i=1, 2, 3,..., M) of the G_0 by using the Eqs.(8)~(10).

$$\tilde{g}_r(j) = \sum_{n=-2}^{2} W_r(n) \cdot g_0\left(\mathrm{int}\left(\frac{j}{2^{-r}} \right) + n \right) \tag{8}$$

$$W_r(n) = \frac{3}{8} e^{-\frac{9\pi}{16}(\Delta k + n)^2} \tag{9}$$

$$\Delta k = \mathrm{int}\left(\frac{j}{2^{-r}} \right) - \left(\frac{j}{2^{-r}} \right) \tag{10}$$

Next, we extend Greenspan's method to the arbitrary scale enlargement method.

(Step 1)

$(EXPAND)_r(L_0)$ (= $\tilde{L}_r$) is calculated from the low resolution Laplacian component L_0 by using the Gaussian interpolation $W_r(n)$. L_0 is calculated by Eqs.(1)~(3).

(Step 2)

$\bar{L}_r(j)$ is given by

$$\bar{l}_r(j) = \begin{cases} T & if \;\; T \le \alpha \tilde{l}_r(j) \\ \alpha\, \tilde{l}_r(j) & if \;\; -T < \tilde{l}_r(j) < T \\ -T & if \;\; \alpha \tilde{l}_r(j) \le -T \end{cases} \tag{11}$$

where T is the threshold and α is a constant which must be pre-determined.

(Step3)

The estimated high resolution Laplacian $\hat{L}_r$ is created by using the $\bar{L}_r$ as follows

$$\hat{L}_r = \bar{L}_r - W_r * \bar{L}_r \tag{12}$$

The estimated $\hat{L}_r$ added to the expanded version of G_0 makes the G_r (see in Eq.(6)).

II-4. Decision of the Parameters

It is necessary to decide the suitable parameters T and α. In order to decide two parameters, we use five images with 256×256 pixels and 8bits. We assume the size of 256×256 as G_0 and the scaling down image corresponding to the enlargement rate (S=1/2^{-r} times (r < 0)) as G_{-r}. The optimal parameters are defined as parameters, which are given the minimum mean square error (MSE) between the G_0 image and the estimated $\hat{G}_0$ image from the G_{-r} image. G_{-r} image are obtained by Gaussian filtering and down sampling process.

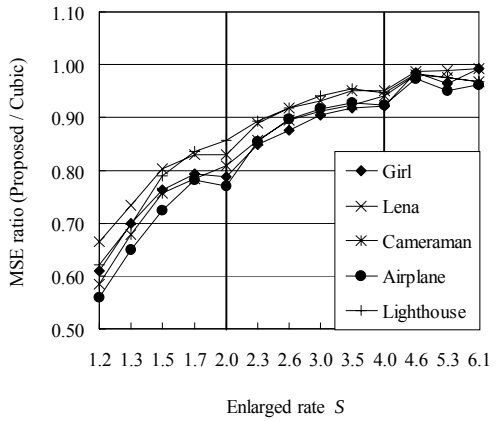

Fig. 2 The decision of scale range.

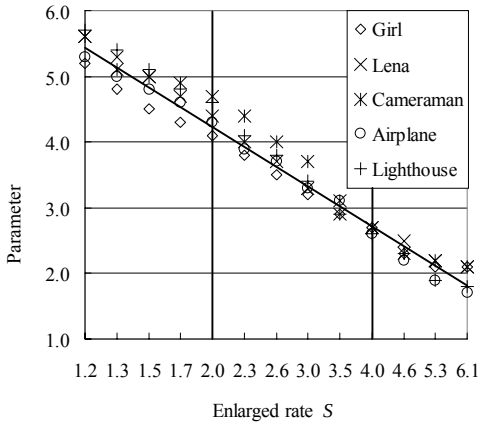

Fig. 3 The suitable α of seven images.

First, we compare our method to the Cubic interpolation (see in Fig. 2). From Fig.2, the proposed method is superior to the Cubic interpolation, not more than 6 times enlarging.

Next, we decided threshold T and parameter α. From Fig.1, the amplitude of the Laplacian component of all layers are almost same one another. The thresholding parameter T is decided as 45 by the experimental results. On the other hand, the parameter α is important to make steeper the slope near the neighborhood of ZCs. The relations between α and the enlargement rate S for five images were shown in Fig.3. Thus, we can derive the relation between α and the enlargement rate S as

$$\alpha = -0.714S + 5.833 \qquad (1 < S \le 6) \tag{13}$$

We compare the proposed arbitrary scale enlargement method to the several methods as follows.

(a) Proposed: The proposed method
(b) Cubic: Cubic interpolation
(c) Hybrid: Hybrid method[7]+Scaling down with the Gaussian filter
(d) Greenspan: Greenspan method[4]+Scaling down with the Gaussian filter

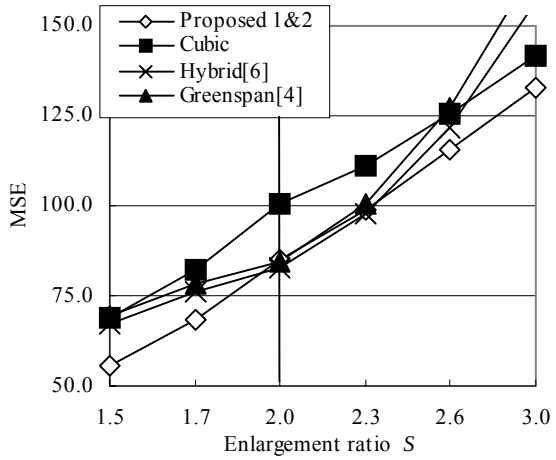

Fig.4 The performance of the proposed method (Lena).

We compare with the five methods concretely by using "Lena". The proposed method is equal to the "Hybrid" and the "Greenspan" for twice enlarging, but that is excellent in all other enlargement rate.

III. THE RESTORATION OF THE LOST INFORMATION BY SAMPLING (2)
- Digital Image Interpolation with Warping of Coordinate Point and Biasing of Signal Amplitude -

III-1. Interpolation with warping of signal amplitude

We present the warping method in order to create the peaks, it is impossible for the conventional method. We consider the one-dimensional (1-D) case. In the case of two-dimensional image we use one-dimensional method by sequential row-wise and column-wise.

Figure 5 shows the concept of the warping technique for signal amplitude, example for the twice size enlarging. The bilinear interpolation result shows the dashed line in Fig.1. When the peak exists between x_k and x_{k+1}, the bilinear interpolation result is smaller than the ideal result. In order to create the peaks, we add the small value to the result of bilinear interpolation.

Let $f(x_k)$ be the value at point x_k. The interpolated point x is located between x_k and x_{k+1}. The distance between x and x_k or x_{k+1} is given by $s = x - x_k$ or $1 - s = x_{k+1} - x$ ($0 \le s \le 1$). The bilinear interpolation result is calculated by

$$\hat{f}(x) = (1-s)\cdot f(x_k) + s \cdot f(x_{k+1}). \tag{14}$$

When twice size enlarging, $s = 0.5$ because x is the center of x_k and x_{k+1}.

It is necessary for creating the peaks to increase or decrease of the value of the result of bilinear interpolation. Let $\bar{f}(x)$ be the result of the proposed interpolation with warping the amplitude as

$$\bar{f}(x) = \hat{f}(x) + l \cdot B. \tag{15}$$

where l is constant and B is defined by

$$B = \frac{C}{2} + \frac{C}{2}\cdot(A-1) \times \mathrm{sgn}\left[\{f(x_{k+1}) - f(x_{k-1})\} \times \{f(x_{k+2}) - f(x_k)\}\right] \tag{16}$$

$$A = \frac{\left|f(x_{k+1}) - f(x_{k-1})\right| - \left|f(x_{k+2}) - f(x_k)\right|}{L-1} \tag{17}$$

$$C = \mathrm{sgn}\left[f(x_k) - f(x_{k-1})\right]\cdot|C| \tag{18}$$

$$|C| = \min\left[s\cdot\left|f(x_k) - f(x_{k-1})\right|, (1-s)\cdot\left|f(x_{k+2}) - f(x_{k+1})\right|\right] \tag{19}$$

where $L = 256$ for 8bits luminance images, $\mathrm{sgn}[\bullet]$ and $\min[\bullet]$ are the sign function and the minimum operation, respectively.

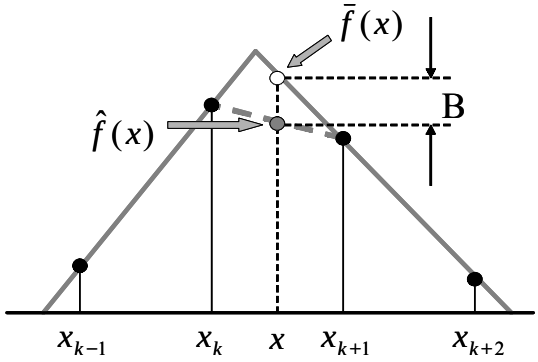

Fig.5 Interpolation with warping of signal amplitude

III-2. Interpolation with warping of coordinate point

In this section, first we explain about the warping method of. Then, we combine the method of section III-1 and the warping method.

In the warping method of [5], s' is used in (14) in place of s. s' is defined by

$$s' = s - kAs(s-1) \tag{20}$$

where k is the parameter which controls the intensity of the warping. "A" is given by Eq.(17). $A = 0$ indicates symmetry. Positive value indicates that the edge is more homogeneous on the right side (see Fig.6), and the pixel to be interpolated belongs to the right objects. Hence pixels on the same side should affect more strongly the interpolated value: accordingly, it should be $s' > s$ if

$A > 0$. The opposite holds if $A < 0$.

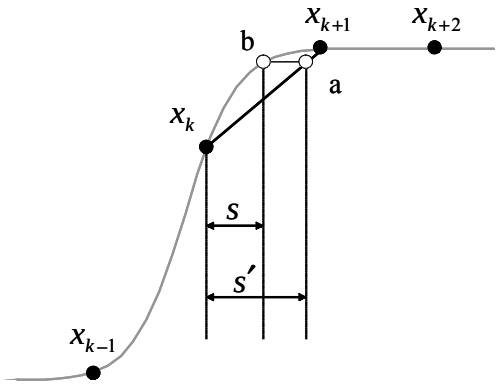

Fig.6 Interpolation with warping of coordinate point

III-3. Interpolation with warping and biasing

We would like to combine the warping method and the biasing method. This procedure is very simple. First, we calculate the warped coordinate points by using Eq.(20). Next, we calculated the biasing of signal amplitude after replacing s with s' in Eqs (16)-(19).

Table 1 Comparing the performance of each methods

(a) Two times enlargement

MSE	Bilinear	Cubic	CW [5]	Proposed (opt.)	Proposed (fix.)
Lena	84.2	73.8	70.7	68.1	68.7
Cameraman	199.6	175.2	168.1	162.9	163.2
Boat	78.7	66.9	62.4	61.4	61.6
Lighthouse	296.5	271.8	268.6	258.9	260.1
Girl	36.3	29.5	30.6	28.0	28.1
Text	173.1	144.0	136.4	129.6	130.9
Airplane	140.7	119.1	115.7	109.3	109.4

(b) Four times enlargement

MSE	Bilinear	Cubic	CW [5]	Proposed (opt.)	Proposed (fix.)
Lena	197.9	178.3	176.7	170.9	171.8
Cameraman	455.1	418.5	410.9	405.2	405.2
Boat	226.9	198.4	205.7	189.8	191.4
Lighthouse	553.5	522.3	516.5	509.8	510.5
Girl	112.7	98.0	100.8	96.5	96.9
Text	496.6	423.5	412.3	397.7	399.8
Airplane	378.8	343.7	345.0	337.2	337.6

III-4. Decision of Parameters

It is necessary to decide the parameter l of Eq.(15) and k of Eq. (20). We derive two parameters based on the mean square error (MSE). We use five images same as Section II. The size of original images is 256×256, we get the $1/2$ size images by low-pass filtering and down sampling, also get the $1/4$ size images. We expand these images to the original size, and calculate MSEs between original image and expanded image for various k or l. We can derive that $k = 2 \sim 4$ and $l = 0.3 \sim 0.7$ are suitable for all test images. Consequently, we can decide $k = 3.0$ and $l = 0.5$ based on MSE. These values of two parameters are robust for a lot of images, since these values are center of suitable regions.

We add new images two images for simulation. Table 1 shows MSEs of the proposed method of $k = 3.0$ and $l = 0.5$ (Proposed(fix.)), the proposed method of optimal parameters (Proposed(opt.)), the method of [5] (CW), the bilinear interpolation (Bilinear) and the cubic interpolation (Cubic). Proposed(fix.) and Proposed(opt.) are same performance on MSE for scaling 2 times or 4 times. This result indicates that the Proposed(fix.) is more effecting than CW and Cubic.

IV. THE RESTORATION OF THE LOST INFORMATION BY QUANTIZATION

IV-1. Procedures of our method

Bit-length of digital images is decided by the quantization. Thus, the resolution of signal amplitude is decided by the quantization. The bit-length expansion technique is necessity for the high-quality display such as the liquid crystal display (LCD) and the plasma display. Moreover, the bit-length expansion technique is also necessary for low-bit length images, which are observed the pseudo-contour. However, strictly speaking, it is impossible to expansion of the bit-length for digital signal.

We have proposed a bit-length expansion method from M gray levels to N=(3(M-1)+1) gray levels. This operation means that two gray-levels are introduced between existing levels. The bit-length expansion method results in the estimation problem of an error image between an M gray level's image and an N gray level's image. The error image is three values pattern image. If the difference between the existing level and the inserted new level is defined as Δ, the N level image is obtained by adding +Δ, 0 or -Δ to the M level image.

The procedures of the three values' error image as follow:

(Step 1)

In order to get the pseudo analog image, M gray level's image is processed by plural ε-filters with various window lengths.

(Step 2)

The pseudo analog image is quantized in N levels and M levels. The difference of two images is the estimated error. If the width of the filter window is small, the error of +Δ and -Δ cannot be calculated in a smooth change part of the background. On the other hand, it is necessary to preserve the signal edge/detail, we should choose the estimated error with small window length at edge/detail region. Thus, we combine the error signals, which are estimated by various window lengths.

(Step 3)

The estimated error is larger than +Δ, we change this value into +Δ. The estimated error is smaller than –Δ, we change this value into –Δ. As a result, the three value error

images are obtained. We add this error image to the M gray level's image.

The block diagram of our method is shown in Fig.7

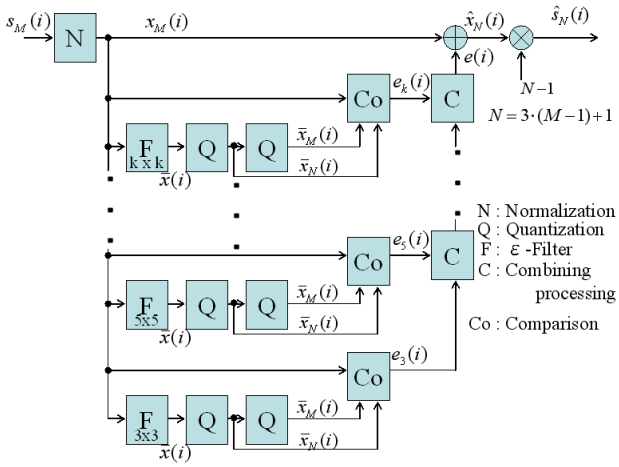

Fig.7 Block diagram of the proposed method

IV-1. Examples

We show a simulation result of our method.

Figure 8(a) shows a Pepper, which is a color image with 4 bit for each component. We make marks in Fig.8(a). We can observe pseudo-contour at the making positions. We apply our method to this image and get the result of Fig.8(b). The pseudo-contour is removed by our method.

V. CONCLUSIONS

In this paper, we introduce restoration methods of the lost information by the analog to digital conversion (ADC). The ADC consists two operations. One is the sampling the other is the quantization.

We explain the enlarging method based on Laplacian pyramid and Warping & Biasing for the restoration of lost information by sampling.

Furthermore, a bit-length expansion method also introduced. We show that the method can remove pseudo-contours of low bit images.

***Abstract*— With the rapid advancement of technology, robots could now be easily equipped with the state of art computing, electronics and communications technologies, with the potential to act as intelligent companions and with important applications in the education, entertainment, games and healthcare industries. The integration of all these technologies is the first step to realizing social robots – robots which will walk amongst humans, playing out their assigned roles whilst interacting with humans in a humanistic way. Social robots can have definite roles and tasks, such as educators, cleaners or guides, with a profound impact on human daily life. This advanced class of robots, just as we humans do, is made up of a complex array of interconnected modules – electronics (inner physical workings), sensing, planning and cognition, and finally, intelligence, interaction and communications. This paper provides an overview of each of these individual aspects, and how advanced technology in these areas can be integrated to form a social robot that can meld seamlessly into the human society.**

***Index Terms*— Social Robots, Machine Intelligence, Human-Robot Interaction, Ubiquitous Robotics**

I. Introduction

Humans are highly adaptive creatures, capable of perceiving the social context of their environment and based on complex sensing and reasoning abilities, adapt and interact with other like agents in their surroundings. Even in cases where a human is transplanted into an entirely different culture where the social norms differ completely from what he/she is used to, adaptation and cultural integration can occur in a short time span. In a world where we envision robots to be an integral part of the social landscape and a competent player amongst humans, we would expect robots to do the same. It is crucial that social robots understand, respond appropriately, and even adapt their behavior based on the cues from human partners and their own understanding of the social environment they are situated within.

A robot that is capable of such advanced functions and complex participation in the workings of the human society term is said to be "sociable" [1]. The ability of a "sociable" robot is to participate pro-actively with the human players in its surroundings, and to meet the humans' expectations of how an able player within their social environment should act. It basically requires the robot to possess an internal understanding and adaptable social model of human society.

There are several core, indispensable modules in the making of a social robot, where the key technical contributions from the fields of electrical/electronic engineering and the computer sciences play crucial roles in shaping its capabilities. Electronic components are getting smaller and smaller, enabling miniaturization of complex circuitry and lower power consumption in robots, and vastly increasing the mobility of robots. Coupled with sophisticated sensing, planning and interaction mechanisms, robots are able to perceive the environment and the humans, direct/focus their attention and gather pertinent information, as well as interact with other agents (humans and other robots) via an understanding of hand gestures and other behavioral cues. Artificial intelligence modules, utilizing the diverse amount of information gathered, as well as interacting with other behavioral modules, allows the social robot to make informed decisions and act in a decidedly 'natural' way. The effective integration of these advanced multi-disciplinary technologies is the main goal at the Edutainment Robotics Laboratory (ERL), Department of Electrical & Computer Engineering, and at the Social Robotics Laboratory (SRL), Interactive Digital Media Institute (IDMI), National University of Singapore (NUS).

These thrusts enable the development of human-centric social robots that adapt dynamically to human intentions, emotions, and needs, and bridge the gap between the three spaces: human space, physical space and information space. The incursion of robots into our everyday lives is unavoidable, and in most cases becoming indispensable. They are not only simple aids and replacements for human activities (vacuuming and cleaning), robots are used in many cases to enrich our lives, for adults and children alike.

Successful research and development in the area of social robots has important implications in several aspects of human society. Social robots, equipped with high level artificial intelligence and adaptive behaviors, can act as capable companions to users from diverse age groups, e.g., as babysitters, personal assistants, and even provide companionship to combat loneliness. In addition to fulfilling the role of an able companion, intelligent social robots can also act as a conduit for bridging the distance between users, where emotions and gestures can be transmitted and manifested on the social robots on either

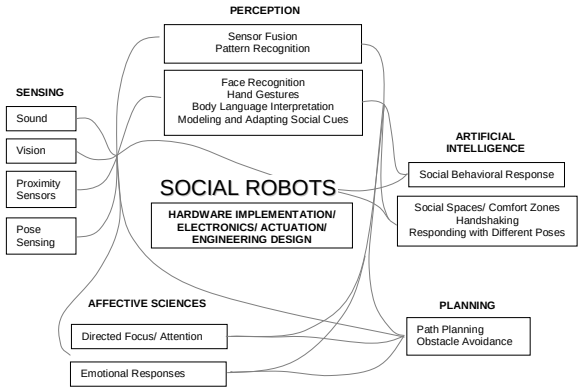

Fig. 1. Overview of the core technologies involved in Social Robotics.

end with humanistic robots serving as realistic personifications of loved ones.

Currently available 'social robots' are clearly inadequate in terms of interactivity, intelligence, mobility and social skills to successfully fulfil the tasks highlighted above. There have been many recent forays by many into the area of social robotics with some commercial examples including the Sony AIBO and QRIO, Hasbro Furby, NEC's PaPeRo, Ugobe's Pleo and WowWee's Robosapien, Robopet, Roboraptor and Chimpanzee, and iRobot's Roomba and Scooba. In addition to social robots developed in the commercial world, many research institutes and universities have been carrying out extensive research and development in the area of social robotics. Examples of sociable robots developed in research institutes and universities include museum guide robots Sage [2], RHINO [3] and Jinny [4], Massachusetts Institute of Technology (MIT) Media Lab's Kismet [5], Leonardo and Huggable [6], CMU's Vikia and Royal Institute of Technology's CERO [7]. A comprehensive survey was conducted on socially interactive robots in [8], where a number of issues pertaining to socially interactive robots were studied.

In this paper, we briefly review the latest advances in the core technologies (as shown in Fig. 1) that form the backbone of social robotics, and also provide an overview of how the field and related technologies are set to evolve in the near future. In the following sections, we first examine the sensing and perception aspects of social robots, followed by advanced planning mechanisms, and finally affective sciences and social behavior generation, as well as decision making and artificial intelligence, for effective interaction with humans.

II. Robot Sensing: Sound and Vision

Sound and visual sensing are crucial for humans, and that is also the case for social robots. These sensing capabilities allow the gathering of crucial information required for navigation, planning and other higher cognitive processes like decision making. Effective sound and vision localization allows robots to focus their attention on pertinent objects/elements within their environment much like how humans act.

A. Sound Localization

Sound localization is a listener's ability to identify the location of a detected sound or the methods in acoustical engineering simulate the placement of an auditory cue in a virtual 3D space. It has attracted much attention in the literature [9]–[19] owing to the wide applications including robot perception [20], human-machine interfaces [21], handicappers' aids [22], [23] and some military applications [24]. Due to the importance of sound localization, it has been greatly explored. Related works can fall into following categories in terms of sensors:

1) Smart audio sensors: Psychoacoustic studies on humans have provided us with information about the cues to locate sound sources, namely, Interaural Time Differences (ITD), Interaural Intensity Differences (IID) and spectrum [25]–[29]. To mimic human dimensional hearing, a neuromorphic microphone was proposed by making use of biologically-based monaural spectrum cues [30]. This microphone relied on a specially shaped reflecting structure - a parabola simulating the pinna's curved surface and a sound source can be located in the front half plane by using echo-time processing. Based on the analysis of biological sound localization systems (such as the barn owl, bats, etc), neural networks have been successfully used to locate sound sources with relative azimuth [10]. In [31] and [32], a simplified model of the auditory system for human beings was developed, which consisted of a three-microphone set and several banks of band-pass filters. Zero-crossing was used to detect the arrival temporal disparities and the histogram mapping method was introduced to localize multiple sound sources in the azimuth direction.

2) Microphone arrays [33]–[36]:

- Relative sound localization
  It focuses on sound localization with respect to the reference frame attached to the microphone arrays. It can be classified into three categories, namely, localization based on beamformer, signal correlation matrix and time difference of arrival (TDOA) [37] respectively. The first is similar to that of radar and can be achieved using beamformer-based energy scans [38], [39], by which output power of a steered-beamformer should be maximized. The second makes use of high resolution spatio-spectral correlation matrix derived from signal received by sensors. TDOA-based localization covers the receptive environment of interest, instead of "focalization", based on high resolution TDOA estimation. Related techniques of relative sound localization include triangulation [24], Least-Square (LS) approach [40], Maximum likelihood technique [41], sensor fusion [42] and so forth.
- Global sound localization
  Global sound localization is similar to Simultaneous Localization and Mapping (SLAM) in the research domain of map building and robotics. It focuses on the source localization with respect to the global reference frame. It consists of two main issues, namely, the relative source localization with respect to the microphone array and the

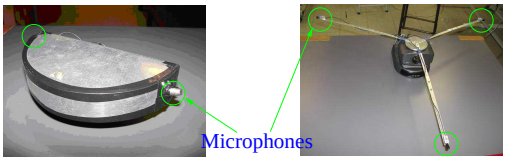

Fig. 2. Microphone sets

localization of microphone array itself with respect to the global reference frame. The latter can be referred to as inverse sound localization problem [43] and has significant impact on the overall sound localization.

B. Localization with Microphone Sets

It is well known that 4 microphones are required for 3D sound localization [11]. However, to further streamline the design and implementation of accurate localization systems on social robots that should be highly mobile, we seek to investigate and improve an implementation using fewer than 4 microphones.

To this end, we have shown that adequate localization can be done with a two-microphone set and a three-microphone set, as shown in Figure 2. A three-microphone set is shown in the right picture of Figure 2. These microphones form a Y-shaped frame whereby all the nodes are connected to a common point. It has been shown that this configuration can be used to estimate azimuth and elevation of a sound source simultaneously.

This technique developed at the SRL and ERL has been successfully applied for sound localization by robots, as well as localization by virtual avatars of robots within the virtual space. As the name specifies, the played music provides spatial feeling for listeners with earphones. Figure 3(a) shows an artificial virtual robotic head which can hear 3D sound in space. Figure 3(b) shows its implementation to an interactive teddy bear, which is able to estimate the direction of a radio receiver and respond appropriately to the aural stimulation.

(a) Sound Localization by a Robot's Avatar in Virtual Space

(b) Teddy bear locating a radio receiver

Fig. 3. Sound Localization in both Physical and Virtual Worlds.

C. Vision-based Interaction

With the rapid developments in the fields of sensing technologies and robotics, there is an increasing need to employ intelligent robots [44] with a friendly human-machine interface

Fig. 4. Human Detection by a Social Robot for Attention Focusing

in a human environment for the purpose of surveillance, monitoring, services and so forth. This necessitates an intelligent visual perception system to robustly detect and identify human beings with a variable background, motivating the investigation of visual human detection using multiple cameras.

Without a prior knowledge and constraints on the background, it is difficult to detect human beings using a monocular camera [45], [46]. Methods employing the use of a monocular camera requires knowledge of the scene's background. This can be achieved by having a stationary camera or a model of the background [47]–[49]. Face detection techniques [50], [51] dispense with this requirement, but is only applicable to frontal views of humans. On the other hand, stereo-vision systems is able to provide depth or scale information to the detection of human beings in a clustered environment, and it enables the spatial object segmentation and also brings about the challenges, e.g., distinguishing humans from human-like objects, in the realization of human detection as a result of this new piece of information. With the advantages of stereo vision, and given that humans, ourselves, utilize such a technique, it is natural to develop robust stereo vision techniques that will give this capability to social robots. Coupled with infrared thermal imaging [52]–[56], the capabilities of social robots can far exceed that of humans, and be valuable aids for a wide range of applications. This is indeed one of the key research thrusts of the Edutainment Robotics and Social Robotics Laboratories, fusing stereo and infrared vision and integrating these visual systems onto a mobile robot (as shown in Fig. 4) to achieve more reliable human detection and identification for social robots. The robot prototype is able to detect humans, estimate the relative direction and distance of him/her, and follow him/her at a comfortable distance.

III. Affective Sciences

A. Human-Robot Interaction

The emotion exchanges and interaction is one of the most important and necessary characteristics of the social robotics. This is also called the affective sciences – the scientific study of emotion. Amongst humans, emotions are conveyed through facial expressions, audio cues, hand and body gestures. Likewise, it is an important factor in the determining the level and type of interactions that occur between a robot and a human. The capacity to emote, and respond to emotes, further

improves the robots ability to engage in fruitful interactions with the human user.

B. Facial Emotion Recognition System

A key component of emotions, and one that social robots must be capable of, is the ability for facial/emotion recognition. It is the first step in synthesizing the aspect of empathy within robots. The ability to mimic human facial expressions lays the foundation for establishing a meaningful nonverbal communication between humans and robots. Facial expression analysis originates from Darwin in the 19th century when he proposed the concept of universal facial expressions in Man and animals [57]. Recently, research on facial recognition and expressing emotions in robots has received much attention since this is the most straightforward and efficient way for the research on affective science of robotics. In 1978, Ekman and Friesen developed the facial action coding system (FACS) for analyzing and synthesizing facial expression based on action units (AU) which describe basic facial movements [58]. In [59]–[61], target oriented approaches were used to infer the human emotion and classify the facial expression from one single image containing one typical facial expression. For facial expression classification, gesture oriented methods [62], [63], using temporal information from a sequence of facial expression motion images, can be employed

Facial expression is a dynamic process, how to fully make use of the dynamic information can be critical to the recognition result. There is a growing that the temporal information is a critical factor in the interpretation of facial expressions [64]. In [65], independent component analysis, optical flow estimation and Gabor wavelet representation methods were used and a 95.5% average recognition rate was achieved.

At the ERL and SRL, we have developed both off-line training method and real-time classifier for facial/emotion recognition system, which are then integrated into the interactive robot platforms for testing and further development. This emotion recognition system is used to identify the emotion of the human, which supporting the nonverbal emotion communication between humans and robots. The objective of the emotion recognition system is for human emotion understanding and intelligent human-robot interface. Our system is based on both the deformation and motion information. The framework of our recognition system is shown in below figure. It starts with the facial image acquisition and ends with 3D facial expression animation.

IV. Robot Navigation: Obstacle Avoidance & Path Planning

Sociable robots, by their nature, is required to work amongst, and in close proximity to humans. Due to the dynamic nature of the working environment and the severe consequences of a human-robot collision, an advanced dynamic obstacle avoidance and path planning system is a prerequisite for all mobile sociable robots.

The potential field method is commonly used for autonomous mobile robot path planning [66]–[80]. The basic concept of the potential field method is to fill the robot's workspace with an artificial potential field in which the robot is attracted to its target position and is repulsed away from the obstacles [66]. This method is particularly attractive because of its elegant mathematical analysis and simplicity. To solve the problem of motion planning in a dynamic environment where the obstacles are moving, one approach is to include time as one of the dimensions of the model world and thus the moving obstacles can be regarded as stationary in the extended world [81]–[83]. Accordingly, the dynamic motion planning problem is reduced to motion planning in stationary environments. Another approach was proposed in [74] and [75] which extended the potential field method to the problems of moving obstacle avoidance by constructing repulsive potential functions which take into account the velocity information. In [75], velocity information of the robot and the obstacle are exploited for better obstacle avoidance.

Global sensor-based planning approaches [84]–[86] build a global world model based on sensory information and use it for path planning. By mapping the entire (accessible) environment, the global approaches can somewhat solve the basic path planning problem which implies the property of "global convergence" of path planning. In contrast, the local sensor-based path planning approaches use local sensory information in a purely reactive fashion. These methods include the potential field methods [66], [67], [71], [87], [88], behavior-based systems [89], [90] and fuzzy logic approaches [91]. Bug algorithms and their variants, combine local planning with global information to solve the problem of a point mobile automaton moving amidst unknown obstacles of arbitrary shape [92]–[95].

As a step towards greater autonomy and robustness in obstacle avoidance, a potential field method has been developed at the ERL, for motion planning of a mobile robot in a dynamic environment where the target and obstacles are moving can be used [88]. This approach does not require that the trajectories of the obstacles to be known a priori.

In addition, an "Instant Goal" approach has been developed in ERL and SRL [96] [97] which allows a physical robot equipped with a rangefinder to follow an obstacle of arbitrary shape. The "Instant Goal" is a local target specially designed for action planning based on sensory input. The Instant Goal Driven method was first presented in [96] where instant goals are generated at each time instant for behavior-based navigation. In [97], the proposed approach allows the robot to move forward along the boundary of an obstacle without collision in obstacle cluttered environments. To facilitate realtime planning, a vector representation, which saves greatly on memory space, is used to represent the local environment sensed by a rangefinder. The search range for each Instant Goal is restricted to a certain scope determined by previous status and current range data input such that the boundary following is performed in the desired direction. The concepts of "safe path" and "passage" are used to distinguish the "disturbing" obstacles from the desired one such that Instant Goals are able to be determined under any complex obstacle condition.

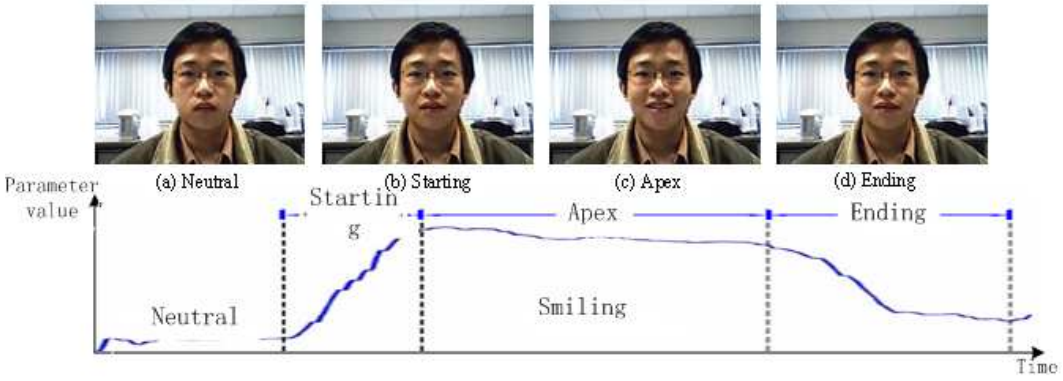

Fig. 5. Emotion Recognition Module at the Edutainment Robotics Laboratory, NUS

Based on the boundary following function, a practical convergent path planner is presented for navigation of a mobile robot without first building a global map of the environment. It uses a Bug-like strategy to switch between the two motion modes in order to achieve global convergence of path planning. A special leave condition is proposed for the robot to decide whether it should leave the currently followed obstacle and switch back to move toward the goal. Rather than assuming the robot is able to follow an obstacle, the path planner is based on the Instant Goal approach, which does not require a range sensor to have a perfect sensing ability. Different from subgoals in the work of [98] which are simply set to be near the polygon vertices in a polygon environment, path planning is accomplished through reaching a series of Instant Goals leading the robot to follow an obstacle in the desired direction in a complex, obstacle cluttered environment.

The potential field method developed in ERL and SRL, combined with robust, convergent approaches, such as the Instant Goal method and modified boundary following [96], [97], the social robot will be able to navigate successfully and safely in dynamic, cluttered environments.

V. Robot Communications

A. Handshaking with Robots

Although not a universal form of greeting, hand shaking is still recognized as one of the most commonly used greeting in the world today and it is commonly associated with the demonstration of good will between the two parties.

In recent years, research in the replication of handshaking behaviors in robots has attracted the attention of roboticists worldwide. In [99], coordinated movements of humans and robots in the act of handshaking is studied. During handshaking between humans, the motions between the humans become coordinated naturally without a master leading and a slave following the motions. As such, there is a need for synchronized motions within handshaking in order for a realistic replication of human handshaking in human-robot interactions. To achieve synchronized handshaking, neural oscillators were used in [99], where human-robot motions are synchronized by feeding the external force applied on the robotic arm into the neural oscillators and adapted. In [100], emotionally acceptable motions for human-robot handshaking, through experimental observations of human handshaking, were proposed and investigated . It has been noted that within human society, handshaking is commonly initiated by party in higher social standings whereas it is not appropriate for those of lower social standings initiate handshaking. Similarly, in human-robot interactions, handshaking should be initiated by humans and not the robot. Although similar comments where made in [100] on the need for robots to respond to an offered handshake from humans and not initiate the handshaking, the procedures used to detect an offered handshake are not clearly detailed.

Fig. 6. Handshaking implemented in a robotic bear.

In our research at the ERL and SRL, we focus on the implementation of a recognition system to accurately interpret the human's intention to offer a handshake and respond to the offer, mimicking the socially accepted behavior associated with the initiation handshaking (as shown in Fig. 6). Additional considerations include the continuation and termination of the handshaking process. In general, handshaking is ended when one party disengages. In implementing this behavior

into human-robot handshaking, we have to first consider the scenario when the human initiates the termination. In this case, once the robot senses that the human has disengaged, the robot will have to stop its hand motions. In an alternative scenario, when the human does not disengage, the robot has to realize that the handshaking has continued for too long and has become unnatural. To indicate that the robot wishes to stop the handshaking, the robot will have to stop the hand motions.

B. Hand Gestures

Hand gestures and behavioral cues are one of the basic mechanisms humans use for conveying their messages. Such a mechanism via gestures have been shown to be a viable form of communication without requiring speech, for instance through sign language. Even with the inclusion of verbal dialogue, body gestures exhibited by individuals also provide vital information about the emotional state and attitudes of an individual. For instance, huge animated movements usually signal a state of excitement or anger, while a dismissive wave of the hand indicates a non-committal state of mind.

A hand gesture identification system, can further improve the robot's level of interactivity and social pro-activity, by being able to identify the hand gestures made by the human. It will also allow communication via sign language, and further emphasizes the diverse role of a social robot in the human society that caters for everyone. Aside from formal sign language, such a system can be made to recognize body language and informal hand signs. A common initiation of handshaking in human interactions is the extending of an open palm. The vision system can differentiate and recognize the open palm. Once an extended open palm is detected, the robot will move its hand towards the palm. Proximity sensors installed at the sides of the robot's hands coupled with a vision system will be required to accurately move the robot's hand near the human's hand to start the handshaking.

C. Social Spaces and Comfort Zones

Apart from direct verbal exchanges and other directly perceivable interaction mechanisms like hand gestures and facial expressions, a fundamental regulator of human social behavior in human-human interactions is the perception of social spaces. There have been extensive studies in psychology and the social sciences about its role in human societies, and how human behavior, attitudes, responses and relationships are influenced by it [101]. The concept of social spaces varies according to a number of factors such as cultural norms, relationships between specific individuals, and social scenarios.

The first step designers of social robots have to take is to synthesize understanding of social cues in human societies. An understanding of the concept of social spaces and synthesis of appropriate behavioral responses are crucial elements. There have been a number of studies conducted regarding the quantitative demarcation of spatial zones based on human-human relationships [102]. Preliminary studies that draw parallels between the human-human and human-machine relationships have also been conducted [103]. These studies also indicate

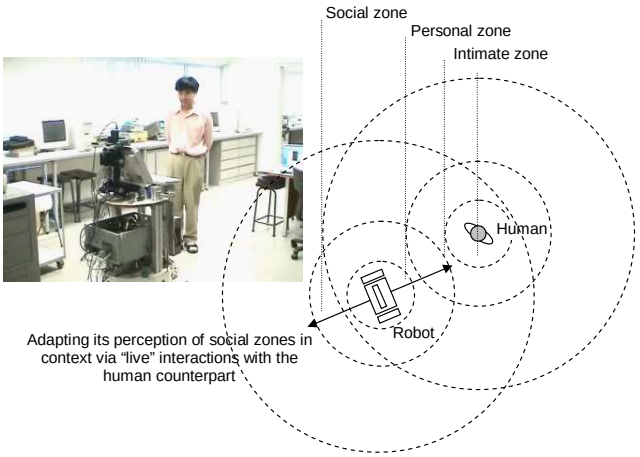

Fig. 7. Social distances and adaptation of the perceived comfort zones between a robot and a human user.

that the gap between social distances adopted for human-human and human-computer interactions narrows based on the perception of the robot's role in society – from merely "socially evocative" to being "sociable" [1]. It also indicates the presence of a continuous feedback loop between the human user and the robot, mediated by human expectations and robot behaviors. Human expectations and the level of acceptance of robots in the social landscape are altered based on how a social robot behaves and how well it reacts to fundamental social cues such as social spaces.

A robot that can respect the comfort zone and social space of each individual human in its surroundings, and eventually learn and adapt its own social space according to the evolution of its personal relationship with these individuals, would find it easier to be recognized as a member of mainstream society. As a move towards "sociable" robots, the issue of social spaces applied to human-robot interactions should be examined in further detail. Simple behavioral responses that enable the robots to keep a predetermined distance from human users, although necessary, is not sufficient for social interactions. The robots have to adapt and learn of the social context it is situated in, and must also be able to infer the level of social relationships between themselves and the human users. Consider the situation where a robot starts interacting with a human user. It first gives the user the priority of determining the comfortable interaction distance, through a series of observations of the distance the user maintains between them. If a user repeatedly backs away from the robot during their interactions, the robot adaptively increases the distance it maintains from the user, and vice versa, as shown in Fig. 7. As with human-human interactions, it is obvious that interaction distances are larger in more formal contexts, where participants are less familiar with each other, and also during interactions between people of differing social statuses. This applies also to human-robot interactions. Through other cognitive modules implemented on the social robot, such as vision and machine intelligence, the robot continually adapts

its model of the social environment as it continues interaction with different people, perhaps gradually closing the interaction distance (through constant feedback/ observations of the human counterpart) as the personal relationship with specific individuals evolve over time.

VI. Decision Making & Computational Intelligence

At one of the highest rungs of the cognitive ladder for socially adept robots is the ability to manipulate, organize and reason about available information, and from there, make relevant operational plans that conform to the abstract objectives of complex missions/tasks demanded of the robots. Overall, this topic is also of interest to engineers/researchers [104] and philosophers [105]–[107] because of the potential impact high level robot cognition have on the moral and ethical fabric of society.

Technical research in this area is thus devoted to the study of the mechanisms that are involved in the decision making process of robots. It ranges from tools for improving the efficiency of computationally intensive processes, to deliberation and planning protocols for the accomplishment of tasks.

In the near future where social robots are integral part of the social landscape, it is inevitable that each will be required to interact with other (humans/artificial) entities around it. The advancement of technology in robotics, control, computer science and communications, has made possible, the deployment of large teams of mobile robots in real life scenarios. This leads to research in Multi-Agent Systems (sometimes referred to as Distributed Artificial Intelligence) [108], consisting of huge numbers of interacting agents, linked together in complex networks. Such agents manifest themselves in the form of virtual robots, humans and embodied mobile robots. Specifically, technical issues involve robust and adaptive task allocation and behavior generation in robotic systems [109]–[111], and scheduling and rescheduling [112] mechanisms. This is a major research thrust at the Social Robotics Laboratory.

Much work can still be done in this area, where the major challenge is the synthesis of an unprecedented level of intelligence in social robots that goes beyond mere user predefined state changes, a level of cognition that mirrors the human decision making process. Open problems still exists in the fields of decision optimization, neural networks and fuzzy logic, and many more.

VII. Conclusions and Future Work

As we look ahead, it seems clear that social robots will play an ever larger role in our world, working for and in cooperation with humans. Social robots will assist in health care, rehabilitation, and therapy. Social robots will work in close proximity to humans, serving as tour guides, office assistants, and household staff. Social robots will engage and entertain. Central to the success of social robots will be close and effective interaction between humans and robots. There is still much that can be done in each of these modules, which involves scientists and researchers from all disciplines of engineering and computer science. We have, in this paper, provided a general review of the core technologies critical to the development of social robots, and also a holistic view of the system and how individual modules (from sensing to perception to cognition and planning) support and augment each other in the overall scheme of things.

Shuzhi Sam Ge

Professor, IEEE Fellow, PhD, DIC, BSc, PEng

Director, Edutainment Robotics Lab, Department of Electrical & Computer Engineering, and Head, Social Robotics Lab, Interactive Digital Media Institute The National University of Singapore
Singapore 117576 Tel: (+65) 6516 6821, Fax: (+65) 6779 1103

E-mail: elegesz@nus.edu.sg , http://vlab.ee.nus.edu.sg/~sge

Professor Shuzhi Sam Ge is Head of Social Robotics Lab, Interactive and Digital Media Institute, and the Director of Edutainment Robotics Lab, Department of Electrical and Computer Engineering, the National University of Singapore. He received his PhD degree and DIC from the Imperial College, London, and BSc degree from Beijing University of Aeronautics & Astronautics. He has published a number of books, over 300 scientific journal and international conference papers, given invited talks/plenary speeches, managed/completed a number of projects of impact, and delivered many working systems and prototyping to industry and funding agencies, the inventor of 3 patents and the 4th one on Interactive e-Book Authoring System filed for PCT. Dr. Ge has received the highest accolades from his University, from Singapore, from China, and from USA. He was the recipient of the 1999 National Technology Award, Singapore; 2001 Young Research Award, NUS; 2002 inaugural Temasek Young Investigator Award, DSTA; 2004 NSF Outstanding Overseas Young Researcher Award, China; and 2006 IEEE Fellowship, USA. In his 2002 inaugural Temasek Young Investigator Award on intelligent control of unmanned vehicles, he delivered many more deliverables in prototypes and software packages to DSTA across sensor fusion, decision making, path planning, and intelligent control.

He serves on the Board of Governors, IEEE Control Systems Society (CSS), as elected member from 2007 to 2009, Chairman of the Technical Committee of Intelligent Control, IEEE CSS since 2005, Dr Ge served as Chairman of IEEE Singapore SMC Chapter (2003), and Chairman of IEEE Singapore R&A Chapter (2004, 2005). Dr Ge served as the founder and General Chair of IEEE Conference on Robotics, Automation & Mechatronics, and IEEE Conference on Cybernetics & Intelligent Systems in 2004, and the Chair of the Steering Committee for the two conferences in Bangkok, 2006. He served/serves as an Associate Editor for a number of flagship journals, Book Editor for Taylor & Francis Automation and Control Engineering Series.

He is the Chairman and founding Director of Personal E-Motion Pte Ltd in delivering interactive digital multimedia authoring platforms and multimedia digital books generation and delivering systems for education and e-publishing.

Computer and Information

Table of Contents

10:50 AM - 12:10 AM — **Session TAM1-3** — **Thursday,10 May 2007**

CMOS Technology

Chairperson : Songphol Kanjanachuchai ,Chulalongkorn University

TAM1-3-1 **10:50 AM** — **High Frequency, High Precision CMOS Half-Wave Rectifier** — **1**
Montree Kumngern, Kobchai Dejhan
Engineering and Research Center for Communication and Information Technology, King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand

TAM1-3-2 **11:10 AM** — **A Modified CMOS Differential-Pair-Based Triangular-and-Trapezoidal to-Sine** — **5**
Kanitpong Pengwon, Ekachai Leelarasmee
Electrical Engineering Department, Chulalongkorn University, Bangkok, Thailand

TAM1-3-3 **11:30 AM** — **A Design of CMOS Class-AB Differential Log-Companding Amplifier** — **9**
Kobkaew Opasjumruskit[1], Apisak Worapishet[2], Ekachai Leelarasamee[1]
[1]IC Design and Application Research Laboratory (IDAR), Department of Electrical Engineering, Chulalongkorn University, Thailand
[2]Mahanakorn Microelectronics Research Centre (MMRC), Mahanakorn University of Technology, Thailand

TAM1-3-4 **11:50 AM** — **A Novel Structure of Wide-Swing CMOS Voltage Buffer** — **13**
Chutham Sawigun, Jirayuth Mahattanakul
Department of Electronic Engineering, Faculty of Engineering, Mahanakorn University of Technology, Bangkok, Thailand

10:50 AM - 12:10 AM — **Session TAM1-8** — **Thursday,10 May 2007**

Integrated Circuits

Chairperson : Chiranut Sa-ngiamsak, Khon Kean University

TAM1-8-1 **10:50 AM** — **A Compact Low Voltage CMOS Four-Quadrant Analog Multiplier** — **17**
N. Kiatwarin[1], W. Ngamkham[2], W. Kiranon[1]
[1]Department of Telecommunication Engineering, Faculty of Engineering, King Mongkut's Institute of Technology Ladkrabang, Thailand
[2]Department of Control and Instrumentation Engineering Mahanakorn University of Technology, Bangkok, Thailand

TAM1-8-2 **11:10 AM** — **Verifying Various Generation of Random Number Sequence on Wave-Pipelined PRNG** — **21**
Tomoaki Sato, Kazuhira Kikuchi, Masa-aki Fukase
Hirosaki University, Bunkyo-cho 3 Hirosaki, Aomori, Japan

TAM1-8-3 **11:30 AM** — **Asynchronous System Bus Enhancement by Interrupt and DMA Technique** — **25**
Sufian Sudeng, Arthit Thongtak
Digital System Engineering Laboratory (DSEL), Department of Computer Engineering, Chulalongkorn University, Bangkok, Thailand

TAM1-8-4 **11:50 AM** — **CMOS compatible Ion Sensitive Field Effect Transistor with Silicon Nitride Membrane for pH Measurement System** — **29**
W. Bunjongpru, O. Trithaveesak, K. Sowsuwan, W. Jeamsaksiri, C. Hruanun, A. Poyai
Thai Microelectronics Center (TMEC), Chachoengsao, Thailand

1:00 PM - 3:00 PM | **Session TPM1-2** | **Thursday,10 May 2007**

Oscillator Circuits

Chairperson : Apinan Thanachaynont, King Mongkut's Institute of Technology Ladkrabang

TPM1-2-1 **1:00 PM** — **Current Tunable Quadrature Oscillator Using Only CCCDBAs and Grounded Capacitors** — **32**

Sumaytee Pisitchalermpong, Danucha Prasertsom, Thanawat Piyatat,
Worapong Tangsrirat, Wanlop Surakampontorn
Research Center for Communication and Information Technology (ReCCIT),
King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand

TPM1-2-2 **1:20 PM** — **Implementation of a Chua's Chaotic Oscillator Using "Roughly-Cubic-Like" Nonlinearity** — **36**

Banlue Srisuchinwong, Wimol San-Um
Sirindhorn International Institute of Technology,
Thammasat University, Bangkadi Campus, Pathumtani, Thailand

TPM1-2-3 **1:40 PM** — **Improved Implementation of Sprott's Chaotic Oscillators Based on Current-Feedback Op Amps** — **38**

Banlue Srisuchinwong, Chun-Hung Liou
Sirindhorn International Institute of Technology,
Thammasat University, Bangkadi Campus, Pathumtani, Thailand

TPM1-2-4 **2:00 PM** — **Multiphase Oscillator using Operational Transconductance Amplifiers** — **41**

Montree Kumngern[1], Montri Somdunyakanok[2], Pipat Prommee[1], Kobchai Dejhan[1]
[1]Research Center for Communication and Information Technology,
King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand
[2]Electrical Engineering Department, Siam University, Bangkok, Thailand

TPM1-2-5 **2:20 PM** — **Dual-mode Multiphase Sinusoidal Oscillator using CDBAs** — **45**

D. Pulsub, W. Surakampontorn
King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand

TPM1-2-5 **2:40 PM** — **A CMOS-based Electronically and Linearly Tunable Quadrature Oscillator** — **49**

Khanittha Kaewdang[1], Wanlop Surakampontorn[2]
[1]Department of Electrical and Electronics Engineering, Faculty of Engineering,
Ubon Rajathanee University, Ubon Rajathanee, Thailand
[2]Research Center for Communication and Information Technology (ReCCIT),
King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand

3:20 PM - 5:00 PM | **Session TPM2-2** | **Thursday,10 May 2007**

Filter Technology

Chairperson : Worapong Tangsrirat, King Mongkut's Institute of Technology Ladkrabang

TPM2-2-1 **3:20 PM** — **Cascadable Three-Input Single-Output Current-Mode Universal Filter Using CDBAs** — **53**

Visawa Sawangarom[1], Teerasilapa Dumawipata[2],
Worapong Tangsrirat[1], Wanlop Surakampontorn[1]
[1]Research Center for Communication and Information Technology (ReCCIT),
King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand
[2]Department of Industrial Electrical Technology (IET), Faculty of Engineering,
King Mongkut's Institute of Technology North Bandkok, Bangkok, Thailand

TPM2-2-2	**Minimum Devices Active-only Current-mode Universal Filter**	**57**
3:40 PM	Pipat Prommee, Montri Somdunyakanok, Montree Kumngern, Kobchai Dejhan *Research Center for Communication and Information Technology (ReCCIT)* *King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand*	
TPM2-2-3	**A Systematic Design of Electronically Tunable Ladder Filters Employing DO-OTAs**	**61**
4:00 PM	Winai Jaikla[1], Montree Siripruchyanun[2] [1]*Electric and Electronic Program, Faculty of Industrial Technology,* *Suan Sunandha Rajabhat University, Bangkok, Thailand* [2]*Department of Teacher Training in Electrical Engineering,* *King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand*	
TPM2-2-4	**A Novel Current-Mode Alternative Topology for Realization of Universal Filter and**	**65**
4:20 PM	**Quadrature Oscillator** Winai Jaikla [1,] Montree Siripruchyanun [2] [1]*Electric and Electronic Program, Faculty of Industrial Technology,* *Suan Sunandha Rajabhat University, Bangkok, Thailand* [2]*Department of Teacher Training in Electrical Engineering,* *King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand*	
TPM2-2-5	**3 Input/ 2 Output Current-Mode Universal Biquad Filter Using Single DO-CCCDTA**	**69**
4:40 PM	Winai Jaikla[1], Montree Siripruchyanun[2] [1]*Electric and Electronic Program, Faculty of Industrial Technology,* *Suan Sunandha Rajabhat University, Bangkok, Thailand* [2]*Department of Teacher Training in Electrical Engineering,* *King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand*	
8:30 AM - 10.10 AM	**Session FAM1-2**	**Friday, 11 May 2007**
	Analog Circuits 1 Chairperson : Banlue Srisuchinwong, Sirindhorn International Institute of Technology	
FAM1-2-1	**Fast Analysis of Analog Design Trade-offs via Geometric Programming**	**73**
8:30 AM	Theerachet Soorapanth *National Electronics and Computer Technology Center, Bangkok, Thailand*	
FAM1-2-2	**A Current-Mode Square-Rooting Circuit Using Negative Feedback Technique**	**77**
8:50 AM	Ittipong Chaisayun *South-East Asia University, Bangkok, Thailand*	
FAM1-2-3	**Application of A Fourier Centroid Shift Method for Estimation of Ultrasonic**	**81**
9:10 AM	**Attenuation Coefficients** M. Lohakan[1,2], N. Pueiam[1], S. Boonsang[1], C. Pintavirooj[1] [1]*Research Center for Communication and Information Technology (ReCCIT), Department of Electronics* *King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand* [2]*Department of Teacher Training in Electrical Engineering,* *King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand*	

FAM1-2-4	**A Compact Class-AB CMOS Variable Gain Amplifier**	**85**
9:30 AM	Phanumas Khumsat[1], s Apinunt Thanachayanont[2], Siraporn Sakphrom[2] *[1]Department of Electrical Engineering,* *Faculty of Engineering, Prince of Songkhla University, Hat-Yai, Thailand* *[2]Research Center of Communications and Information Technology,* *King Mongkut's Institute of Technology Ladkrabang , Bangkok, Thailand*	
FAM1-2-5	**Realization of Current Conveyors-based Floating Simulators Employing Grounded**	**89**
9:50 AM	**Passive Elements** Winai Jaikla[1,] Montree Siripruchyanun[2] *[1]Electric and Electronic Program, Faculty of Industrial Technology,* *Suan Sunandha Rajabhat University, Bangkok, Thailand* *[2]Department of Teacher Training in Electrical Engineering,* *King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand*	
8:30 AM - 10:10 AM	**Session FAM1-3** **Electrical Analysis**	**Friday, 11 May 2007**
	Chairperson : Werachate Khan-ngenn, King Mongkut's Institute of Technology Ladkrabang	
FAM1-3-1	**A Simplified Active Input EMI Filter of Common-mode Voltage Cancellation for**	**93**
8:30 AM	**Induction Motor Drive** C. Khun[1], V. Tarateeraseth[2], W. Khan-ngern[1], Masaaki Kando[3] *[1]Research Center for Communications and Information Technology (ReCCIT),* *King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand* *[2]Faculty of Engineering, Srinakharinwirot University, Nakornnayok, Thailand* *[3]Department of Electrical and Electric Engineer, Tokai University, Japan*	
FAM1-3-2	**The Comparison of the Input Impedance Measurement of SMPS between**	**97**
8:50 AM	**the Resonance Method and the Insertion Loss Method** K. Kiatgamjorn[1], V. Tarateeraseth[2], W. Khan-ngern[1] *[1]Research Center for Communications and Information Technology (ReCCIT),* *King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand* *[2]Faculty of Engineering, Srinakharinwirot University, Nakornnayok, Thailand*	
FAM1-3-3	**Trade-off between EMI Separator and RF Current Probe for Conducted EMI Testing**	**101**
9:10 AM	D. Sakulhirirak[1], V. Tarateeraseth[2], W. Khan-ngern[1], N. Yoothanom[3] *[1]Research Center for Communications and Information Technology (ReCCIT),* *King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand* *[2]Faculty of Engineering, Srinakharinwirot University, Nakornnayok, Thailand* *[3]Sripatum University, Faculty of Engineering, Bangkok, Thailand*	
FAM1-3-4	**The Relation of Critical Current Negative Resistance and External Magnetic Field in**	**105**
9:30 AM	**GdBa2Cu3O7-x Superconducting Material** Wisit Wongsuttitum[1], Wisut Titiroongruang[1], Masamori Iida[2] *[1]Electronics Research Center, King Mongkut's Institute of Technology Ladkrabang, Thailand* *[2]Tokai University Junior College, Tokyo, Japan*	
FAM1-3-5	**Implementation of Electrical Capacitance Tomography using Analytical**	**109**
9:50 AM	**Sensitivity Maps** Denchai Worasawate, Phuwaphat Klongpramong *Kasetsart Advanced RF and ElectromagNetics Laboratory,* *Department of Electrical Engineering, Kasetsart University, Bangkok, Thailand*	

10:30 AM - 12:10 AM **Session FAM2-2** **Friday, 11 May 2007**

Analog Circuits 2

Chairperson : Banlue Srisuchinwong , Sirindhorn International Institute of Technology

FAM2-2-1 **Composite Four-Terminal Floating Nullor with Variable Voltage and Current Gains** **113**
10:30 AM
Jirawat Hirunporm[1], Sumalee Unhavanich[2], Worapong Tangsrirat[1],
Wanlop Surakampontorn[1]
[1]*Research Center for Communication and Information Technology (ReCCIT),*
King Mongkut's Institute of Technology Ladkrabang, Ladkrabang, Thailand
[2]*Department of Industrial Electrical Technology (IET),*
King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand

FAM2-2-2 **Current-mode Universal Biquad Including Minimum Component Count Circuits** **117**
10:50 AM
Pratya Mongkolwai, Tattaya Pukkalanun, Worapng Tangsrirat
Research Center for Communication and Information Technology (ReCCIT),
King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand

FAM2-2-3 **A Study of Adaptive Forward Error Control in Audio Communication using Smooth** **121**
11:10 AM **Method**
Phichet Moungnoul, Kornhathai Klappong, Wiphada Inkiew, Somyot Junnapiya
Research Center for Communication and Information Technology (ReCCIT),
King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand

FAM2-2-4 **Rectangular Wave Delta Modulation Buck Regulator for Voltage Regulator Modules** **125**
11:30 AM
J. Ngarmnil, K. Sooksood
Department of Electronic Engineering, Faculty of Engineering,
Mahanakorn University of Technology, Bangkok, Thailand

FAM2-2-5 **Dual Input All-Pass Networks Using MO-OTA and its Application** **129**
11:50 AM
Pipat Prommee[1], Krit Angkeaw[2], Jirasak Chanwutitum[2], Kobchai Dejhan[1]
[1]*Research Center for Communication and Information Technology (ReCCIT),*
King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand
[2]*Industrial Electrical Technology Department, Faculty of Engineering,*
King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand

10:30 AM - 12:10 AM **Session FAM2-3** **Friday, 11 May 2007**

Electronic Devices

Chairperson : Boonying Charoen, Khon Kean University

FAM2-3-1 **A Physics-Based InP/InGaAs SHBT Model for SPICE simulation** **133**
10:30 AM
Suchat Osaklang[1], Chiranut Sangiamsak[2]
[1]*Graduate School, Department of Electrical Engineering,*
Khon Kaen University, Thailand
[2]*Department of Electrical Engineering,*
Khon Kaen University, Thailand

FAM2-3-2	**Devices Design, Fabrication and Characterizations of 0.8 µm CMOS Technology**	**137**
10:50 AM	A. Ruangphanit[1], N. Phongphanchantra [1,2], P. Meesapawong[1], C. Hruanan[1], S. Niemcharoen[2], R.Muanghlua[2] *[1]Thai MicroElectronics Center(TMEC), National Electronics and Computer Technology Center ,Chachoengsao, Thailand* *[2]Electronics Research Center, King Mongkut's Institute of Technology Ladkrabang Lampratue District, Thailand*	
FAM2-3-3	**Characteristics of GaAs-based Phototransistors after high-power operation**	**141**
11:10 AM	N. Thudsalingkarnsakul, S. Thainoi, S. Kanjanachuchai *Semiconductor Device Research Laboratory, Department of Electrical Engineering, Chulalongkorn University, Bangkok, Thailand*	
FAM2-3-4	**CMOS Digital-to-Analog Converter**	**145**
11:30 AM	Pipat Prommee[1], Krit Angkeaw[1], Kobchai Dejhan[1], Montri Somdunyakanok[2], Jirasak Chanwutitum[3] *[1]Research Center for Communication and Information Technology(ReCCIT), King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand* *[2]Faculty of Engineering, Siam University, Bangkok, Thailand.* *[3]Industrial Electrical Technology Department, Faculty of Engineering, King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand*	
FAM2-3-5	**Degradation Characteristics of Blue Light-Emitting Diodes under Accelerated DC**	**149**
11:50 AM	**Aging Process** T. Limwongse, S. Thainoi, S. Kanjanachuchai *Semiconductor Device Research Laboratory, Department of Electrical Engineering, Faculty of Engineering, Chulalongkorn University, Bangkok, Thailand*	

1:00 PM - 3:00 PM — **Session FPM1-2** — **Friday, 11 May 2007**

Electronic Circuits

Chairperson : Boonying Charoen, Khon Kean University

FAM1-2-1	**FPGA Implementation of Acoustic Echo Canceller with Low Resource Utilization**	**153**
1:00 PM	Sompop Janyavilas[1], Ekaroon Piluck[2], Phaophak Sirisuk[3], Monai Krairiksh[1] *[1]Research Center for Communications and Information Technology (ReCCIT), King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand* *[2]Department of Electronic Engineering, Mahanakorn University of Technology, Bangkok, Thailand* *[3]Department of Computer Engineering Mahanakorn University of Technology, Bangkok, Thailand*	
FAM1-2-2	**Analog Nonlinear Circuits Based On the Voltage Level Shift Buffer**	**157**
1:20 PM	Ittipong Chaisayun[1], Kobchai Dejhan[2] *[1]South-East Asia University Bangkok, Thailand* *[2]King Mongkut's Institute of Technology Ladkrabang Ladkrabang, Bangkok, Thailand*	
FAM1-2-3	**Quantitative Estimation of Ultrasonic Attenuation Coefficients in A Solid Immersed**	**161**
1:40 PM	**Case with Multinarrow Band Technique** M. Lohakan[1,2], N. Pueiam[1], S. Boonsang[1], C. Pintavirooj[1] *[1]Research Center for Communication and Information Technology (ReCCIT), Department of Electronics, King Mongkut's Institute of Technology Ladkrabang, Thailand* *[2]Department of Teacher Training in Electrical Engineering, King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand*	

FAM1-2-4	**High-Value Floating Controlled Resistor**	**165**
2:00 PM	Wirote Jongchanachavawat, Montree Kumngern, Kobchai Dejhan *Research Center for Communication and Information Technology (ReCCIT),* *King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand*	
FAM1-2-5	**A Fully-Swing Adiabatic Circuit for Low Power Applications**	**168**
2:20 PM	Rungruang Sangpratheep, Kasin Vichienchom *King Mongkut's Integrated Circuits Lab (KMICL), Department of Electronics,* *King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand*	
FAM1-2-6	**Effect of Resonances on Shielding Effectiveness in Enclosure with Apertures**	**172**
2:40 PM	P. Dangkham[1], P. Sujintanarat[1], S. Chaichana[1], K. Aunchaleevarapan[2], P. Teekaput[1] *[1]Faculty of Engineering, Chulalongkorn University, Bangkok, Thailand* *[2]Electrical and Electronic Products Testing Center, NECTEC, NSTDA,* *King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand*	
1:00 PM - 3:00 PM	**Session FPM1-7**	**Friday, 11 May 2007**
	Microelectronics	
	Chairperson : Songphol Kanjanachuchai, Chulalongkorn University	
FPM1-7-1	**Quartz Crystal Microbalance Humidity Sensor using Electrospun PANI Sensing Layer**	**176**
1:00 PM	K. Jaruwongrungsee[1], A. Tuantranont[1], Y. Wanna[2], A. Wisitsoraat[1], T. Lomas[1] *[1]Nanoelectronics and MEMS Laboratory, National Electronics,* *Computer Technology Center Thailand Science Park, Pathumthani, Thailand* *[2]National Nanotechnology Center, Pathumthani, Thailand*	
FPM1-7-2	**Optical Gas Sensor Array Based on Metallo-Phthalocyanines and Metallo-Porphyrins**	**180**
1:20 PM	Sureeporn Uttiya[1], Teerakiat Kerdcharoen[1], Paisarn Daungjak Na Ayutthaya[2], Worawan Bhanthumnavin[3], Radchada Buntem[4], Sirapat Pratontep[5] *[1]Center of Nanoscience and Nanotechnology, Department of Physics,Faculty of Science,* *Mahidol University, Bangkok, Thailand* *[2]Institute of Science, Walailak University, Nakorn Srithammarat, Thailand* *[3]Department of Chemistry, Faculty of Science, Chulalongkorn University, Bangkok, Thailand* *[4]Department of Chemistry, Faculty of Science, Silpakorn University, Nakorn Pathom, Thailand* *[5]National Nanotechnology Center, National Science and Technology Development Agency,* *Thailand Science Park, Pathumthani, Thailand*	
FPM1-7-3	**Symmetrical Wheatstone MEMS Cantilever Sensors with On-chip Resistors for**	**184**
1:40 PM	**Temperature Feedback** Adisorn Tuantranont, K. Jaruwongrungsee, T. Lomas, A. Jomphoak, A. Wisitsoraat *Nanoelectronics and MEMS Laboratory, National Electronics and Computer Technology Center,* *Thailand Science Park, Pathumthani, Thailand*	
FPM1-7-4	**Fabrication and Characterization of Polydimethylsiloxane (PDMS) Microfluidic**	**187**
2:00 PM	**Channels** Thitima Maturos, Tanom Lomas, Adisorn Tuantranont, Anurat Wisitsora-at *Nanoelectronics and MEMS Laboratory, National Electronics and Computer Technology Center,* *Thailand Science Park, Pathumthani, Thailand*	

FPM1-7-5	**Gas Sensing Characterization of Ion-Assisted Ebeam Evaporated TiO2 Thin Films**	**191**
2:20 PM	**with Nanometer Scale Thickness**	
	A. Wisitsoraat[1], C. Promjuntuk[2], V. Patthanasettakul[1], A. Tuantranont[1]	
	[1]Nanoelectronics and MEMS Laboratory,	
	National Electronics and Computer Technology Center (NECTEC), Thailand	
	[2]Department of Physics, Faculty of Sciences and Technology,	
	Nakhonratchasima Rajabhat University, Nakhonratchasima, Thailand	
FPM1-7-6	**Maskless Etching of Microfabricated Structures with Low-Power Focused Ion Beam**	**194**
2:40 PM	Peerasak Chantngarm	
	Department of Electronics and Telecommunication Engineering,	
	Pathumwan Institute of Technology, Bangkok, Thailand	
1:00 PM - 3:00 PM	**Session TPM1-8**	**Thursday,10 May 2007**
	Control Emgineering 1	
	Chairperson : Chairperson : Kazushi Nakano, The University of Electro-Communications	
TPM1-8-1	**Fuzzy Control for Robot Manipulator Based on Geometric Error**	**198**
1:00 PM	Heydar Toossian Shandiz, Khalil Syahlooei	
	Shahrood University of Technology, Electrical Engineering Faculty, Shahrood, Iran	
TPM1-8-2	**Fuzzy Logic Based Embedded Controller for Control System Education**	**202**
1:20 PM	N. Jasungnuen, P. Janchaichanakun, P.Koseeyaporn	
	Department of Teacher Training in Electrical Engineering,	
	King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand	
TPM1-8-3	**Electromagnetic Flux Density Controlled by Fuzzy Logic Method**	**205**
1:40 PM	Satean Tunyasrirut, Santi Wangnipparnto	
	Faculty of Engineering, Pathumwan Institute of Technology, Pathumwan, Bangkok, Thailand	
TPM1-8-4	**Fuzzy I-PD Controller for Two-Link Robot Manipulator**	**209**
2:00 PM	Wicharn Chatrattanawuth[1], Songmoung Nundrakwang[1], Taworn Benjanarasuth[1],	
	Jongkol Ngamwiwit[1], Noriyuki Komine[2]	
	[1]Research Center for Communication and Information Technology (ReCCIT),	
	King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand	
	[2]School of Information Science and Technology, Tokai University, Kanagawa, Japan	
TPM1-8-5	**A New Modal of Variable Air Volume Diffuser for Thermal Comfort based on**	**213**
2:20 PM	**Fuzzy Logic Control**	
	Yingrak Auttawaitkul[1], Veerapol Monyakul[2], Apichit Therdyothin[1]	
	[1]School of Energy, Environment and Materials,	
	King Mongkut's University of Technology Thonburi, Bangkok, Thailand	
	[2]National Science and Technology Development Agency (NSTDA),Thailand	
TPM1-8-6	**Simultaneous Perturbation Approach to Neural Control of a Flexible System**	**217**
2:40 PM	Jorge Ivan Medina Martinez[1], Kazushi Nakano[1], Umerujan Sawut[2]	
	[1]The University of Electro-Communications, Chofu-ga-oka, Chofu, Tokyo, Japan	
	[2]Nikki Co., Ltd., Kamiechi, Atsugi, Kanagawa, Japan	

3:20 PM - 5:00 PM | **Session TPM2-8** | **Thursday,10 May 2007**

Control Engineering 2

Chairperson : Pramin Artrit, Khon Kean University

TPM2-8-1 **Design of PID Controllers via Genetic Algorithm for Benchmark Systems** **221**
3:20 PM
C. Thammarat, P. Sukserm, D. Puangdownreong
Department of Electrical Engineering, Faculty of Engineering,
South-East Asia University, Bangkok, Thailand

TPM2-8-2 **A Design Method for Modified PID Controllers for Time-delay Plants and Their** **225**
3:40 PM **Application**
Kou Yamada, Takaaki Hagiwara, Yosuke Shimizu
Department of Mechanical System Engineering, Gunma Universitym, Kiryu, Gunma, Japan

TPM2-8-3 **DC Motor Identification and Tuning PID Controller Using Particle Swarm** **229**
Optimization
4:00 PM
Poomyos Payakkawan[1], Poj Tangamchit[1], Saravuth Pothiya[2]
[1]Department of Control System and Instrumentation Engineering,
King Mongkut's University of Technology Thonburi, Bangkok, Thailand
[2]Department of Electrical Engineering, North Eastern University, Khon Kaen, Thailand

TPM2-8-4 **Simplified PI Controller for Two-Inertia System** **233**
4:20 PM
Peerapon Pattanavijit[1], Songmoung Nundrakwang[1], Taworn Benjanarasuth[1],
Jongkol Ngamwiwit[1], Noriyuki Komine[2]
[1]Research Center for Communication and Information Technology (ReCCIT),
King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand
[2]School of Information Science and Technology, Tokai University, Kanagawa, Japan

TPM2-8-5 **Hybrid PD - Sliding Mode Controller Designed for Inverted Pendulum System** **237**
4:40 PM
Samatthachai Panya[1], Jongkol Ngamwiwit[1], Taworn Benjanarasuth[1],
Songmoung Nundrakwang[1], Noriyuki Komine[2]
[1]Research Center for Communication and Information Technology (ReCCIT),
King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand
[2]School of Information Science and Technology, Tokai University, Kanagawa, Japan

1:00 PM - 2:40 PM | **Session FPM1-3** | **Friday,11 May 2007**

Control Engineering 3

Chairperson : Wudhichai Assawinchaichote, King Mongkut's University of Technology Thonburi

FPM1-3-1 **Control Strategies of Doubly Fed Induction Generator of Wind Turbine for Maximum** **241**
1:00 PM **Active Power with Minimum Copper Losses**
Bunlung Neammanee, Somporn Sirisumrannukul
Department of Electrical Engineering, Faculty of Engineering,
King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand

FPM1-3-2 **Soft-Switching Single-Phase Inverter for Small Grid-Connected PV Systems** **245**
1:20 PM
D. Amorndechaphon[1], S. Premrudeepreechacharn[2], K. Chamnongthai[3]
[1]Department of Electrical Engineering, Naresuan University Phayao Campus, Phayao, Thailand
[2]Department of Electrical Engineering, Chiangmai University, Chiangmai, Thailand
[3]Department of Electronics and Communication Engineering,
King Mongkut's University of Technology Thonburi, Bangkok, Thailand

FPM1-3-3	**Control and Implementation of Line Side Converter for Doubly Fed Induction**	**249**
1:40 PM	**Generator of Wind Turbine**	
	Watee Sudmee, Bunlung Neammanee	
	Department of Electrical Engineering, Faculty of Engineering,	
	King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand	
FPM1-3-4	**Thermal Conductivity Tester**	**253**
2:00 PM	Santi Wangnipparnto, Tianchai Suksri	
	Faculty of Engineering, Pathumwan Institute of Technology, Bangkok, Thailand	
FPM1-3-5	**An Enhanced Adaptive Voltage Control in Gas Tungsten Arc Welding**	**257**
2:20 PM	Poolsak Koseepaporn	
	Department of Teacher Training in Electrical Engineering, Faculty of Technical Education,	
	King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand	
FPM1-3-6	**Robust Hα Fuzzy Control Design for Nonlinear Two-Time scale System with**	
2:40 PM	**Markovian Jumps based on LMI Approach**	
	Wudhichai Assawinchaichote[1], Sing Kiong Nguang[2]	
	[1]King Mongkut's University of Technology Thonburi, Bangkok, Thailand	
	[2]The Department of Electrical and Computer	
	Engineering, The University of Auckland	

10:50 AM - 12:10 AM	**Session TAM1-4**	**Thursday,10 May 2007**
	High Voltage Engineering 1	
	Chairperson : Thanapong Suwanasri, King Mongkut's Institute of Technology North Bangkok	
TAM1-4-1	**Study Effect of Different Shape of Rod-rod Gaps on Positive DC**	**261**
10:50 AM	T. Boonwern, S. Chotigo	
	Department of Electrical Engineering, Faculty of Engineering,	
	King Mongkut's University of Technology Thonburi, Bangkok, Thailand	
TAM1-4-2	**A Preliminary Study of Dissipation Factor (tan δ) in Dielectric of Cables Produced in**	**265**
11:10 AM	**Thailand**	
	A. Aurairatch, S. Kleesuwan	
	Department of Electrical Engineering, Faculty of Engineering,	
	King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand	
TAM1-4-3	**Partial Discharge Measurement for High Voltage Cable Terminators Using Air**	**269**
11:30 AM	**Compression**	
	P. Apiratikul[1], P. Boonchiam[1], B. Plangklang[1], T. Suwanasri[2]	
	[1]Department of Electrical Engineering,	
	Rajamangala University of Technology Thanyaburi, Pathumthani, Thailand	
	[2]The Sirindhorn International Thai-German Graduate School of Engineering,	
	King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand	
TAM1-4-4	**Development and Construction of Dielectric Heating Machine**	**273**
11:50 AM	Prasit Chanmontree, Ekarin Vasanasong	
	Department of Electrical Power Engineering,	
	Mahanakorn University of Technology, Bangkok, Thailand	

10:50 AM - 12:10 AM **Session TAM1-6** **Thursday,10 May 2007**

Power Electronics 1

Chairperson : Viboon Chunkag, , King Mongkut's Institute of Technology North Bangkok

TAM1-6-1 **Performance Comparison between Average-Value and Instantaneous-Value Voltage** **277**
10:50 AM **Controls of a Single-Phase AC Chopper**
E. Sugprajun, S. Polmai
Department of Electrical Engineering, Faculty of Engineering,
King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand

TAM1-6-2 **Power Electronics-Based Fuel Cell Emulator** **281**
11:10 AM
Siriroj Sirisukprasert, Trin Saengsuwan
Department of Electrical Engineering, The Faculty of Engineering,
Kasetsart University, Bangkok, Thailand

TAM1-6-3 **The Comparative Study and Design Guidelines of a High Frequency Transformer for** **285**
11:30 AM **Improving Cross Regulation in Multiple-Output Flyback Converters**
Pairote Sangampai, Kusumal Chalermyanont, Anuwat Prasertsit, Surapon Theinmontri
Prince of Songkla University, Faculty of Engineering, Songkla, Thailand

TAM1-6-4 **Analysis and Design of Portable AC Power-pack with Full-bridge Series-loaded** **289**
11:50 AM **Resonant Converter**
Karun Wanthong, Viboon Chunkag
Department of Electrical Engineering, Faculty of Engineering,
King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand

1:00 PM - 3:00 PM **Session TPM1-4** **Thursday,10 May 2007**

Power Systems 1

Chairperson : Natthaphob Nimpitiwan, Bangkok University

TPM1-4-1 **Particle Swarm Optimization for Optimal DG Placement in Distribution System** **293**
1:00 PM
W. Krueasuk, W. Chankaipol, S. Hintamai, K. Chayakulkheeree
Power System and Electrical Energy Research Group,
Department of Electrical Engineering, Sripatum University, Bangkok, Thailand

TPM1-4-2 **A Graph Theory Approach in Reliability Improvement of a Radial Distribution System** **297**
1:20 PM **with PV Grid-Connected Systems**
P. Sritakaew[1], A. Sangswang[2]
[1]*Department of Electrical Engineering, Faculty of Engineering,*
Rajamangala University of Technology Lanna Chiangrai, Chiangrai, Thailand
[2]*Department of Electrical Engineering, Faculty of Engineering,*
King Mongkut's University of Technology Thonburi, Bangkok, Thailand

TPM1-4-3 **Analysis of AC Losses in Superconducting Transmission Line** **301**
1:40 PM
T. Satiramatekul
Department of Computer Engineering, Kasetsart University, Kamphaengsaen Campus, Thailand

TPM1-4-4 **Power Quality Improvement by Use of a New Topology of Fault Current Limiter** **305**
2:00 PM
Seyed Hossein Hosseini[1], M. Abapour[2], M. Tarafdar Hagh[2]
[1]*Electrical Engineering Department, Islamic Azad University of Bonab, Bonab, Iran*
[2]*Faculty of Electric & Electronic Engineering, University of Tabriz, Tabriz, Iran*

TPM1-4-5 **2:20 PM**	**Genetic Algorithm Application for DSP-Based Maximum Power Point Tracking in PV Generation System** Somsak Senapukdee, Ekarin Vasanasong *Department of Electrical Power Engineering,* *Mahanakorn University of Technology, Bangkok, Thailand*	**309**
TPM1-4-6 **2:40 PM**	**Adaptive Characteristic of Mho Distance Relay for Compensation of the Phase to Phase Fault Resistance** D. Surachet, T. Saengsuwan *Department of Electrical Engineering, Kasetsart University, Bangkok, Thailand*	**313**

1:00 PM - 3:00 PM **Session TPM1-6** **Thursday,10 May 2007**

Power Electronics 2

Chairperson : Itsada Boonyaroonate, King Mongkut's University of Technology Thonburi

TPM1-6-1 **1:00 PM**	**A Novel Control Method of a Switched-Capacitor AC-DC Converter for Small Power Applications** Kei Eguchi[1], Hongbing Zhu[2], Ichirou Oota[3], Shinya Terada[4], Fumio Ueno[4] *[1]Faculty of Education, Shizuoka University, Shizuoka, Japan* *[2]Department of Computer Science,* *Hiroshima Kokusai Gakuin University, Nakano Aki-ku, Hiroshima, Japan* *[3]Department of Information and Communication,* *Kumamoto National College of Technology, Kumamoto-ken, Japan* *[4]Department of Electrical System and Computer Engineering,* *Sojo University, Ikeda, Kumamoto, Japan*	**317**
TPM1-6-2 **1:20 PM**	**Approximate 2DOF Digital Control for DC-DC Converter with Additional Zeros** Eiji Takegami[1], Kohji Higuchi[2], Kazushi Nakno[2], Satoshi Tomioka[1], Kazushi Watanbe[1] *[1]DENSEI-LAMBDA K.K., Togawa, Settaya, Nagaoka, Japan* *[2]Department of Electronic Engineering,* *University of Electro-Communications, Chofu, Tokyo, Japan*	**321**
TPM1-6-3 **1:40 PM**	**New Automatic Multi-Stage Bumpless Mode Switching Digital Control for PWM Power Amplifier using Load Estimation** Ryosuke Okazaki[1], Koji Matsushita[2], Kohji Higuchi[1], Kazushi Nakano[1], Tatsuyoshi Kajikawa[1], Fumiho Chino[2] *[1]Department of Electronic Engineering,* *The University of Electro-Communications, Chofu, Tokyo, Japan* *[2]NF Corporation, Tunashimahigashi,Kohoku-ku, Yokohama, Japan*	**325**
TPM1-6-4 **2:00 PM**	**A Quasi-Constant Frequency Hysteretic Current-Programmed Converters with Control of Bifurcation** Noppadol Khaehintung[1], Chaiboon Kangsajian[1], Phaophak Sirisuk[2] *[1]Department of Control and Instrumentation Engineering,* *Mahanakorn University of Technology, Bangkok, Thailand* *[2]Department of Computer Engineering, Mahanakorn University of Technology, Thailand*	**329**

TPM1-6-5	**The Adaptive P&O Algorithm with a Hysteretic Current-mode Converter for**	**333**
2:20 PM	**a Solar-powered Battery Charger**	
	Noppadol Khaehintung[1], Phaophak Sirisuk[2]	
	[1]Department of Control and Instrumentation Engineering,	
	Mahanakorn University of Technology, Bangkok, Thailand	
	[2]Department of Computer Engineering,	
	Mahanakorn University of Technology, Bangkok, Thailand	
TPM1-6-6	**Proposal for Simple Repetitive Controllers**	**337**
2:40 PM	Kou Yamada, Hiroshi Takenaga, Yusuke Saitou, Keiji Satoh	
	Department of Mechanical System Engineering, Gunma University, Kiryu, Gunma Japan	
3:20 PM - 5:00 PM	**Session TPM2-4**	**Thursday,10 May 2007**
	High Voltage Engineering 2	
	Chairperson : Kittipong Tanmitr, Khon Kaen University	
TPM2-4-1	**Dielectric Investigation of Fresh Fruits**	**341**
3:20 PM	K. Tonmitr, A. Kaewrawang, S. Swatdiponphallop, A. Suksri,	
	A. Siritaratiwat, P.Bursri	
	Department of Electrical Engineering, Khon Kaen University, Khon Kaen, Thailand	
TPM2-4-2	**Construction of A 100 kV Capacitive Voltage Divider**	**345**
3:40 PM	J.Sarasook, S. Chotigo, B.Puengsiri	
	Department of Electrical Engineering, Faculty of Engineering,	
	King Mongkut's University of Technology Thonburi, Bangkok, Thailand	
TPM2-4-3	**The Hydrophobic of Polymeric Insulator under Industrial Dust Pollution and**	**349**
4:00 PM	**A Comparison with Artificial Pollution**	
	Apisit Chaisaengsukkul, Norasage Pattanadech, Siriwat Potivejkul	
	Electrical Engineering Department, Faculty of Engineering,	
	King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand	
TPM2-4-4	**A Comparison of Corona Inception Phenomena between Porcelain and Polymeric**	**353**
4:20 PM	**Insulators under Dust Pollution in Thailand**	
	Apisit Chaisaengsukkul, Siriwat Potivejkul, Norasage Pattanadech	
	Electrical Engineering Department, Faculty of Engineering,	
	King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand	
TPM2-4-5	**Modulation Circuit for VLF Transformer**	**357**
4:40 PM	S. Chotigo, S. Seesanga	
	Department of Electrical Engineering, Faculty of Engineering,	
	King Mongkut's University of Technology Thonburi, Bangkok, Thailand	
3:20 PM - 5:00 PM	**Session TPM2-6**	**Thursday,10 May 2007**
	Power Electronics 3	
	Chairperson : Itsada Boonyaroonate, King Mongkut's University of Technology Thonburi	
TPM2-6-1	**The Challenges of Near-Future EMC Facility**	**361**
3:20 PM	Vichate Ungvichian	
	EMI Lab., Florida Atlantic University, Boca Raton, Florida	

TPM2-6-2 **3:40 PM**	**Development of an FPGA-Based Gate Signal Generator for a Flying-Capacitor Inverter** S. Khummanee, S.Polmai *Department of Electrical Engineering, Faculty of Engineering,* *King Mongkut's Institute of Technology Ladkrabang , Bangkok, Thailand*	**366**
TPM2-6-3 **4:00 PM**	**Comparison Between Phase- and Level-shifted PWM Schemes for Flying Capacitor Multilevel Inverter** S. Ketsakoon, S. Polmai *Department of Electrical Engineering, Faculty of Engineering,* *King Mongkut's Institute of Technology Ladkrabang , Bangkok, Thailand*	**370**
TPM2-6-4 **4:20 PM**	**A New Online Control Method for Multicell Converter Based on Duty Cycle Control** Seyed Hossein Hosseini[1], M. Almaleki[2] [1]*Department Electrical Engineering, Islamic Azad University of Bonab, Bonab, Iran,* [2]*Faculty of Electric & Electronic Engineering, University of Tabriz, Tabriz, Iran*	**374**
TPM2-6-5 **4:40 PM**	**A High-Frequency Induction Cooker using Quasi-resonant Converter** Saichol Chudjuarjeen[1], Chayant Kumpai[2] [1]*Department of electrical engineering, Rajamangala University of Technology Krungthep, Rajamangala University of Technology Krungthep, Bangkok, Thailand* [2]*Department of electrical engineering, King Mongkut's University of Technology Thonburi, King Mongkut's University of Technology Thonburi, Bangkok, Thailand*	**378**

8:30 AM - 9:50 AM **Session FAM1-4** **Friday,11 May 2007**

Power Systems 2

Chairperson : Ekarin Vasanasong, Mahanakorn University of Technology

FAM1-4-1 **8:30 AM**	**New Method in Nonlinear State Estimation Single Machine Infinite Bus** Heydar Toossian Shandiz, Ahmad Hajipoor *Shahrood University of Technology, 7 Th Tir Square, Shahrood, Iran*	**382**
FAM1-4-2 **8:50 AM**	**Assessment of Reliability Worth in Distribution Systems with Substation Originated Outage by Sequential Monte Carlo Simulation** Somchai Songsiri, Somporn Sirisumrannukul *Department of Electrical Engineering, Faculty of Engineering,* *King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand*	**386**
FAM1-4-3 **9:10 AM**	**Detailed Analysis of Load Voltage Compensation** Paisan Boonchiam[1], Nadarajah Mithulananthan[2] [1]*Department of Electrical Engineering,* *Rajamangala University of Technology Thanyaburi, Pathumthani, Thailand* [2]*Energy Field of Study, Asian Institute of Technology, Thailand*	**390**
FAM1-4-4 **9:30 AM**	**A New Voltage dip and Grid Unbalance Detection Method for Distribution Static Synchronous Compensator Application** Thip Manmek[1], Chathura P. Mudannayake[2], Colin Grantham[2] [1]*Department of Control and Instrumentation Engineering,* *Mahanakorn University of Technology, Bangkok, Thailand* [2]*School of Electrical Engineering and Telecommunication,* *The University of New South Wales, Sydney, Australia*	**394**

10:30 AM - 12:10 AM **Session FAM2-4** **Friday,11 May 2007**

Electric Machinery

Chairperson : Ekarin Vasanasong, Mahanakorn University of Technology

FAM2-4-1 **Starting Jerk Reduction for Switched Reluctance Motors Using Initial Rotor Position** **398**
10:30 AM **Estimation Method**
P. Jitkreeyarn[1, 2], K. Tungpimolrut[1], P. Nakmahachalasint[2]
[1]*National Electronics and Computer Technology Center, Thailand Science Park, Pathumthani, Thailand*
[2]*Faculty of Engineering, Thammasat University, Pathumthani, Thailand*

FAM2-4-2 **Linear Model of a Switched Reluctance Machine using Flux Tube Analysis** **402**
10:50 AM C. Boonkham, S. Kittiratsatcha
Department of Electrical Engineering, Faculty of Engineering, King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand

FAM2-4-3 **Field Efficiency Estimation Technique for Inverter-Fed Induction Motor** **406**
11:10 AM T.Phumiphak[1] , C. Chat-uthai[2]
[1]*Department of Electrical Power Engineering, Mahanakorn University of Technology, Bangkok, Thailand*
[2]*Department of Electrical Engineering, King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand*

FAM2-4-4 **Design of Economical Small Transformer Base on Temperature Rise Evaluation** **410**
11:30 AM T.Phophongviwat[1], C. Chat-uthai[2]
[1]*Department of Electrical Power Engineering, Mahanakorn University of Technology, Bangkok, Thailand*
[2]*Department of Electrical Engineering, King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand*

FAM2-4-5 **Steady State and Dynamic Behaviors of Doubly Fed Induction Machines in Wind** **414**
11:50 AM **Energy Conversion Systems**
S. Wangsathitwong[1], S. Sirisumrannukul[1], S. Chatratana[2], W. Deleroi[3]
[1]*King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand*
[2]*Technology Management Center, National Science and Technology Development Agency, Thailand Science Park, Phatumthani, Thailand*
[3]*B-4728 Corsostraße 3, Hergenrath, Belgium*

10:30 AM - 11:50 AM **Session FAM2-10** **Friday,11 May 2007**

SS : Electrical Power

Chairperson : Natthaphob Nimpitiwan, Bangkok University

FAM2-10-1 **Design of Power Transformer Winding Fault Model using PSCAD/EMTDC** **418**
10:30 AM Dusit Uthitsunthorn, Teratam Bunyagul
Department of Electrical Engineering, Faculty of Engineering, King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand

FAM2-10-2 **10:50 AM**	**A study of Efficiency Improvement Tracking Algorithm for Maximum Power Point Tracking of Photovoltaic System** Chamnan. Ratsame[1], Tanes. Tanitteeapan[1], Sirichai. Thepa[2], Narong. Mungkung[1], Itsda Boonyaroonate[3] *[1]Department of Electrical Technology Education,* *[2]Division of Energy Technology,* *[3]Department of Electrical Engineering,* *King Mongkut 's University of Technology Thonburi, Bangkok, Thailand*	**422**
FAM2-10-3 **11:10 AM**	**Vibration Signal Analysis for Condition Monitoring of High Voltage Circuit Breakers** T. Suwanasri[1], N. Charbkeaw[2], T. Bunyagul[2] *[1]The Sirindhorn International Thai-German Graduate School of Engineering* *King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand* *[2]Electrical Engineering Department, Faculty of Engineering* *King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand*	**426**
FAM2-10-4 **11:30 AM**	**Generator Participating Factors for Sensitivity Analysis in a Deregulated Electricity Supply Industry** C. Adsoongnoen[1], T. Suwanasri[2] *[1]Department of Electrical and Computer Engineering, Faculty of Engineering,* *Naresuan University Phitsanulok, Thailand* *[2]The Sirindhorn International Thai-German Graduate School of Engineering,* *King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand*	**430**

1:00PM - 3:00PM	**Session FPM1-4** **Power Systems 3** Chairperson : Surachai Limyingcharoen, Khon Kaen University	**Friday,11 May 2007**
FPM1-4-1 **1:00 PM**	**A Network Topology Processor for Accurate Power System State Estimation** Warayut Kampeerawat[1], Surachai Limyingcharoen[2], Anupap Meesomboon[2] *[1]Graduate School, Department of Electrical Engineering, Khon Kaen University, Thailand* *[2]Department of Electrical Engineering, Khon Kaen University, Thailand*	**434**
FPM1-4-2 **1:20 PM**	**Topology Error Detection by Using Fast Approximate Power Flow with Power Transfer Distribution Factors (PTDFs)** Warayut Kampeerawat[1], Anupap Meesomboon[2] *[1]Graduate School, Department of Electrical Engineering, Khon Kaen University, Thailand* *[2]Department of Electrical Engineering, Khon Kaen University, Thailand*	**438**
FPM1-4-3 **1:40 PM**	**Ant Colony Optimization to Solve the Economic Dispatch Problem with Nonsmooth Cost Functions** Phakhapong Thanitakul, Yuttapoom Chernklang, Wisut Somsamai, Saravuth Pothiya *Department of Electrical Engineering, North Eastern University, Khon Kaen, Thailand*	**442**
FPM1-4-4 **2:00 PM**	**Relevant Factors for Failure Rate Estimation of Overhead Distribution Feeders** N. Teera-achariyakul, D. Rerkpreedapong *Department of Electrical Engineering, Kasetsart University, Bangkok, Thailand*	**446**

FPM1-4-5 **2:20 PM**	**Congestion Management in a Hybrid Pool and Bilateral Market** Komson Daroj[1], Bundhit Eua-Arporn[2] *Department of Electrical Engineering, Faculty of Engineering,* *[1]Ubonratchathani University ,Ubonratchathani, Thailand* *[2]Chulalongkorn University ,Bangkok, Thailand*	**450**
FPM1-4-6 **2:40 PM**	**Fault Diagnosis in Transmission Systems for Alarm Processing by Fuzzy Relation and Fault Tree Analysis** Radomboon Taksana, Somporn Sirisumrannukul *Department of Electrical Engineering, Faculty of Engineering,* *King Mongkut's Institute of Technology North Bangkok, Bangkok, Thailand*	**454**

3:20 PM - 5:00 PM — **Session FPM2-4** — **Friday,11 May 2007**

Power Systems 4

Chairperson : Teratam Bunyagul, King Mongkut's Institute of Technology North Bangkok

FPM2-4-1 **3:20 PM**	**Analysis of Substation Ground Grid for Ground Potential Rise Effect Reduction in Two-Layer Soil** A. Puttarach, N. Chakpitak , T. Kasirawat, C. Pongsriwat *ChiangMai University , ChiangMai, Thailand*	**458**
FPM2-4-2 **3:40 PM**	**Design of Automatic Generation Control Using the Method of Inequalities** Raksanai Nidhiritdhikrai, Suchin Arunsawatwong, Bundhit Eua-arporn *Department of Electrical Engineering, Faculty of Engineering,* *Chulalongkorn University, Bangkok, Thailand*	**462**
FPM2-4-3 **4:00 PM**	**Optimal Feeder Routing in Distribution System with Demand Uncertainty** S. Wattanasophona[1], B. Eua-Arpornb[2] *[1]Department of Electrical Engineering, Faculty of Engineering,* *Dhurakij Pundit University, Bangkok, Thailand* *[2]Department of Electrical Engineering, Chulalongkorn University, Bangkok, Thailand*	**466**
FPM2-4-4 **4:20 PM**	**Optimal Capacitor Banks Placement and N-1 Contingency Improvement Using Excels Solver: Case of Laos PDR.** S. Hungsasutra, A.Suksri, J. Triyangkulsri, M. Vonglokham *Department of Electrical Engineering, Faculty of Engineering,* *Khon Kaen University, Khon Kaen, Thailand*	**470**
FPM2-4-5 **4:40 PM**	**Voltage Sag Compensation Capability by Parallel Type Compensator with Series Inductor** Sumate Naetiladdanon *Department of Electrical Engineering* *King Mongkut's University of Technology Thonburi, Bangkok, Thailand*	**474**

8:30 AM - 10:10 AM	Session FAM1-7	Friday,11 May 2007

Material Technology

Chairperson : Chanchana Thanachaynont, National Metal and Materials Technology Center

FAM1-7-1 **8:30 AM**	**Application of Nanoporous Silicon for Visible Light Photodetector** N. Atiwongsangthong, S. Niemcharoen, K. Sato, W. Titiroongruang *Electronics Research Center, Faculty of Engineering,* *King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand*	**478**
FAM1-7-2 **8:50 AM**	**Computational Molecular Modeling and Simulation of Functionalized Carbon Nanotubes** Chatchawal Wongchoosuk[1], Sriprajak Krongsuk[2], Teerakiat Kerdcharoen[1,3] [1]*Department of Physics and Center of Nanoscience and Nanotechnology, Mahidol University, Bangkok, Thailand* [2]*Department of Physics, Khon Kaen University, Khon Kaen, Thailand* [3]*Networked Laboratory of Nanodevice Engineering, National Nanotechnology Center, Pathumthani, Thailand*	**482**
FAM1-7-3 **9:10 AM**	**The Electronic and Energetic Properties of Linearly Fused Single-walled Carbon Nanotubes by Pentagon-Heptagon Pair Defects** Md.Shafiqzzaman[1], Anurak Udomvech[1,2], Teerakiat Kerdcharoen[1] [1]*Department of Physics and Center of Nanoscience and Nanotechnology, Mahidol University, Bangkok, Thailand* [2]*Department of Physics, Thaksin University, Songkhla, Thailand*	**485**
FAM1-7-4 **9:30 AM**	**Optical Profiling on Lateral Spreading of Space-Charge-Region Metal-Semiconductor-Metal Structures** S.Khunkhao[1], A.Thaworn[1], S.Somdetsakun[1], S.Nuanloy[1], S.Korchareon[2], S. Niemcharoen[2] [1]*Department of Electrical engineering, Sripatum University, Bangkok, Thailand* [2]*Electronics Research Center, Faculty of Engineering, King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand*	**489**
FAM1-7-5 **9:50 AM**	**Influences of Fabrication Process on Aggregation of Conjugated Polymer in Thin Films and its Roles on the Performance of Plastic Solar Cells** Kasin Kasemsuwan[1], Chanchana Thanachayanont[2], Rakchart Traiphol[3], Teerakiat Kerdcharoen[1] [1]*Department of Physics and Center of Nanoscience and Nanotechnology, Mahidol University, Thailand* [2]*National Metal and Materials Technology Center, Thailand* [3]*Department of Chemistry, Faculty of Science, Naresuan University, Thailand*	**493**

10:30 AM - 12:10 AM | **Session FAM2-7** | **Friday,11 May 2007**

Biologocal EE

Chairperson : Werapon Jiracharit, King Mongkut's University of Technology Thonburi

FAM2-7-1 **Application of an Electronic Nose for Body Odor Recognition: Opportunity and Problem** **497**
10:30 AM
Sanchai Harnsoongnoen[1], Mario Lutz[2], Neti Waranuch[3], Adisorn Tuantranont[4], Teerakiat Kerdcharoen[2]
[1]Department of Physics, Faculty of Science, Mahasarakham University, Mahasarakham, Thailand
[2]Department of Physics and Center of Nanoscience and Nanotechnology, Faculty of Science, Mahidol University, Bangkok, Thailand
[3]Cosmetics and Natural Products Research Center, Faculty of Pharmaceutical Sciences, Naresuan University, Phitsanuloke, Thailand
[4]Nanoelectronic and MEMS Lab, National Electronic and Computer Technology Center, Pathumthani, Thailand

FAM2-7-2 **Lighting System for Growth Enhancement of Thai Orchids** **501**
10:50 AM
Phanumas Khumsat, Kamplon Panprayoon
Department of Electrical Engineering, Prince of Songkla Univesity, Hat-Yai, Thailand

FAM2-7-3 **Electronic Nose System for Orange Juice Freshness Quality Control** **505**
11:10 AM
Wattanasit Pimpao[1, 2], Assawapong Sappat[1], Teerakiat Kerdcharoen[3], Manas Sangworasil[2]
[1]Nanoelectronics and MEMS Laboratory, National Electronics and Computer Technology Center (NECTEC), Thailand Science Park, Pathumthani, Thailand
[2]Department of Electronics, Faculty of Engineering, King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand
[3]Department of Physics, Center of Nanoscience and Nanotechnology, Faculty of Science, Mahidol University, Bangkok, Thailand

FAM2-7-4 **A Wireless Heart Rate Monitor for Fitness Exercise Researches Using 2.4 GHz RF Transceivers** **509**
11:30 AM
W. Siwaprapakorn[1], B. Charoen[2]
[1]Graduate School, Faculty of Engineering, Khon Kaen University, Thailand
[2]Department of Electrical Engineering, Faculty of Engineering, Khon Kaen University, Thailand

FAM2-7-5 **An Algorithm of 3D Objects Connection for Dental Bridge Design** **513**
11:50 AM
Teeraporn Kusalanukhun, Chanjira Sinthanayothin, Wichit Tharanon
Advanced Dental Technology Center (ADTEC), National Science and Technology Development Agency (NSTDA), Thailand Science Park, Pathumthani, Thailand

1:00 PM - 3:00 PM | **Session FPM1-6** | **Friday,11 May 2007**

Biometric

Chairperson : Somying Thainimit, Kasetsart University

FPM1-6-1 **Adaptive Thresholding for Iris Recognition** **517**
1:00 PM
Peeranat Thoonsaengngam, Somying Thainimit
Kasetsart Signal and Image Processing Laboratory (KSIP Lab), Department of Electrical Engineering, Kasetsart University, Bangkok, Thailand

FPM1-6-2	**On-Line Signature Verification Based on Time-Frequency Characteristics**	**521**
1:20 PM	**of Barycenter Trajectory**	
	P.Thumwarin[1], N.Suthithummathat[1], T.Matsuura[2]	
	[1]Research Center for Communications and Information Technology,	
	King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand	
	[2]Faculty of Information Technology and Electronics, Tokai University, Japan	
FPM1-6-3	**Signature Identification Using Linear Predictive Code Coefficients and Neural Network**	**525**
1:40 PM	T. Wijitpornchai, J. Koseeyaporn, P. Wardkein	
	Department of Telecommunication Engineering, Faculty of Engineering,	
	King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand	
FPM1-6-4	**Generalized N-Tuple Machine on Signature Verification**	**529**
2:00 PM	Phongsan Nunsuk, Yuttana Kitjaidure	
	King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand.	
FPM1-6-5	**Detection Segment Retinal Blood Vessel of Anatomical Structures in Retinal Image**	**533**
2:20 PM	Chaichana Thanapong[1], Sookpotharom Supot[1,2], Turmchokkasam Sirichai[2],	
	Pintavirooj Chuchart[1], Sangworasil Manas[1,2]	
	[1]Faculty of Engineering, Computer Research and Service Center,	
	King Mongkut's Institute of Technology Landkrabang, Bangkok, Thailand	
	[2]School of Engineering, Bangkok University, Pathumtani, Thailand	
FPM1-6-6	**Identification of Carcinoma in Situ from Segmented Squamous Cervical Cells**	**537**
2:40 PM	C. Aupayagoson, W. Chiracharit, K. Chamnongthai	
	Department of Electronic and Telecommunication Engineering,	
	King Mongkut's University of Technology Thonburi, Bangkok, Thailand	

1:00 PM - 3:00 PM	**Session FPM1-10**	**Friday,11 May 2007**
	SS : Hard Disk Drives	
	Chairperson : Kamon Jirasereeamornkul, King Mongkut's University of Technology Thonburi	
FPM1-10-1	**Effect of D.C. Field-Induced Breakdown on GMR Heads at Slider-Bar Level**	**541**
1:00 PM	A. Siritaratiwat [1,2], N. Suwannata[2], C. Sukprong [2]	
	[1]Industrial/University Cooperative Research Center in HDD Component,	
	Khon Kaen University, Khon Kaen, Thailand	
	[2]Department of Electrical Engineering, Khon Kaen University, Khon Kaen, Thailand	
FPM1-10-2	**A Study of RFID-Electromagnetic Field Effect on Recording Heads in Writing Process**	**545**
1:20 PM	A. Pratoomthip[1,2], C. Sa-ngiamsak[2], A. Siritaratiwat[2]	
	[1]Graduate school, Khon Kaen University, Thailand	
	[2]Department of Electrical Engineering, Khon Kaen University, Thailand	
FPM1-10-3	**The Effect of Head Protrusion on Recording Field for Perpendicular Recording System**	**549**
1:40 PM	D. Tongsomporn[1], A. Siritaratiwat [2], N. Afzulpurkar[3], B. Bargmann[4]	
	[1]Microelectronics Field of Study, Asian Institute of Technology, Thailand	
	[2]KKU-Seagate Cooperation Research Laboratory, Department of Electrical Engineering,	
	Khon Kaen University, Thailand	
	[3]School of Engineering and Technology, Asian Institute of Technology, Thailand	
	[4]Seagate Technology (Thailand) Co., Ltd., Nakorn Ratchasima, Thailand	

FPM1-10-4	**Design of High-Rate Modified Array Codes for Magnetic Recording System**	**553**
2:00 PM	W. Singhaudom, S. Noppanakeepong, P. Suphithi *Research Center for Communications and Information Technology (ReCCIT),* *I/U CRC in Data Storage Technology and Applications,* *King Mongkut's Institute of Technology Ladkrabang, Bankok, Thailand*	
FPM1-10-5	**Subblock Encoder Design of Modified Array-Based Low-Density Parity-Check Codes**	**557**
2:20 PM	P. Leekul[1], S. Chivapreecha[1], K. Sripimanwat[2], P. Supnithi[1] [1]*Research Center for Communications and Information Technology,* *I/U CRC in Data Storage Technology and Applications,* *King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand* [2]*National Electronics and Computer Technology (NECTEC),* *Thailand Science Park, Patumthani, Thailand*	
FPM1-10-6	**Timing Recovery in Magnetic Recording Systems**	**561**
2:40 PM	Piya Kovintavewat *Faculty of Science and Technology,* *Nakhon Pathom Rajabhat University, Nakhon Pathom, Thailand*	
3:20 PM - 5:00 AM	**Session FPM2-2**	**Friday,11 May 2007**
	Medical Technology Chairperson : Supawadee Swatdiponphallop, Khon Kaen University	
FPM2-2-1	**ECG Classification Using Fisher's Discriminant and Fuzzy c-mean**	**565**
3:20 PM	Sayan Rakbanjong, Yuttana Kitjaidure *King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand*	
FPM2-2-2	**ECG Data Compression by Wavelet-Based Average Beat Subtraction (WABS)**	**569**
3:40 PM	S. Pathoumvanh[1], S. Airphaiboon[1], M. Sangworasil[1], K. Hamamoto[2] [1]*Research Center for Communications and Information Technology (ReCCIT),* *King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand* [2]*Tokai University, Information Media Technology Department, Kanagawa, Japan*	
FPM2-2-3	**Classification of Muscular Contraction Using EMG Topological Mapping**	**573**
4:00 PM	D. Sueaseenak[1,3], T. Chanwimalueang[1], K. Wong-ek[2], N. Laoopugsin[3], C. Pintavirooj[1] [1]*Research Center for Communication and Information Technology (ReCCIT),* *Department of Electronics, King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand* [2]*Department of Medical Technology, Faculty of Applied Health Science,* *Thammasat University, Pratumthanee, Thailand* [3]*Faculty of Medicine, Srinakharinwirot University, Nakorn Nayok, Thailand*	
FPM2-2-4	**An Automatic Classification of Microcalcification Clusters Using Shape and**	**577**
4:20 PM	**Distribution Features** W. Chiracharit *Department of Electronic and Telecommunication Engineering,* *King Mongkut's University of Technology Thonburi, Bangkok, Thailand*	
FPM2-2-5	**3D Shape-Recovery System Based on Photographic Tomography with Flexible Camera**	**581**
4:40 PM	**Orientation** P. Greesuradej, S. Gimjumpa, M. Sangworasil, C. Pintavirooj *Research Center for Communications and Technology (ReCCIT),* *King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand*	

3:20 PM - 4:40 PM | **Session FPM2-3** | **Friday,11 May 2007**

General EE

Chairperson : Punnarumol Temdee, Mae Fah Luang University

FPM2-3-1	**Production Planning and Scheduling Approach in a Supply Chain**	**585**
3:20 PM	R. Masuchun *Faculty of Engineering, King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand*	
FPM2-3-2	**Distributed Context Aware System for Travel Time Estimation Based on**	**589**
3:40 PM	**Cellular Probes in Metropolitan Environment** Panraphee Raphiphan[1], Arkady Zaslavsky[1], Wasan Pattara-Atikom[2], Passakon Prathombutr[2] [1]*Caufield School of Information Technology, Monash University, Caulfield East, Australia* [2]*National Electronics and Computer Technology Center,* *Thailand Science Park, Pathumthani, Thailand*	
FPM2-3-3	**Ontology Development: An Integrated Engineering Approach**	**593**

***Abstract*–In this paper, a high frequency and high precision CMOS half-wave rectifier circuit with positive and negative outputs is presented. The proposed circuit consists of a voltage-to-current converter, a precision current-mode rectifier with operating in class-AB, and two current-to-voltage converters. A voltage input signal is changed into a current signal by the voltage-to-current converter. The class-AB current mode rectifiers rectify these current signals, resulting in positive and negative half-wave current signals that are converted to positive and negative half-wave voltage signals by the current-to-voltage converters. The circuit exhibits low component counts, high frequency operation, good temperature stability and suitable of IC fabrication. The simulation results are used to verify the performance of the proposed circuit. Simulated rectifier performance with standard 0.5μm CMOS technology using ±1.2V supply voltage shows the proposed half-wave rectifier circuit provides an operating frequency more than 250MHz and excellent temperature stability.**

I. INTRODUCTION

Precision rectifier is one of important nonlinear circuits extensively used in wattmeter, AC voltmeter, RF demodulator, function fitting, triangular-wave frequency doubling, error measurements and RMS to DC conversions. Usually, a rectifier can be realized by using diodes but diode rectifier is limited by the threshold voltage of diodes. As a result diode-only rectifiers are used in only those applications in which the precision in the range of threshold voltage is insignificant, such as RF demodulators and DC voltage supply rectifiers. To overcome this problem is based on the use of operational amplifiers (op-amps), diodes, and resistors [1]-[4]. However, the classical problem with conventional precision rectifiers based on op-amps and diodes is that during the non-conduction/conduction transition of the diodes the op-amps must recover with a finite small-signal dv/dt (slew-rate) resulting in significant distortion during the zero crossing of the input signal. Moreover, op-amps-based precision rectifier circuits are limited to a frequency performance well below the gain-bandwidth product (GBW) of op-amps [5]. This problem was improved by designing the rectifier circuit by the use of the current rectifying techniques [5]-[11]. The current conveyors-based current-mode rectifier circuits were presented in [5]-[7] enjoy the high precision. However, the proposed circuits require a floating resistor and grounded resistors, which is not ideal for IC implementation and some of these have problem about temperature stability [5],[6]. In [7] was realized a current-mode rectifier circuit based on the use of one current conveyor and bipolar transistors operating in class-B, this circuit is a realization that enjoys the high precision rectifier. However, the two grounded resistors are used and the high frequency performance is limited in this scheme. In [8]-[9] proposed the current-mode CMOS rectifier circuits operating in class-AB. This technique requires the signal current to be greater than four times of the bias current to avoid the square-law error of MOS transistors. However, the circuit features wide-band capability. Recently, a dual output CMOS half-wave rectifier circuit has been proposed in [10]. This circuit composed of two sections. The first is rectifier circuit uses the V-I converter to change the input voltage into currents, the diodes to rectify the currents, and the I-V converters to change the rectified currents into the output voltage. Second is the bias voltage source circuit, it used the diodes bias voltages to clad the output voltage excursion during the zero crossings. The advantages of this circuit are: (i) all of MOS transistors are used, thus the circuit suitable for IC fabrication, (ii) employs a ±1.2V supply voltage and provides an operating frequencies up to 100MHz, and (iii) high accuracy and good temperature stability by using the bias voltage source circuit. In [11] proposed a rectifier circuit by using all MOS transistors suitable for IC fabrication and high operating frequency up to 200MHz.

In this paper, a high frequency CMOS half-wave rectifier circuit is presented. The proposed circuit consists of a voltage-to-current converter, a current-mode precision rectifier with operating in class-AB to support the high frequency operation, and two current-to-voltage converters. In particular, the proposed half-wave rectifier circuit has the following features:

- The proposed rectifier uses 31 MOS transistors whereas the proposed rectifier in [10] uses 44 MOS transistors; hence when the rectifier circuits are fabricated, the proposed rectifier will be used small area of chip than the previous rectifier.
- The proposed rectifier using supply voltage about ±1.2V is equal to the rectifier circuit in [10]. However, the proposed rectifier provides an operating frequency more than 250MHz, whereas in [10] identified by authors is 100MHz (simulated results with 0.5μm CMOS model obtained though MIETEC).
- The proposed half-wave rectifier provides excellent temperature stability without compensation circuit.

II. CIRCUIT REALZATION

The proposed CMOS half-wave rectifier circuit realization scheme consisting of three main components: the V-I converter, the current-mode rectifiers, and the I-V converters, as shown in Fig. 1. The V-I converter is composed of negative-type CCII (CCII-) (M1-M17) and input resistor R_{in} (MR1-MR2), the precision current rectifier is current mirrors (MC1-MC4) and current sources and (I_1-I_5), and I-V converters are composed of resistors R_{o1} (MR3-MR4) and R_{o2} (MR5-MR6). The operation of the half-wave rectifier circuit is as follows. When the input voltage V_{in} is applied into the circuit, it is converted to current i_z by negative-type CCII (CCII-) and a grounded resistor R_{in}. The grounded resistors can be implemented by two matched MOS transistors are diode-connected [12]. In Fig. 1(b), assume MR1 and MR2 operating in saturation region and have the same characteristics. The resistance value of MOS resistor of Fig. 1(b) can be expressed as [12]:

$$R = \frac{1}{2K(V_{DD} - V_{TH})} \tag{1}$$

where $K=\mu_O C_{OX}(W/L)$, V_{TH}=threshold voltage, V_{DD}=-V_{SS}=supply voltage, μ_O is the carrier mobility, C_{OX} is the gate capacitance per unit area, W and L are the channel width and length, respectively. Therefore the current i_z can be written as

$$i_z = \frac{V_{in}}{R_{in}} \tag{2}$$

The MOS transistor MD2 and the current source I_1 generate a constant voltages V_A, and the MOS transistor MD4 and the current source I_2 generate constant voltages V_B to provide bias voltage for MOS transistors MD1 and MD3, respectively. The constant voltage V_A and V_B should be fairly close to the threshold voltage of MOS transistors MD2 and MD4, respectively, to obtain precision results, and cause them to operating in class-AB. CM1 and CM2 is applied by the current sources I_3 and I_4, respectively, which ensures that two current mirrors are on all the times to the improving frequency response and overall system linearity. When i_z>0, this current is fed through MD1 and then is reflected by CM1 to the output current of CM1 as I_{o1} (+i_z). In addition, when i_z<0, this current is fed through MD3 and then is reflected by CM2 to the output current of CM2 as I_{o2} (+i_z). The relations between the input current, i_z, and the output current of CM1 as I_{o1}, and the output current of CM2 as I_{o2} can be expressed as

$$i > 0; I_{o1} = +i_z + I_5 \tag{3}$$
$$i < 0; I_{o2} = +i_z + I_6 \tag{4}$$

Since the constant current sources, I_5 and I_6, compensate the offset currents, I_3+I_1 and I_4+I_2, respectively, from (4) and (4), the currents I_{o1} and I_{o2} can be rewritten as

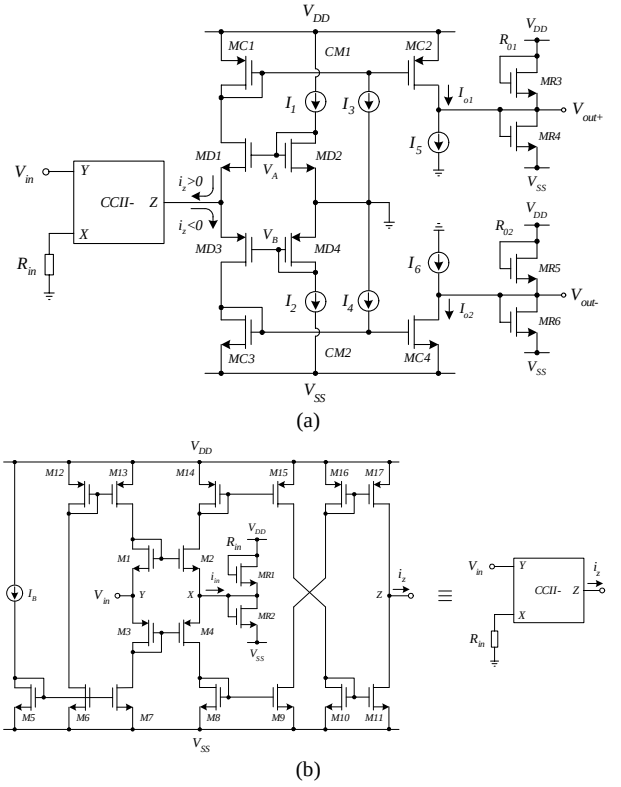

Fig. 1. (a) Proposed half-wave rectifier circuit, (b) a voltage to current converter circuit using CCII- and MOS resistor.

Since the constant current sources, I_5 and I_6, compensate the offset currents, I_3+I_1 and I_4+I_2, respectively, from (4) and (4), the currents I_{o1} and I_{o2} can be rewritten as

$$i > 0; I_{o1} = +i_z \tag{5}$$
$$i < 0; I_{o2} = +i_z \tag{6}$$

Suppose R_{o1}=R_{o2}=R_{in}, with the use of the closely matched MR1 to MR6, we can write the relations between V_{in}, and V_{out+} as

$$V_{in} > 0; V_{out+} = V_{in} \tag{7}$$
$$V_{in} < 0; V_{out+} = 0 \tag{8}$$

and the relations between V_{in}, and V_{out}- as

$$V_{in} > 0; V_{out-} = 0 \tag{9}$$
$$V_{in} < 0; V_{out-} = V_{in} \tag{10}$$

This means that the proposed rectifier can be operated as positive and negative half-wave rectifier into a single circuit.

III. SIMULATION RESULTS

In order to test the ideal designed, the scheme of dual output half-wave rectifier of Fig. 1 has been simulated using PSPICE simulation program. For the circuit simulation, the 0.5μm CMOS model obtained though MIETEC as listed in [10] is used. The aspect ratios (W/L) of MOS transistors are: 10μm/0.6μm for M1-M2, M5-

M11, MD1-MD2, MC3-MC4; 40µm/0.6µm for M3-M4, M12-M17; 30µm/0.6µm for MD3-MD4, MC1-MC2; 4µm/0.6µm for MR1-MR2; 2µm/0.6µm for MR3-MR6. The supply voltage used is ±1.2V. The current sources I_B=50µA, I_1=I_2=5µA, and I_3=I_4=100µA. The first test applied an input signal of amplitude 200mV peak and frequencies100MHz and 250MHz. The results of these tests are shown in figures 2 and 3, respectively. As is evident, satisfied half-wave rectified signals are produced at all two frequencies. This is as a direct result of the operation of the class-AB and the fast action of the voltage-to-current converter using the CCII. The amplitude errors between the input and output signals in figure 3 results from the decrease of the gain of the proposed rectifier for the operation at high frequency. It can correct by increase the value of R_{o1} and R_{o2}.

Several solutions to improve the poor temperature characteristic have been proposed. The good temperature stability can be achieved. However, it is causes of few problems such as use of many transistors [10], the precision decreasing at the high frequency [13], and the solving technique only suitable for bipolar technology [14]. To demonstrate the temperature performance of proposed circuit of Fig. 1, we simulate the proposed circuit in Fig. 1 at the frequency of 100MHz by changing temperatures form 50°C to 100°.

Fig. 3. Operation of half-wave rectifier at the input signal frequency 250MHz: (a) the input and positive half-wave output V_{out+} and (b) the input and negative half-wave output V_{out-}.

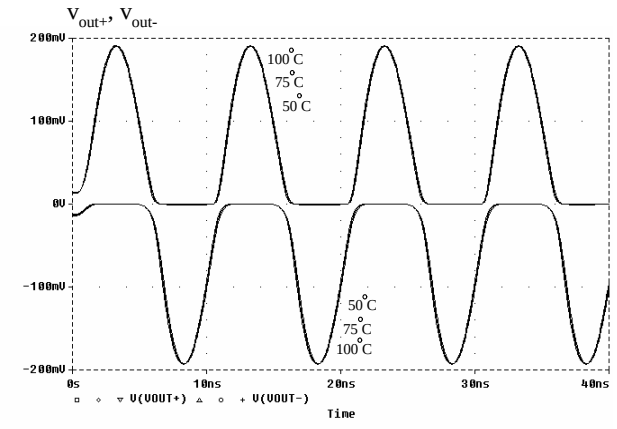

Fig. 4. Output wave forms at different temperature at the input signal frequency 100MHz.

Fig. 4 shows the output waveforms of the proposed rectifier at temperature of 50°C, 75°C, and 100°C. In Fig. 4, it can see that the proposed circuit very temperature stable without the compensation technique. In [8], [9] recommended that the class-AB technique requires the signal current to be greater than four times of the bias current to avoid the square-law error of MOS transistors.

This limitation can be corrected by setting the quiescent currents. The changing of the quiescent currents is directly proportional to the zero crossing. To demonstrate this point, we simulate the proposed rectifier in Fig. 1 again. Fig. 5(a) shown the operation of half-wave rectifier at the bias currents I_1=I_2=1µA and the input signal frequency 100MHz for 25mV_{peak}, (a) the input and output V_{out+}, (b) the input and output V_{out-}. Note that the precision and frequency range parameters of proposed rectifier can be controlled. Two parameters dependence on the setting of the quiescent currents, $I_1$and I_2, The low quiescent current may limit the high frequency capability of the proposed rectifier. In this case may be is an advantage for application. When we want to application in high precision system, the precision rectifier can be given. Again, if we want to application in high frequency system, the frequency range can be controlled.

IV. CONCLUSIONS

A high frequency and high precision CMOS half-wave rectifier circuit was presented. The proposed circuit have distinguish in used of a negative-type CCII, current mirrors, and current sources and its combine a positive half-wave rectifier, a negative half-wave rectifier into single circuit. Although, the proposed rectifier is based on previously reported circuit conveyor rectifier but with the different circuit structure, the proposed half-wave rectifier yields features superior to the previously proposed current conveyor rectifier in view of the voltage employed, the power consumption, the number of devices, the operating frequency, and the temperature stability. The configuration described is very suitable for integrated circuit implementation in both bipolar and CMOS technology. The performance of the proposed circuit is confirmed from PSPICE simulation results.

***Abstract* - To simplify structure of a sinusoidal generator without serious performance degradation is one of major challenges in circuit design. An extremely simplified architecture triangular-and-trapezoidal-to-sine converter is presented. Curve of output signal, generated by the converter, is also low sensitive to temperature. Results from HSPICE simulations show that the approximated signal with a total harmonic content of 0.54 percent and an SFDR of –46 dBc at 1 kHz is achieved. The SDFR of output signal is adequate to be used in instrumentation systems.**

I. INTRODUCTION

Sinusoidal-function generators have been used in widely ranges of applications such as in modern communication module, instrument and motor control application. For communication applications, a waveform with -60 dBc of SFDR or better is acceptable while only -40 dBc one is required for instrument applications [2]. Many techniques to realize sinusoidal waveforms have been reported. Most of them, such as [1], [3] and [6], are based on nonlinear or picewise-linear approximations because it is difficult to directly generate a sinusoidal waveform.

Fig. 1 shows the general structure of sinusoidal generators that is divided into two parts. The first part is a signal generator, which is controlled by other circuits. The generator could employ triangular and trapezoidal function generators that are basic building blocks, [5]. The signals are fed to the second part called a converter. It converts linear signals to sinusoidal signals using nonlinear approximations. The study adopts this architecture to realize sinusoidal waveform. This paper reports the modification of the design of the converter structure, based on MOS differential pair amplifiers. The purposed circuits are based on n-well CMOS technology that provide isolated n-well PMOS transistor, which is useful to eliminate the body effect.

II. NONLINEAR FUNCTIONS

A set of nonlinear functions, whose domain and range are $\{x|\ 0 \le x \le 1\}$, is used to approximate an ideal sinusoidal function in the 1st quadrant. These functions are defined in (1) as shown in Fig. 2 (a).

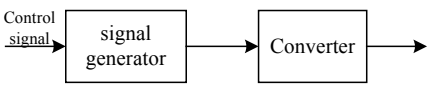

Fig. 1. General structure of sinusoidal generators

On the specified domain, the first function that is always lower than the sine function is named *the inner function* or $f_I(x)$. The second function is always larger than the sine function, so it is called the outer function or $f_O(x)$. These properties of the two functions are averaged and this average results in the average function denoted by $f_A(x)$. Since it is very close to the sine function, the error between the average and sine functions can be observed and shown in Fig. 2 (b).

A triangular-and-trapezoidal-to-sine converter (TTSC) is employed to generate the average function. The TTSC inputs, generated by amplifiers whose details are not reported in this paper, consist of two triangular waveforms (v_A and v_B), two trapezoidal waveforms (v_M and v_N) and constant voltage reference (V_{REF}). The amplifiers provide four input waveforms, derived from a triangular waveform denoted by v_{PH}. The signals are expressed in (2) that shown in Fig. 4.

$$\begin{aligned} f_I &= x\sqrt{2-x^2} \\ f_O &= x(2-x) \\ f_A &= (f_I + f_O)/2 \\ f_S(x) &= \sin(\pi/2\, x) \end{aligned} \tag{1}$$

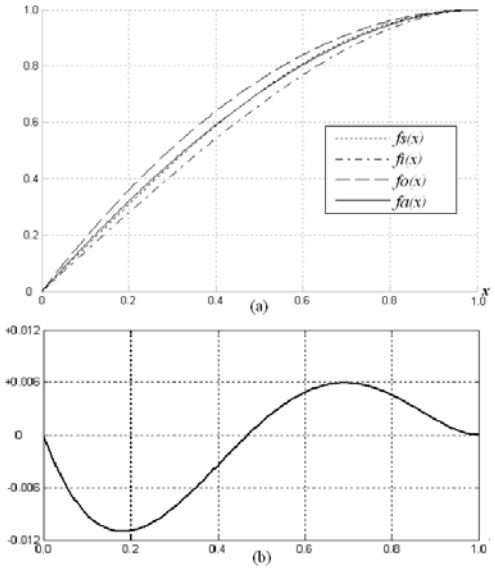

Fig. 2. (a) Nonlinear functions (b) $f_S(x) - f_A(x)$

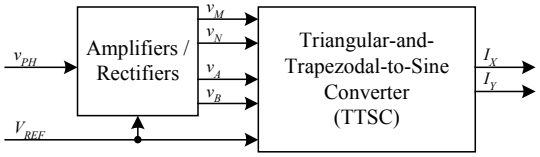

Fig. 3. Block diagram

$$
\begin{aligned}
v_A &= \frac{d_{AB}}{2V_{PH-PK}} v_{PH} + V_{CM} \\
v_B &= \frac{-d_{AB}}{2V_{PH-PK}} v_{PH} + V_{CM} \\
v_M &= \min\left\{ \frac{d_{MN}}{V_{PH-PK}} v_{PH} + d_{MN},\ d_{MN} \right\} \\
v_N &= \min\left\{ -\frac{d_{MN}}{V_{PH-PK}} v_{PH} + d_{MN},\ d_{MN} \right\}
\end{aligned}
\tag{2}
$$

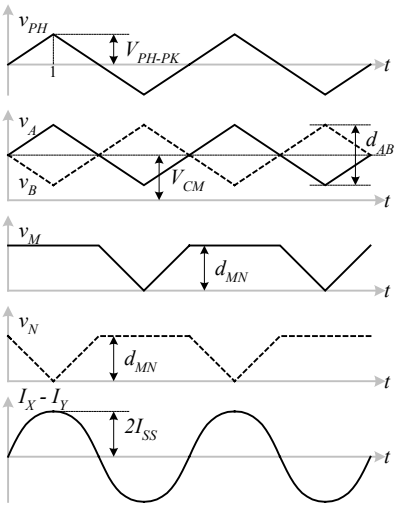

Fig. 4. Input and output signals of TTSC

Fig. 5 shows more details of the TTSC block diagram. The $(v_A - v_B)$ is a differential signal whose common-mode voltage denoted by V_{CM}. The v_A and v_B are fed directly into the inner function generator, while v_M and v_N are pre-compensated before being fed into the outer function generator. Finally, outputs of the two generators are summed and divided by 2 in order to achieve the average function. Dividing the summation by 2 is not necessary because the curve of the final output $(I_X - I_Y)$, which is two times of the average function, is also close to a sine function.

III. Practical Design

There are three kinds of building block circuits used to construct the TTSC, shown in Fig. 5. The inner function generator employs a differential pair amplifier. Secondly, the outer function generator composes of two MOS transistors. The two MOS transistors can be considered as a very basic differential amplifier without a current tail. The third circuit is a threshold-voltage compensated circuit denoted by THVC.

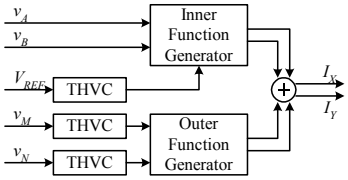

Fig. 5. Structure of TTSC

A. Square Law Based Functions

In order to generate the inner function, v_A and v_B are fed at the inputs of a differential pair amplifier, shown in Fig. 6 (a). According to Razavi [4], given that the second order effects are neglected, the description of a relation between $(v_A - v_B)$ and $(i_A - i_B)$ using square law model as shown in (3) can be achieved based on the assumption that two NMOS transistors, M_A and M_B, are identical match and in a saturated region.

$$
(i_A - i_B) = k_{AB}(v_A - v_B)\sqrt{\frac{2I_{SS}}{k_{AB}} - (v_A - v_B)^2} \tag{3}
$$

where

$k_{AB} = \frac{1}{2}\mu C_{ox}(W/L)_{AB}$

$(W/L)_{AB}$ aspect ratio of M_A and M_B

When v_A is more highly positive enough than v_B, it causes M_B to turn off. As a result, M_A drains the entire current. In this condition, $(i_A - i_B)$ equals to I_{SS}. We define a minimum value of $|vA - vB|$ that can put the circuit into the condition, as d_{AB}. The proper value of d_{AB} is expressed in (4).

$$
d_{AB} = \sqrt{I_{SS}/k_{AB}} \tag{4}
$$

From Fig. 4, $(v_A - v_B)$ equals to d_{AB} when t = 1. Equation (5) which is a normalized function is derived from (4) and (3) which is divided by I_{SS}.

$$
\frac{(i_A - i_B)}{I_{SS}} = t\sqrt{2 - t^2} \tag{5}
$$

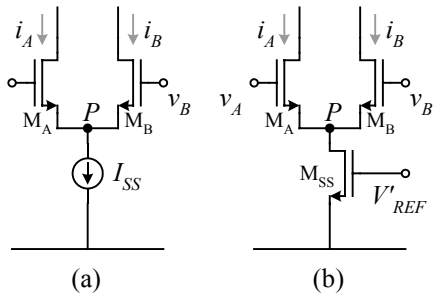

Fig. 6. A differential pair amplifier with (a) an ideal current source (b) an NMOS as bias current

Sweeping $(v_A - v_B)$ over the proper range of $\pm d_{AB}$ brings the achievement of the inner function in (5). Unfortunately, if temperature increases, k_{AB} will considerably decrease while d_{AB} remains constant. The output cannot reach I_{SS} while input

reaches its maximum d_{AB}. This causes a *pointed distortion*, shown in Fig 7. On the other hand, when temperature decreases, k_{AB} considerably increases. The output reaches I_{ss} while the input is lower than d_{AB}. This causes another kind of distortion, called *clipped distortion* [1].

To eliminate temperature dependency, M_{SS} is used as bias current instead of an ideal current source I_{SS}, shown in Fig. 6 (b). The ratio of M_A and M_{SS} aspect-ratio is given by $(W/L)_{AB} = F_1(W/L)_{SS}$. The override voltage of M_{SS} is $V'_{REF} - V_{TH}$ and V_P is high enough to put M_{SS} in saturated region. Because the value of V_P tracks V_{CM}, the minimum value of V_{CM} should agree with the expression in (7) in order to ensure that M_{SS} is in saturated region. Then the proper value of d_{AB} is redefined as (6).

$$d_{AB} = (V'_{REF} - V_{TH}) \Big/ \sqrt{F_1} \tag{6}$$

$$V_{CM} \geq \left(1 + 1\Big/\sqrt{2F_1}\right)(V'_{REF} - V_{TH}) + V_{TH} \tag{7}$$

The right-hand side of (6) remains sensitive to temperature because V_{TH} also depends on temperature. However, (6) is more practical than (4) because k_{AB} is more sensitive to temperature than V_{TH}, reported in [2]. V_{TH} effect can be compensated with a THVC circuit, shown below.

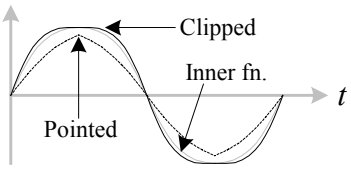

Fig. 7. Distortions due to change of k_{AB}

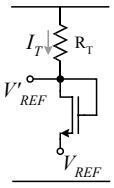

Figure 8. A threshold voltage compensated circuit

$$\frac{\sqrt{V_{DD} - V'_{REF}}}{V'_{REF} - V_{REF} - V_{TH}} = \sqrt{\tfrac{1}{2}\mu C_{ox}(W/L)_T R_T} \tag{8}$$

The expression in (8) is achieved from applying Ohm's law and square law to the circuit shown in Fig. 8. Enlarging the right-hand side of (8) makes V'_{REF} close to $V_{REF} + V_{TH}$. Then the value of term $(W/L)_T R_T$ should be large. Again, the proper value of d_{AB} is redefined as (9).

$$d_{AB} = V_{REF} \Big/ \sqrt{F_1} \tag{9}$$

From (9), the proper input range becomes temperature independent. From (5), by replacing I_{SS} with $k_{SS}V^2_{REF}$, the inner function becomes (10). Although the function's amplitude depends on k_{SS} whose temperature-dependency is very high, the function's curve is not changed.

$$\frac{(i_A - i_B)}{k_{SS}V^2_{REF}} = t\sqrt{2 - t^2} \tag{10}$$

Let's revisit the expression of the outer function in (1). In order to achieve the outer function, $x(2\text{-}x)$, negative, shift and mirror operations are requested to perform on a basic square function, x^2. As a result, the outer function generator circuit is nothing more than two identical match NMOS transistors whose characteristics obey the square law, shown in Fig. 9 (a). The gate terminals of two NMOS transistors: M_M and M_N, are driven by threshold voltage compensated signals, v'_M and v'_N. The effective override voltages are v_M and v_N, respectively. The maximum current, created by M_M and M_N, must equal the current generated by M_{SS} in the inner function generator. This gives an expression, shown in (11). And the ratio of $M_{M,N}$ and M_{SS} aspect-ratio is given by $(W/L)_{MN} = F_2(W/L)_{SS}$. Then the relation between d_{NM} and V_{REF} is expressed in (12).

$$k_{MN}d^2_{MN} = k_{SS}V^2_{REF} \tag{11}$$

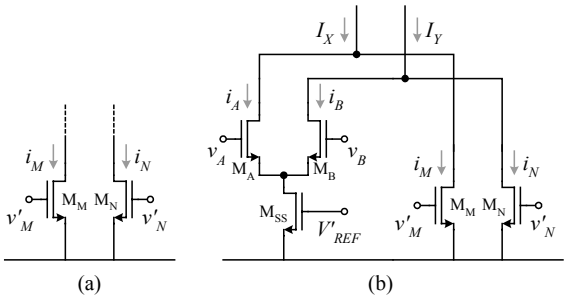

Fig. 9 (a) A differential amplifier without a current tail
(b) a combination of the inner and outer function generators

$$d_{MN} = V_{REF} \Big/ \sqrt{F_2} \tag{12}$$

$$i_M - i_N = k_{MN}v^2_M - k_{MN}v^2_N \tag{13}$$

From Fig. 4, on the range $0 \leq t \leq 1$, v_M is constant and equals d_{MN} while v_N changes with a negative slope, $-d_{MN}$. Thus, v_N can be written in term of t, shown below.

$$v_N(t) = d_{MN} - d_{MN}t \tag{14}$$

From (11) and (14), (13) is rearranged to achieve the outer function, expressed in (15). Like the inner function, amplitude of the outer function is also proportional to k_{SS}, but its curve is not. If constant in amplitude is request, the output can be multiplied by a current which is inverse proportional to mobility, purposed in [2].

To achieve the final output of TTSC, the outputs of the two generators are connected to each other, shown in Fig. 9 (b). $I_X = i_A + i_M$ and $I_Y = i_B + i_N$, then the final output is defined in a

differential term of (I_X – I_Y), shown in (16). A normalized function of the averaged function is derived from (10), (15) and (16) divided by $k_{SS}V^2_{REF}$, shown in (17).

$$\frac{(i_M - i_N)}{k_{SS}V_{REF}^2} = 1-(1-t)^2 = t(2-t) \quad (15)$$

$$I_X - I_Y = (i_A - i_B) + (i_M - i_N) \quad (16)$$

$$\frac{I_X - I_Y}{k_{SS}V_{REF}^2} = t\sqrt{2-t^2} + t(2-t) \quad (17)$$

B. Second-Order Effects

All functions derived previously are based on square law model. Two second-order effects are neglected in the previous analysis. They are short-channel and body effects. The volume of short-channel effect can be indicated by λ-parameter. The λ in a short-channel transistor is larger than in a long-channel transistor. In order to make the effects less significant, long-channel transistors should be used in the design.

For another effect, the body effect is not significant in the operation of the differential pair amplifier, although the source terminals of M_A and M_B are not connected to V_{SS}. The different voltage between bulk and source terminals causes an increase in threshold voltage. If common-mode voltage of differential input is high enough, the increase in threshold voltage can be neglected, as shown in (7). The body effect causes significant effects in operation of M_M, M_N and M_{SS}. These transistors are driven by compensated voltages, which are outputs of THVC circuits. Including the body effect, output voltage of THVC circuit, shown in Fig. 8, can be expressed in (18).

$$V'_i = V_i + V_{TH0} + \gamma\left(\sqrt{2\phi_{FB} - V_i} - \sqrt{2\phi_{FB}}\right) + \sqrt{\frac{2I_T}{\mu C_{ox}(W/L)_T}} \quad (18)$$

where V_{TH0} is threshold voltage without the body effect.

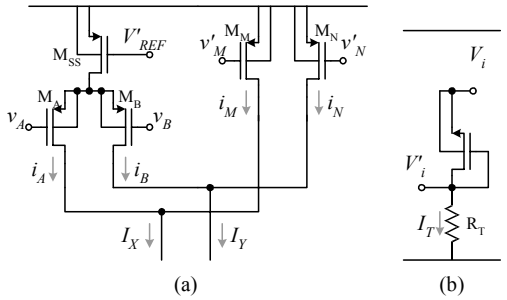

Fig. 10. A PMOS version of (a) TTSC (b) THVC

Errors in compensation are the 3rd and the last term of the right-hand side in (18). The value of the last term is very small because $(W/L)_T$ is large. The 3rd term is the body effect that can be completely removed by connecting the bulk terminal to its own source terminal. The bulk-source connection in NMOS is not allowed in general CMOS process. PMOS transistors are employed instead of NMOS transistors, as shown in Fig. 10. Each PMOS is also located in an isolated n-well to minimize the body effect.

IV. Simulation Results

A 0.18-micron n-well CMOS technology is used to model the test circuit, implemented with PMOS as shown in Fig. 10, for HSPICE simulating. Fig. 11 shows output curve in the temperature range of 0 to 100 °C, and Table I indicates that output with better than – 40 dBc of SFDR is achieved on the temperature range of 0 to 75 °C.

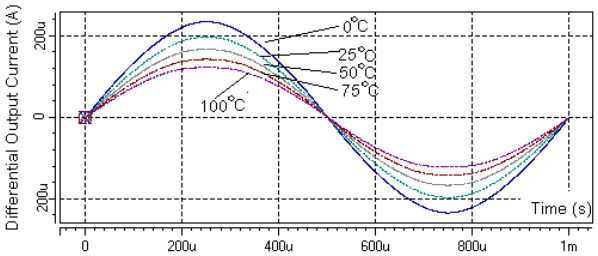

Fig. 11. Output signals in various temperature conditions

TABLE I
HSPICE Simulation Results

Temperature (°C)	THD (%)	SFDR (dBc)	20*log(a_N/a_1)		
			a_3	a_5	a_7
0	0. 878	-43.8	-44.6	-43.8	-61.2
25	0. 538	-46.4	-58.3	-46.4	-53.5
50	0. 616	-47.2	-47.2	-51.0	-49.3
75	1.089	-40.0	-40.0	-67.2	-46.9
100	1.729	-35.7	-35.7	-53.2	-45.3

V. Conclusion

The design of CMOS nonlinear circuits for sinusoidal function approximations and a threshold voltage compensated circuit reported in this paper. These circuits are non-complicated CMOS circuits. They are fed by triangular and trapezoidal waveform in order to convert the input signal to a sinusoidal waveform. The HSPICE simulations show that the circuits generate a sinusoidal waveform with total harmonic content of 0.538 percent and SFDR = – 46.4 dBc at 1 kHz, at the room temperature 25 °C. The purposed architecture provides a moderate level of performance which is needed in some instrumentation systems.

Abstract – This paper presents a new low-voltage and low-power amplifier based on the class-AB differential log-companding technique. The circuit has been designed using a 0.25 μm CMOS process. The proposed amplifier consumes less than 3.2 μW from 0.6 V supply voltage at the maximum input current. The CMRR of this circuit is 35.76 dB; thus, it has very high performance in eliminating the common mode signal. The presented technique can be applied to many applications, such as filter, reference voltage, rectifier, etc.

I. INTRODUCTION

The main purposes in developing a better amplifier for hearing aid chips are shrinking its area, reducing power consumption and improving noise rejection. A previous hearing-aid amplifier [1] was designed based on the log-companding technique using CMOS technology [1], allowing its operation at 1 V. This design utilizes a class-A amplifier which consumes large amount of power at zero input. A class-AB integrator [2], which is also based on the log-companding technique, is proposed to reduce the power consumption. This circuit generates positive and negative voltages from a single input, and then passes them through a non-linear processing. The results are used to generate a single-ended output. Since the input and the output are both single-ended, this circuit is differential only in the non-linear processing section. In this work, a truly differential class-AB amplifier is developed by exploiting complementary NMOS and PMOS transistors. The quiescent current flowing through PMOS is reused in NMOS, thus this amplifier can consume lower power. Because of the class-AB operation, the proposed amplifier can handle larger input compared to the amplifier in [1]. Moreover, the differential structure improves common mode signal rejection. The proposed technique is suitable for portable application where the power is limited and the supply voltage is as low as 0.6 V.

II. DESIGN PRINCIPLES

A. Log-Companding Technique

The signal in the current form (I-domain) is compressed into the voltage form (V-domain) by a compressor. Then, the compressed signal V_{in} is processed by a non-linear function. Finally, the processed signal V_{out} is expanded back to the I-domain by an expander. From the I-domain point-of-view, the overall process is a linear function. The block diagram of this technique is shown in Fig. 1. The compression in this technique helps lowering the supply voltage required for the non-linear processing section. The log-companding technique can be used with many types of transistors, such as BJT and CMOS. To use a CMOS transistor in a log-companding circuit, the transistor must be operated in the subthreshold region that gives exactly the logarithmic compression and exponential expansion.

B. MOS characteristics in the subthreshold region

MOS transistors can operate in 3 main regions corresponding to the voltage between gate and source of the transistor (V_{gs}) comparing with the threshold voltage (V_{TO}). If $V_{gs} << V_{TO}$, this region is called *Weak Inversion* (or Subthreshold). On the other hand, if $V_{gs} >> V_{TO}$ this region is called *Strong Inversion* which further categorized into saturation region and triode region. Elsewhere, the region that V_{gs} is close to V_{TO} is called *Moderate Inversion*. MOS that operates in the subthreshold region has logarithmic characteristic. Equation of NMOS that operates in the subthreshold region from EKV model [3] is shown in eq. (1)

$$I_{DN} = I_{SN} \exp\left[\frac{V_{GB} - V_{TON}}{n_N U_t}\right]\left(\exp\left[-\frac{V_{SB}}{U_t}\right] - \exp\left[-\frac{V_{DB}}{U_t}\right]\right) \quad (1)$$

$$V_{SB,DB} >> \frac{V_{GB} - V_{TO}}{n} \text{ and } I_S = 2n\beta U_t^2$$

Whereas I_{Sx} is the specific current, $ß_x$ is the current multiplier, n_x is the subthreshold slope, U_t is the thermal potential and V_{TOx} is the threshold voltage. The *x* in the subscript can be N or P denoting parameters of NMOS and PMOS respectively or omitted in case of generic parameters that share between NMOS and PMOS

For PMOS, the equation is shown in eq. (2).

$$I_{DP} = -I_{SP} \exp\left[\frac{-V_{GB} - V_{TOP}}{n_P U_t}\right]\left(\exp\left[\frac{V_{SB}}{U_t}\right] - \exp\left[\frac{V_{DB}}{U_t}\right]\right) \quad (2)$$

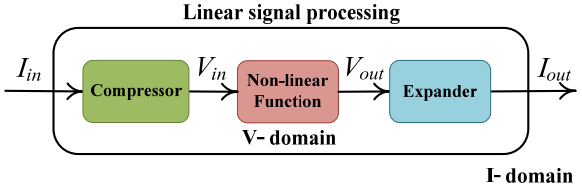

Fig. 1. Log-companding signal processing

For a CMOS model used in this work, we used BSIM3 level 49 [5] which gives V_{TON} of approximately 0.5V and PMOS's V_{TOP} of approximately 0.6V.

III. Proposed Circuit and Analysis

The proposed class-AB differential amplifier based on log-companding technique consists of the compressor to logarithmically compress the input currents into voltages and the expander to convert these voltages exponentially back into the output currents. The amplifier's gain can be controlled by adjusting V_{SB} of NMOS and PMOS in the compressor.

A. Compressor

The compressor circuit is shown in Fig. 2(a). It is sufficient to consider only half of the circuit because of the symmetry. If parameters n, I_S, $|V_{TO}|$ and $|V_{SB}|$ between NMOS and PMOS are equal, I_{ip} can be separated into I_{p1} and I_{n1} as shown in eq. (3).

$$I_{ip} = I_{N1} + I_{P1}$$
$$I_{ip} = I_{SS}\exp\left[\frac{V_{ip}}{nU_t}\right] - I_{SS}\exp\left[\frac{-V_{ip}}{nU_t}\right] \quad (3)$$

Where $$I_{SS} = I_S \exp\left[\frac{-V_{TO} - n|V_{SB}|}{nU_t}\right]$$

Rearranging the above equation, V_{ip} can be expressed in term of I_{ip} as shown in eq.(4)

$$V_{ip} = nU_t \sinh^{-1}\left[\frac{I_{ip}}{2I_{SS}}\right] \quad (4)$$

In general, n, I_S, $|V_{TO}|$ and $|V_{SB}|$ of NMOS and PMOS may not be identical. Difference in coefficient and exponent of I_{p1} and I_{n1} yields implicit function of V_{ip}; thus, it is difficult to write V_{ip} in term of I_{in} ($V_{ip} = f(kI_{in})$, k is arbitrary constant) directly. However, we can still expand V_{ip} and V_{in} using both NMOS expander and PMOS expander. This can be shown straightforward that even in the case of unmatched NMOS and PMOS parameters, the proposed expander still operate correctly.

B. Expander

The basic expander is shown in Fig. 2(b). This circuit expands V_{ip} and V_{in} exponentially into I_{op} and I_{on} respectively. The equation of the basic expander is shown in eq. (5) and (6).

$$I_{op} = I_N \exp\left[\frac{V_{ip}}{n_N U_t}\right] + I_P \exp\left[\frac{-V_{ip}}{n_P U_t}\right] \quad (5)$$

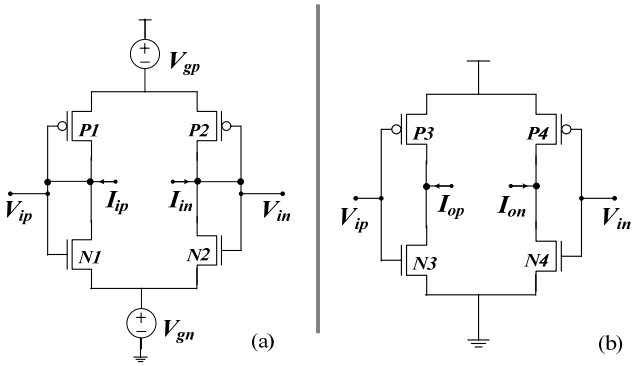

Fig. 2. (a)The proposed class-AB compressor (b) The basic expander

$$I_{on} = -I_P \exp\left[\frac{-V_{in}}{n_P U_t}\right] - I_N \exp\left[\frac{V_{in}}{n_N U_t}\right] \quad (6)$$

Where $I_N = I_{SN}\exp\left[\frac{-V_{TON}}{n_N U_t}\right]$ and $I_P = -I_{SP}\exp\left[\frac{-V_{TOP}+V_{DD}}{n_P U_t}\right]$

The basic expander's equation can be rewritten as $I_{op} = g(V_{ip})$ whereas $g(x)$ is the inverse function of $f(x)$. When we combine the compressor in Fig. 2(a) and the basic expander in Fig. 2(b) together to make a basic class-AB amplifier, the amplifier's transfer function is $I_{op} = g\,(f\,(k \bullet I_{ip})) = k \bullet I_{ip}$. The transfer function is obtained by substituting V_{ip} in eq. (5) with the term in eq. (4). In general case, the transfer function is still valid even V_{ip} is an implicit function of I_{ip} (the proof is beyond the scope of this paper). Choosing $V_{gp} = V_{gn} = V_{gain}$ simplifies the transfer function of the amplifier which is shown in eq. (7).

$$\frac{I_{op} - I_{on}}{I_{ip} - I_{in}} = \exp\left(\frac{V_{gain}}{U_t}\right) \quad (7)$$

From the equation, the gain of this amplifier can be varied by changing the value V_{gain}. Although the basic expander exhibits a good performance in cancelling the effect of I_N, I_P, n_N and n_P, this circuit cannot eliminate the common mode noise from the input. To solve this problem, we need to construct a true differential expander.

C. Amplifier

Based on the basic idea in [6], the proposed differential expander is shown in Fig. 3. This circuit proposes better common mode noise rejection.

The circuit expands V_{ip} and V_{in} exponentially into differential output currents. V_{ip} is expanded exponentially by N3, N4, P3 and P4, while expanding V_{in} is done by N5, N6, P5 and P6. A current expanded from V_{in} by N6 is copied to subtract with a current expanded from V_{ip} by N4 to

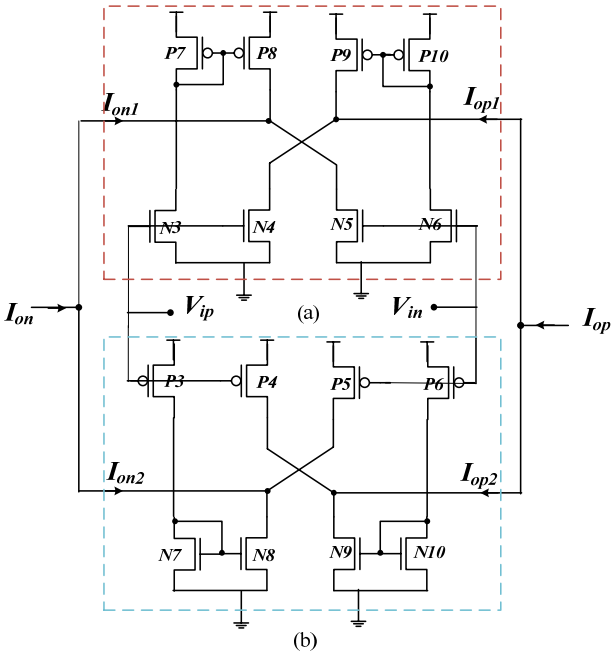

Fig. 3. Proposed (a) NMOS expander (b) PMOS expander

generate I_{op1}. The same is true for an expanded current from P6 and P4 subtracting each other to generate I_{op2}. Finally, I_{op1} and I_{op2} are combined to generate I_{op}. An equation of I_{op} is shown in eq. (8). I_{on} is generated in the same way with an equation shown in eq. (9).

$$I_{op} = I_N\left(\exp\left[V_{ip}/\left(n_N U_t\right)\right] - \exp\left[V_{in}/\left(n_N U_t\right)\right]\right) + I_P\left(\exp\left[-V_{in}/\left(n_P U_t\right)\right] - \exp\left[-V_{ip}/\left(n_P U_t\right)\right]\right) \quad (8)$$

$$I_{on} = I_N\left(\exp\left[V_{in}/\left(n_N U_t\right)\right] - \exp\left[V_{ip}/\left(n_N U_t\right)\right]\right) + I_P\left(\exp\left[-V_{ip}/\left(n_P U_t\right)\right] - \exp\left[-V_{in}/\left(n_P U_t\right)\right]\right) \quad (9)$$

When I_{ip} increases positively, according to the operation of the compressor, it increases V_{ip} and decreases V_{in}. Then, the expander gives an increased I_{op} and a decreased I_{on} creating differential output currents. In common mode operation, a matched change in V_{ip} and V_{in} makes no change to I_{op} and I_{on} because changed in expanded currents are cancelled internally. Therefore, this expander can reject common mode input.

To construct the amplifier based on the diagram shown in Fig. 1, we combine the class-AB compressor and the differential expander together. The proposed amplifier's gain can be controlled by adjusting V_{gain} in the compressor. Based on the calculation, the gain of this amplifier is 2 times larger than in eq. (7) because of the differential operation. This technique not only reduces the required supply voltage of the compressor but also decreases the number of CMOS used in the class-AB compressor from ref. [2]. Moreover, the differential expander exhibits better common mode rejection capability.

IV. Simulation Results

To prove that the proposed compressor can compress the signal logarithmically, the current $I_{ip} = -I_{in}$ are fed into the circuit and the output V_{ip} and V_{in} are plotted. From Fig. 4 and Fig. 5, the V_{ip} and V_{in} are plotting with I_{ip} in linear and logarithmic scale respectively. Notice that V_{ip} and V_{in} make straight line in the logarithmic scale. Moreover, the proposed expander can also expand V_{ip} and V_{in} exponentially. Fig. 6 and Fig. 7 show the variation of I_{op} and $|I_{on}|$ with respect to V_{ip} in linear and logarithmic scale of the output current respectively. Also remarked that logarithmic values of I_{op} and $|I_{on}|$ are proportional to V_{ip}.

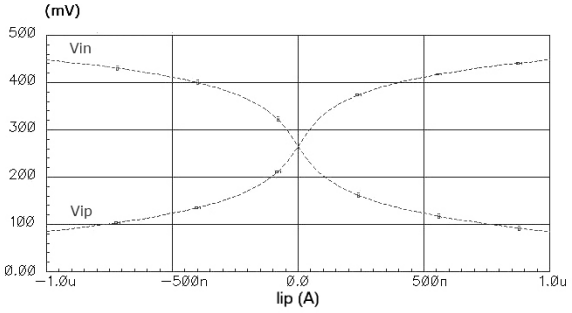

Fig. 4 Variation of V_{ip} and V_{in} respect to I_{ip} in linear scale

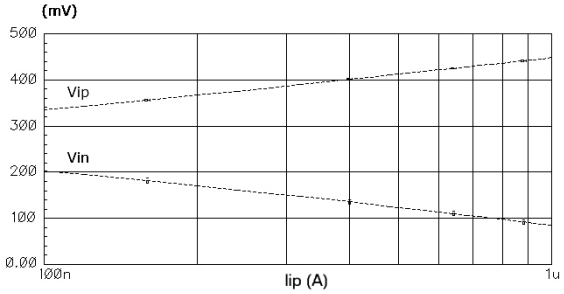

Fig. 5. Variation of V_{ip} and V_{in} respect to I_{ip} in logarithmic scale

The proposed amplifier should have a transfer function 2 times larger than in eq. (7). The simulated result in Fig. 8 shows that the amplifier is operating as expected, except for a minute offset current in I_{op} and I_{on} which will be cancelled automatically by the differential output scheme.

Parameters of MOS used in the proposed amplifier are shown in TABLE I. We can see that the circuit draws very low current at DC state from TABLE II. There are offset currents in I_{op} and I_{on} due to bias currents which affect the linearity of the amplifier's gain. This makes the result slightly differ from what we expected. Nevertheless, the proposed circuit has differential output that can finally eliminate the offset value in the output current. As mentioned in the previous section, the gain of this amplifier is affected by the value of V_{gain}. The gain of amplifier respect to V_{gain} is shown in Fig. 9.

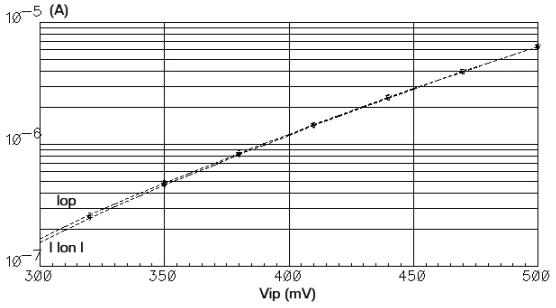

Fig. 7. Variation of I_{op} and $|I_{on}|$ in logarithmic scale respect to V_{ip}

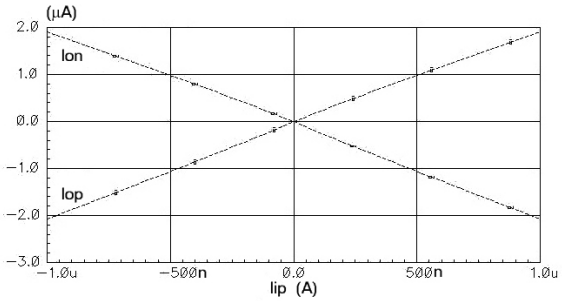

Fig. 8 Shows output currents varied with the input current

The linearity of the proposed circuit is defined by THD (Total Harmonic Distortion). From the simulation result shown in Fig. 10, THD of the proposed circuit is 0.55% and CMRR is 35.76 dB from 1μA sinusoidal input. The frequency range of the circuit is up to 200 kHz which is satisfactory for audio application. The small signal gain from frequency analysis shown in Fig. 11 is approximately 2.02. Because of the differential structure, this circuit has very high performance in eliminating the common mode input. Moreover, the power consumption of the circuit is 291nW while the circuit operates in quiescent state. At the maximum input state the circuit consumes 3.16 μW from 0.6 V supply voltage. The summary of the proposed amplifier's performance is shown in TABLE III.

TABLE II QUIESCENT VALUE OF THE CIRCUIT

CMRR	35.76 dB	Maximum Input

V. CONCLUSION AND FUTURE WORK

Log-companding technique can reduce circuit's supply voltage value. Moreover, class-AB and differential technique are used to decrease total power consumption and eliminate common mode noise. In this work, the circuit is operated well with 0.6 V supply voltage. The total power consumption is 3.16422 μW. The amplifier gain can be varied from -40 dB to 38 dB, the THD of the circuit is 0.55%, and the CMRR of the proposed amplifier is 35.76 dB. These techniques can be used in many others applications. The future work is to design a log-companding filter based on these techniques.

Abstract— **This paper presents a novel structure of wide-swing CMOS voltage buffer, which is based on the flipped voltage follower. When compared with the previously established buffer based on the same principle, the proposed circuit is less complex and consumes less power while attaining wide bandwidth and high slew-rate. Simulated results of the proposed buffer using a 0.35μm CMOS process are provided.**

I. INTRODUCTION

Analog voltage buffers or voltage followers can be found in various analog applications such as current conveyors [1], current feedback amplifiers [2], output stages of power amplifiers and line drivers [3], and analog filter realizations [4]. In order to drive large capacitive loads with high speed and attain high signal-to-noise ratios, analog buffers must provide an output current and voltage swing range which is as high as possible. To meet these requirements, a fast, unity-gain class-AB amplifier circuit with rail-to-rail signal capability is required. Combining the class-AB operation and rail-to-rail signal swing usually requires a complicated biasing circuit to extend the common-mode input range of the buffer [5]. Unfortunately, this increases the buffer complexity and power consumption.

In this paper, we describe a compact, class-AB CMOS analog buffer with rail-to-rail signal capability, which dispenses with the requirement for a complicated biasing circuit. The circuit employs the complementary class-AB differential transconductor proposed in [6] and its common-mode input range limitation is solved by inserting level shifters into the local feedback path of the transconductor. Although, this technique is similar to the voltage buffer proposed in [7], our approach avoids the complicated biasing circuit required in [7] to stabilize the circuit DC operating points when the input signal goes either excessively high or low. As a result, the overall buffer complexity and quiescent power consumption are reduced, while still attaining rail-to-rail signal swing and high driving ability.

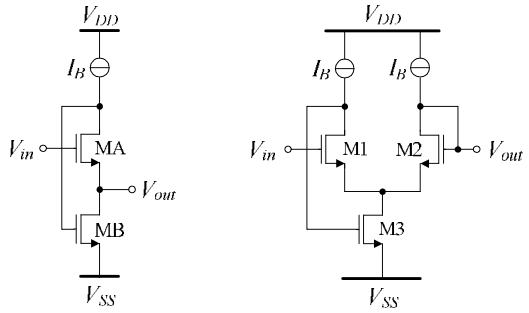

Figure1. (a) Flipped voltage follower. (b) Buffer without level shifting.

The remaining sections of the paper are organized as follows. Section II provides an overview of previous works in analog rail-to-rail buffer design and Section III presents the proposed circuit. Simulated results using parameters for a 0.35μm CMOS process are presented in Section IV and conclusions suitably drawn in Section V.

II. PREVIOUS BUFFERS

A. Flipped Voltage Follower

Fig. 1a shows the high accuracy buffer which is called "flipped voltage follower" by the fact that a bias current I_B is injected to drain instead of source terminals of MA. Compared with the traditional source follower circuit, following behavior of the circuit in Fig.1a is far better because the drain current of MA is regulated by constant current source resulting in constant gate-source voltage as well. Moreover a very large loop gain provided by common source circuit MB, which is embedded in a local negative feedback loop of the circuit, forcing a small signal output resistance of this circuit to be very low [9] and the feedback mechanism can be simplify by a feedback block diagram shown in Fig 2, where g_{mi} is a small signal transconductance gain of each transistor and r_{ds} is a drain-source resistance and r_B is an output resistance of the

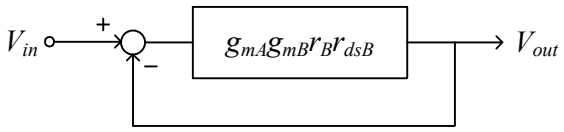

Figure 2. Feedback block diagram of the flipped voltage follower.

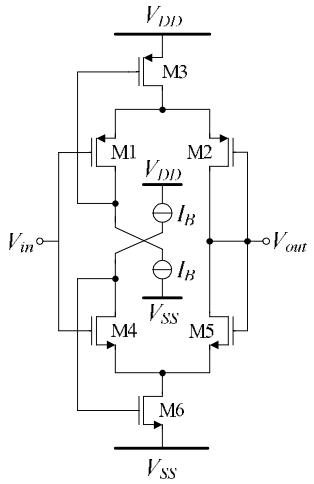

Figure 3. Class-AB buffer in [6].

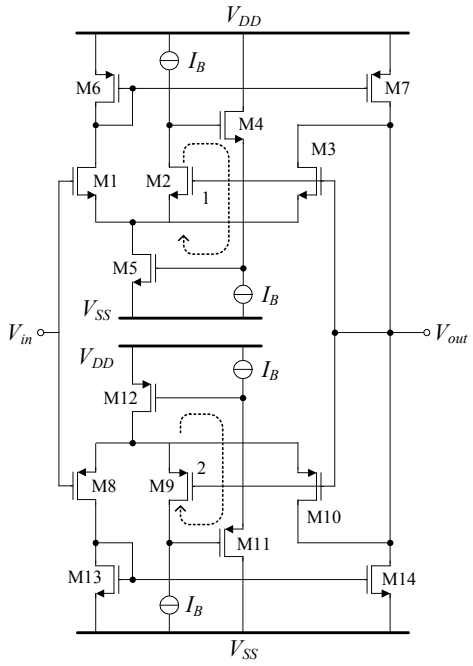

Figure 4. Proposed rail-to-rail buffer.

current source I_B. To compensate for a DC level shifting between input and output voltages of the circuit in Fig.1a, the circuit in Fig.1b is employed. This circuit operates as a single stage amplifier connected in unity gain feedback scheme which also maintains equality between input and output voltages by a large loop gain of a global feedback path. When large signal characteristics are considered, it can be seen that both circuits in Figs. 1a and 1b can maximally push current to load by I_B, whereas pull currents can be much higher.

To fulfill the asymmetrical output currents of both circuits, a buffer circuit providing fully class-AB characteristic is proposed in [6] and shown in Fig.3. It is simply realized by stacking the circuit in Fig. 1b in a complementary fashion. The circuit is compact and has very low quiescent power consumption given by

$$P = 3I_B\left(V_{DD} - V_{SS}\right). \tag{1}$$

Moreover, it provides a class-AB output current suitable for large capacitive loads but its signal swing is limited by the circuit topology itself. An attempt to extend signal swing of the buffer has been done in [7]. Although, however, the signal swing is successfully enhanced, the overall circuit is bulky and required almost quadrupling of power consumption of the buffer in Fig.3.

III. PROPOSED CIRCUIT

Fig. 4 shows the proposed rail-to-rail CMOS analog buffer. The circuit can be divided into two parts; the upper circuit consisting of devices M1-M7 and the lower circuit of devices M8-M14. Each of these sub-circuits resembles a single-stage class-AB amplifier. The purpose of level shifters, M4-M5 and M11-M12 are to provide negative feedback loops (1 and 2), thereby extending the input common-mode range [7].

By virtue of the negative feedback around loops 1 and 2, the impedances at the source terminals of M2 and M9 are forced to be very low. As a result, the gate-source voltages of M2 (V_{GS2}) and M9 (V_{SG9}) are kept nearly constant, causing the current at the circuit output node to feature class-AB behavior [9]. Considering the circuit in Fig. 3 without M3 and M10 we can see that it may properly operate as a unity-gain amplifier or voltage buffer. However, when the input voltage (V_{in}) goes low or high and exceeds the following range:

$$V_{SS} + \left(V_{eff5} + V_{eff2} + V_{Tn}\right) \le V_{in} \le V_{DD} - \left(V_{eff12} + V_{eff9} + \left|V_{Tp}\right|\right) \tag{2}$$

where V_{eff} is the effective or saturation voltage, V_{Tn} and V_{Tp} are the threshold voltages of n and p channel devices respectively, either the upper or the lower sub-circuit will be forced out of the active region. As a result, there will be no DC current to support the output branch of the rest of the circuit, leading to inevitable shut down of the entire buffer circuit.

Here, the main objective of inserting M3 and M10 into the circuit in Fig. 4 is to widen its input range, i.e., to be higher than (2). Since the gate-source voltages of M3 and M10 are respectively copied from M2 and M9, their current conducting behavior will be similar and controlled by V_{in}. Devices M3 and M10 function as controlled constant current sources and stabilize the DC current of the output branch devices M7 and M14. The DC stabilizing mechanism will be considered next.

First consider the case when $V_{in} = 0$. By virtue of the negative feedback from the output node (V_{out}) to the inverting input terminals (gate terminals of M2, M3, M9 and M10), the input and output voltages are forced to be identical, i.e., $V_{in} = V_{out} = 0$. At this point, both the upper (M1-M5) and lower (M8-M12) input pairs are biased in the active region, and the drain currents of M1 and M8 (both equal to I_B) are copied to the output branches via the current mirrors M6-M7 and M13-M14. Also, M3 and M10 are active with drain currents of $I_{D3} = I_{D10} = I_B$. In this situation, we can see that no DC operating problem occurs because the drain current of M7 (I_{D7}) is fully absorbed by a drain current of M14 (I_{D14}) and the total current consumption is $8I_B$ then static power consumption of this circuit can be calculated as

$$P = 8I_B\left(V_{DD} - V_{SS}\right), \tag{3}$$

showing that this circuit consumes less power than the buffer in [7]. Interestingly, M3 and M10 may appear to be redundant. Although true when $V_{in} = 0$, for $V_{in} \neq 0$, M3 and M10 play a significant role as discussed next.

When a positive V_{in} is applied and reaches the upper limit of (2), M12 will be forced to enter the triode region. If V_{in} goes higher than this limit, I_{D12} will be reduced and M8-M10 will be pushed out of the active region, eventually resulting in zero drain current in M8-M10 and M13-M14. However, the upper sub-circuit will still continue to work properly because I_{D7} can be fully absorbed by I_{D3} (even if M14 is already turned-off). In the reverse situation, i.e., when V_{in} goes more negative than the lower limit of (2), the lower sub-circuit will be fully functional, whereas the upper sub-circuit will be turned off. Thus, we can find that the input range of the buffer is extended from (2) to be

$$V_{DD} - \left(V_{eff11} + V_{eff12} + 3\left|V_{Tp}\right|\right) \le V_{in} \le V_{SS} + \left(V_{eff4} + V_{eff5} + V_{Tn}\right). \tag{4}$$

Hence, by appropriate choice of the voltage supply rails and effective voltages in (4), we can achieve rail-to-rail capability. To show the compactness of the proposed circuit a component of the proposed buffer, excluding bias circuits, is summarized in Table 1.

Table1: List of Components and Current Consumption of the proposed circuit.

Parameter	Fig.3
Transistor count	14
Current sources	4
Current consumption	$8I_B$

Table2: Transistor Dimensions.
(channel length L = 1μm for all transistors)

Transistor	W [μm]

Table3: Performance Summary.

Circuit performance	Value
Bandwidth	6.8MHz
Slew rate: positive, negative	61.3V/μs, 68.2V/μs
THD@1.4V_p, 100KHz	-42dB
Static power consumption	282 μW

IV. SIMULTION RESULTS

The circuit in Fig.4 was simulated using SPICE with parameters for a 0.35 μm CMOS process ($V_{Tn} \cong 0.55$V and $V_{Tp} \cong -0.71$V). The transistor dimensions are listed in Table 2. Capacitive load of 10pF were used, and the supply voltage ($V_{DD} = -V_{SS}$) and bias current I_B were set to 1.5V and 10μA, respectively.

The DC characteristic of the buffer circuits is shown in Fig.5. The tracking behavior, between the input and output voltages is shown in Fig.5a, and the offset error is shown in Fig.5b. It can thus be seen that the output voltages of the proposed buffer follow the input voltage for almost the entire range of the voltage supply and the offset of the proposed buffer is very low.

The operating speed of the proposed buffer was evaluated by applying a 1.4V, 2 MHz square signal at the input. The transient response is depicted in Fig. 6 showing that the step response of the proposed buffer is faster than 60V/μs.

The circuit linearity was evaluated by simulated total harmonic distortion (THD) with a 100 kHz sinusoidal input voltage with varying amplitude. The result is shown in Fig. 7 where it can be seen that less than -40_{dB}THD of the proposed buffer is achieved for amplitudes in excess of 1.4V. Finally, for a 10pF load, the buffer exhibited a bandwidth of 6.8 MHz and details of other simulated parameters are summarized in Table 3.

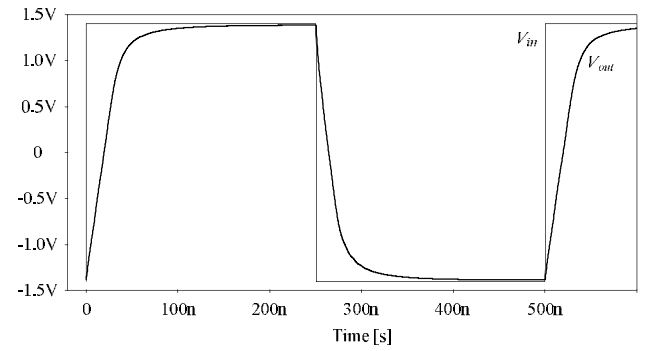

Figure 6. Transient response of the proposed buffer.

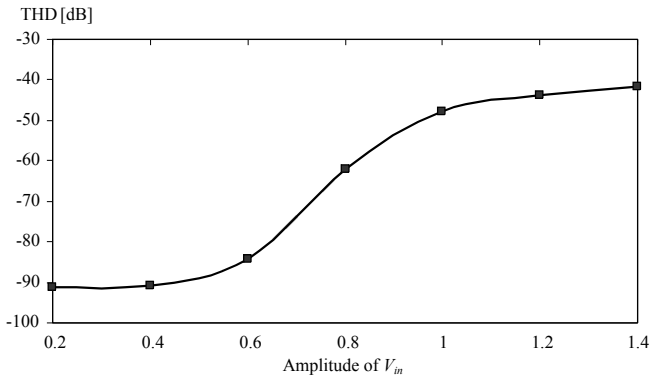

Figure 7. Simulated total harmonic distortion.

V. CONCLUSION

A novel compact structure of the high-performance class-AB CMOS analog voltage buffer has been presented. The proposed buffer combines high driving capability and rail-to-rail signal swing. The circuit complexity and quiescent power consumption of the proposed circuit are lower compared with a previously reported buffer based on the same principle. Simulated results have been provided to show the performance of the circuit.

***Abstract*-In this paper, a compact low-voltage CMOS four-quadrant analog multiplier is proposed. The proposed circuit is obtained by rearranging circuit topology of a recently reported multiplier which is unpractical since the circuit topology itself needs an ideal voltage reference to form a multiplication function. By doing so, the ideal voltage reference is no longer required leading to achieve a new multiplier circuit with real compactness. Simulated results using PSPICE for 0.35μm CMOS process show that main performances of the proposed multiplier, including linearity, bandwidth and power consumption, are successfully improved.**

I. INTRODUCTION

Analog multipliers are found in many applications such as modulator, frequency doublers, absolute value circuit, and etc. These applications are required to operate in low voltage environment for improving their power efficiency and incorporating with mixed signal systems to be used in portable applications [1]. A number of circuit techniques for realizing a CMOS analog multiplier had been collected and systematically evaluated by G. Han and E. Sanchez-Sinencio [2].

According to [2], there are several means to realize a four quadrant analog multiplier and it is also suggested by [3] that using saturated MOSFET in strong inversion is more practical than any other means. Recently, based on a square-law relation of saturated MOSFET, various compact multiplier architectures which are constituted by a circuit cell called a "flipped voltage follower: FVF" [4], have been chronologically proposed in [5]-[8]. Most of them feature wide input range, high operating frequency and low power consumption which are resulted from excellent manipulations of the square-law function in high compactness structures.

Focusing on the latest version in [8], which is seemed to be the most compact circuit, it is found that the overall multiplier circuit can not be called compact since it requires an extra voltage reference connected between the resistive loads. To generate the extra voltage reference, more power consumption and circuit complexity are unavoidable.

In this paper, we propose a new multiplier circuit which is based on a similar technique to [8] but an arrangement of the circuit in transistor level is improved such that the extra voltage reference becomes redundant and can be eliminated. We then obtain a four quadrant analog multiplier with real compact structure. Therefore, some circuit performances of the proposed multiplier are successfully improved. In order to validate the circuit performances, the proposed multiplier has been simulated in PSPICE by using model parameter for 0.35 micron CMOS process. The results show that bandwidth, linearity and power consumption of the proposed circuit are better than those of the circuit in [8].

The remaining of this paper is organized in the following sections, a basic concept for realizing the analog multiplier is introduced in Section II. Next, a modification of square rooting circuit used to form an analog multiplier is described in Section III. The proposed multiplier circuit is illustrated in Section IV. In addition, simulated results of the proposed multiplier and conclusion are presented in Section V and VI, respectively.

II. BASIC CONCEPT

Realizing a proposed analog multiplier and the multiplier in [8] is based on a similar approach showing in Fig. 1. It comprises a pair of common source amplifier (M1 and M2), which acts as input transistors to provide output currents in term of squaring functions of input voltages (V_1 and V_2), and two identical voltage controlled square root blocks which operate as non-linear cancellation paths. Injecting the output currents of the input transistors into the square root blocks, a differential output current of the overall circuit will become a multiplication function of two input signals V_{12} and V_{34}. More detail of mathematical analysis using square-law relation of saturated MOSFET in strong inversion will be shown in the paragraph below.

Assuming the MOSFET M1 and M2 are biased in active region and neglecting channel length modulation effect, the current I_A and I_B can be respectively found as

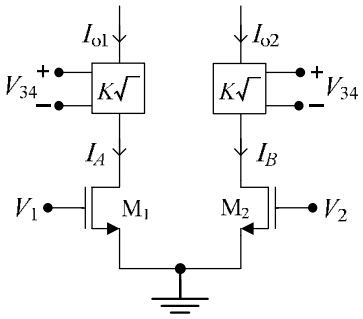

Figure 1. Basic concept for realizing a four quadrant analog multiplier.

$$I_A = \beta_n (V_1 - V_{tn})^2 \tag{1}$$

and

$$I_B = \beta_n (V_2 - V_{tn})^2 , \tag{2}$$

where $\beta_n = 0.5\mu_n C_{ox}(W/L)$ is a transconductance parameter of each MOSFET and V_{tn} is the threshold voltage of NMOS transistor.

From (1) and (2), the relationship between the current I_A and I_B and the differential input voltage $V_{12} = V_1 - V_2$ can be given by

$$\sqrt{I_A} - \sqrt{I_B} = V_{12}\sqrt{\beta_n} \tag{3}$$

The drain currents I_A and I_B are fed into the square root blocks controlled by V_{34}, results in

$$I_{out} = I_{o1} - I_{o2} = KV_{34}\left(\sqrt{I_A} - \sqrt{I_B}\right) \tag{4}$$

where K is the gain of the square root blocks.

Substituting (3) into (4), yields

$$I_{out} = K\sqrt{\beta_n} V_{12} V_{34} \tag{5}$$

It can be seen that an output current appeared in (5) is in form of a multiplication function between two input signals V_{12} and V_{34}.

Based on this approach, both linear transconductor [9] and four-quadrant analog multiplier [10] have been proposed. Unfortunately, the early works in [9] and [10] require more than 3V for supply voltage which is not sufficiently low for modern analog design. Subsequently, a new square rooting circuit operated under 1.5V single supply was proposed in [11] which can be applied as a compact four quadrant analog multiplier as well [8]. However, the multiplier in [8] is not practical since it requires an ideal voltage reference to create the multiplication function.

In the next section, the improved square root circuit which is more suitable for realizing an analog multiplier will be described.

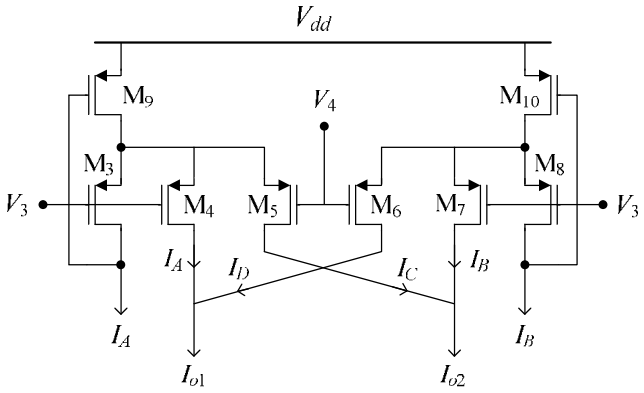

Figure 2. The proposed square rooting circuit.

III. SQUARE ROOTING CIRCUIT

A proposed square rooting circuit which is improved from [11] is shown in Fig.2. Using square-law relation of saturated MOSFET in strong inversion and setting M3-M8 to be identical, the currents I_C and I_D are found to be

$$I_C = \beta_p \left(V_{34} + \sqrt{\frac{I_A}{\beta_p}} \right)^2 \tag{6}$$

and

$$I_D = \beta_p \left(V_{34} + \sqrt{\frac{I_B}{\beta_p}} \right)^2 , \tag{7}$$

where $\beta_p = 0.5\mu_p C_{ox}(W/L)$ is a transconductance parameter of each PMOS transistor and $V_{34} = V_3 - V_4$ is a differential control voltage.

Considering (6) and (7) in conjunction with the fact that $I_A + I_D = I_{o1}$ and $I_B + I_C = I_{o2}$ leading to

$$I_{o1} = \beta_p V_{34}^2 + 2V_{34}\sqrt{\beta_p}\sqrt{I_A} + I_A + I_B \tag{8}$$

and

$$I_{o2} = \beta_p V_{34}^2 + 2V_{34}\sqrt{\beta_p}\sqrt{I_B} + I_A + I_B \tag{9}$$

Subtracting (8) and (9), results in

$$I_{out} = I_{o1} - I_{o2} = 2V_{34}\sqrt{\beta_p}\left(\sqrt{I_A} - \sqrt{I_B}\right) \tag{10}$$

It is obvious that the output current of the improved square root circuit is a function of a square root of I_A and I_B and its gain can be adjusted by the voltage V_{34} and transconductance parameter β_p .

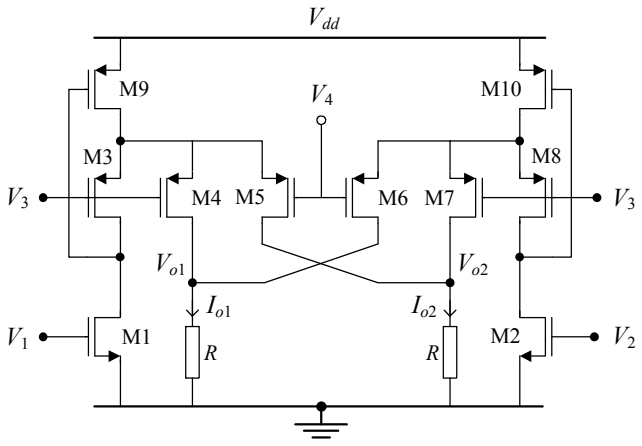

Figure 3. The proposed four quadrant analog multiplier circuit.

IV. Proposed Multiplier Circuit

Fig.3 shows the proposed multiplier circuit which is constituted by substituting the square rooting circuit in Fig. 2 into the square root blocks of Fig.1. Focusing on the differential output voltage we have found that

$$V_{out} = V_{o1} - V_{o2} = R\left(I_{o1} - I_{o2}\right), \tag{11}$$

Substituting (10) into (11), differential output voltage can be found as

$$V_{out} = 2RV_{34}\sqrt{\beta_p}\left(\sqrt{I_A} - \sqrt{I_B}\right) \tag{12}$$

Finally, substituting (3) into (12) yields

$$V_{out} = 2R\sqrt{\beta_n\beta_p}V_{12}V_{34} \tag{13}$$

Now, we have an output offset-free four quadrant analog multiplier and its gain can be adjusted by the load resistor R and the dimensions of each MOSFET.

V. Simulation Results

The multiplier circuit in Fig. 3 was designed and simulated by using PSPICE for 0.35 micron CMOS process parameter with main parameters $V_{tn} \cong 0.51$ and $V_{tp} \cong -0.66$. The input voltage V_{12} and V_{34} are set to be balance with common mode voltages of $V_{C1} = 1$V and $V_{C2} = 0.2$V, respectively and supply voltage V_{DD} is set at 1.8V. Transistor dimensions are listed in Table 1. Trying to avoid channel length modulation and short channel effects, the channel lengths of all transistors are set to be two times longer than 0.35 micron. The load resistors R are chosen to be 2.5 kΩ. At the quiescent point, power consumption of the proposed multiplier is 165 μW.

Fig. 4 shows simulated DC transfer characteristics of the proposed multiplier, when V_{12} was swept continuously from -0.4V to 0.4V while V_{34} was varied from -0.4V to 0.4V with 0.1V step size. It can be observed that the linear range of V_{12} is approximately ±0.4V.

Transient response of the multiplier operated as amplitude modulator is shown in Fig. 5. A 0.4V, 25 kHz sinusoidal carrier signal V_{12} shown in Fig. 5(a) was multiplied by a 0.4V, 1 kHz sinusoidal modulating signal V_{34} shown in Fig. 5(b). A resulting waveform is shown in Fig. 5(c).

Frequency response of the multiplier for various gains was set by sweeping V_{34} from 0.1V to 0.4V with 0.1V step size as the same condition of DC sweep and the results show in Fig. 6 demonstrating that bandwidth of the proposed circuit is higher than 110 MHz for all gains.

Circuit linearity is examined by simulated total harmonic distortion (THD), when V_{34} was fixed at 0.4V and applying various amplitudes of 25 kHz sinusoidal V_{12}. The result is displayed in Fig. 7 that less than 0.6% THD is achieved for V_{12} amplitude about 0.4V.

Comparative results of the simulated performances between this work and [8] are shown in table II.

VI. CONCLUSION

A new square rooting circuit can be used for realizing a CMOS four-quadrant analog multiplier has been presented. The resulting multiplier circuit is improved to be more compact than the previous work. The extra voltage reference is not required for the proposed circuit. As a result, the proposed multiplier provides high bandwidth, high linearity and low static power consumption. Simulation results are given to verify the multiplier circuit performances.

Verifying Various Generation of Random Number Sequence on Wave-Pipelined PRNG

Tomoaki Sato, Kazuhira Kikuchi, and Masa-aki Fukase
Hirosaki University
Bunkyo-cho 3
Hirosaki, Aomori 036-8561 JAPAN

***Abstract*- A circuit design by using wave-pipeline technology is very useful to achieve a high-speed and low-power circuit. Wave-pipelined PRNG (Pseudo-Random Number Generator) has not only these features but also the function to change the order of the pseudo-random number sequence easily by changing an operation clock frequency of the output register. However, the function has not yet so far verified. Thus, it is verified in this paper by the gate-level simulation for wave-pipelined PRNG added to output registers.**

I. INTRODUCTION

A strong cipher is needed for an embedded device including a mobile phone or PDA connected with the Internet [1]. In addition, the embedded device requires a circuit operating with high-speed and low-power consumption. Wave-pipelined PRNG (Pseudo-Random Number Generator) [2] is one of the circuits that can satisfy these demands.

Wave-pipeline technique that enables a pipeline operation without using a register [3]-[5] is very useful to achieve a circuit operating with high-speed and low-power consumption [6]. Nevertheless, wave-pipeline technique applied up to now has been limited to only combination logical circuits. Thus, we have exploited wave-pipelined LFSR (Linier Feedback Shift Register) [7], [8]. Wave-pipelined PRNG is composed of LFSR.

We have evaluated wave-pipelined PRNG in view of performance, operation speed, and power consumption. We have also found that wave-pipelined PRNG is able to generate various random number sequences easily by controlling the operation clock frequency [9]. However, the generation has not so far verified.

This paper presents the verification of random number generation by wave-pipelined PRNG. We add output registers to wave-pipelined PRNG and verify the output value of registers by gate-level simulation. As a result, wave-pipelined PRNG is shown that various random number sequences easily generated.

II. WAVE-PIPELINE TECHNIQUE

Not only high clock frequency but also low power dissipation can be obtained at the same time by wave-pipelining [3]-[5]. It exploits high throughput combinational logic blocks in which as many as data are launched unless they conflict. Although wave-pipelining was attempted to the entire region of a processor, it was viewed pessimistically because it requires removing general registers as well as pipeline registers from processors. It seems hard to eliminate general registers playing fundamental roles in sequential circuits. The insufficient power of CAD tools so far developed is another reason why wave-pipelines have been applied out of processors.

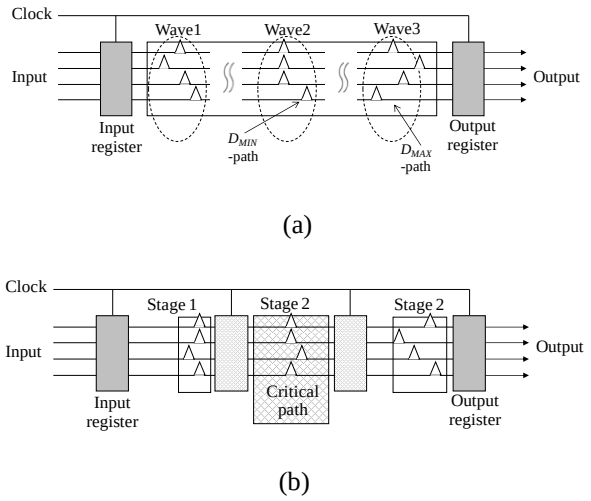

Figure 1. Synchronization of pipelines. (a) Wave-pipeline. (b) Conventional pipeline

Accordingly, design and evaluation methods for wave-pipelines have not yet established well compared with those for conventional pipelines. Mostly wave-pipelines have been so far applied to simple unifunctional circuits such as adders, multi-pliers, counters, and DRAM. Regarding multifunctional wave-pipelines, a wave-pipelined ALU has recently appeared [10]-[13].

Then, a microprocessor developed by using wave-pipelines in part appeared [14]. It is 14-segment ULTRASPARC-III whose second and third instruction fetch segments have been wave-pipelined. Another example is an asynchronous wave-pipeline, though it is not compatible with conventional processors. Wave-pipelined LFSR that is a sequential circuit had not been achieved [2].

The signal path of combinational circuit is uneven of delay time. The most high-speed signal in one group in a clock has the possibility to collide with the slow signal in just before clock. The problem was solved to wave-pipelined combinational circuit shown in Figure 1 (a) by the delay time of all signal paths is brought close at the delay time of critical path.

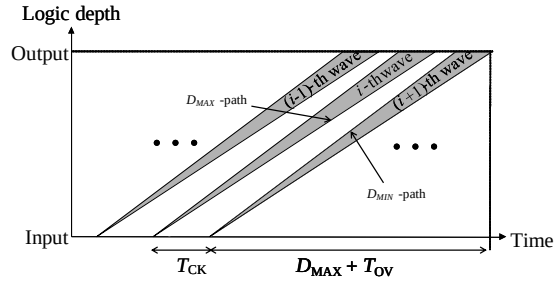

Figure 2. Wave model of Figure 1 (a)

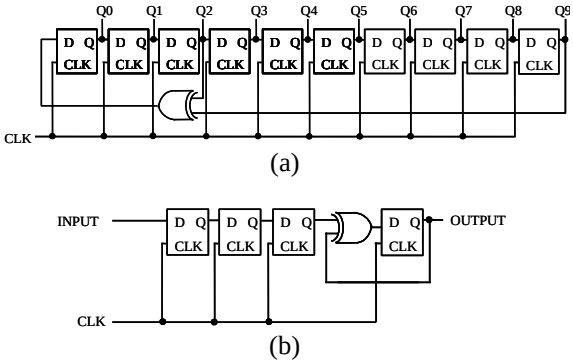

Figure 3. Conventional LFSR. (a) PRNG. (b) CRC

The relation between the clock cycle and delays is obtained as follows [4].

$$T_{CK} > (D_{MAX} - D_{MIN}) + T_{OV}. \qquad (1)$$

Here,

T_{CK}: Clock cycle time

T_{OV}: Overhead time

From Eq. (1), $D_{MAX} - D_{MIN}$ should be close to 0 as much as possible in order to obtain minimum T_{ck}. One of solution to satisfy this requirement can be conceived from Figure 2 that shows relation between time and logical depth.

III. WAVE-PIPELINED PRNG

A. *Wave-pipelined LFSR*

A LFSR circuit includes all circuit that multiplied return by shift register in some arithmetic circuit as shown in Figure 3 [2]. A PRNG of Figure 3 (a) and a CRC Circuit of Figure 3 (b) are a LFSR circuit. CRC-32 used for Ethernet hardware is composed of 32 registers, and initial value of WEP that is encryption of wireless LAN uses PRNG composed of 24 registers.

The use of a lot of registers is a cause of the increase of power consumption with a clock. Because the use of a wireless LAN is indispensable in a mobile computing, the CRC processing circuit and the WEP processing circuit become indispensable. Therefore, power consumption is increased in using it.

B. *Design of Wave-pipelined PRNG*

Table I shows development environment, and Figure 4 shows the logic circuit of conventional PRNG and Wave-pipelined PRNG. Wave-pipeline technique should adjust delay time by the methods other than the use of a register. Here, we adjust delay time by using buffers.

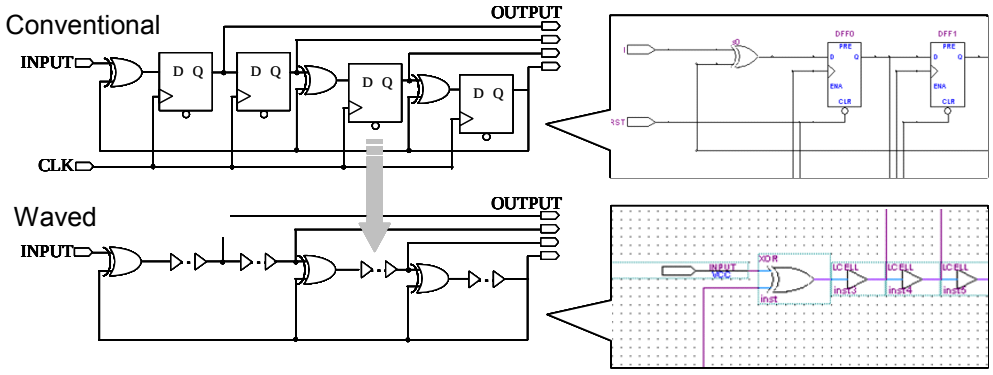

Figure 4. The logic circuit of conventional PRNG and Wave-pipelined PRNG.

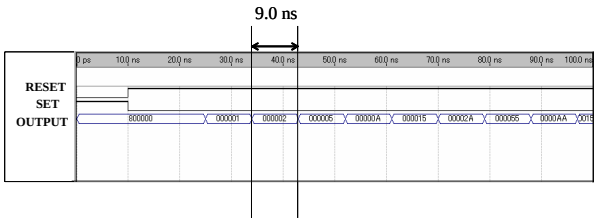

Figure 5. Gate-level simulation result of 24-bit waved-PRNG.

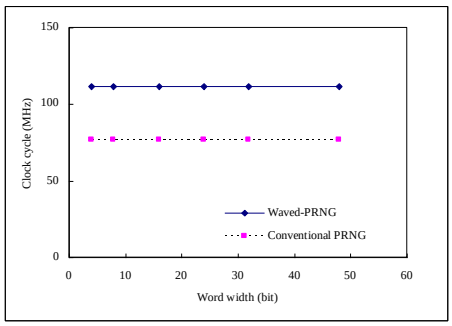

Figure 6. Operation speed of waved-PRNG circuit vs. conventional PRNG circuit.

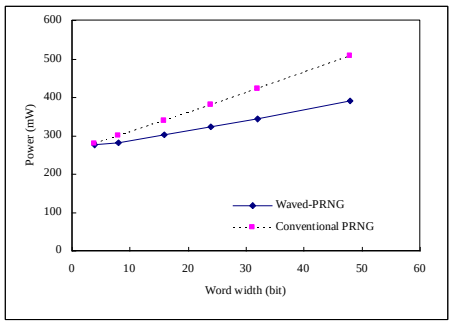

Figure 7. Power consumption of waved-PRNG circuit vs. conventional PRNG circuit.

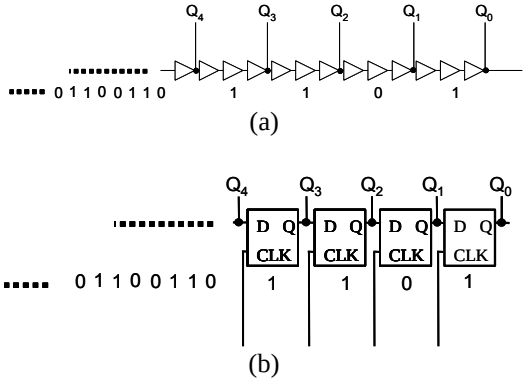

Figure 8. PRNG operation. (a) Wave-pipelined PRNG circuit. (b) Conventional PRNG circuit.

C. Evaluation of operation clock speed and power consumption

We have evaluated Wave-pipelined PRNG by using the development environment in Table I. Figure 5 shows the gate-level simulation result of 24-bit Wave-pipelined PRNG. According to the result of gate-level simulation, it shows that the 24-bit Wave-pipelined PRNG circuit operates normally without using a register and by 111.1 MHz.

Figure 6 shows the evaluation result of operation speed of conventional PRNG circuit and Wave-pipelined PRNG circuit. Figure 7 shows the evaluation result of power consumption of them. According to Figure 6 and Figure 7, Wave-pipelined PRNG circuit is unities high-speed and low-power consumption operation. Plotting word width of Figure 6 and Figure 7 are 4, 8, 16, 24, 32, and 48 bits respectively.

IV. VERIFYING RANDOM NUMBER SEQUENCES

We discuss that the Wave-pipelined PRNG circuit generates various random number sequences by controlling the operation clock frequency. As shown in Figure 8 (a), the Wave-pipelined PRNG generates random numbers. Figure 9 shows output when the operation clock speed is reduced by half and 1/3. There is a definite relation between clock frequency and random output. This does not hold for

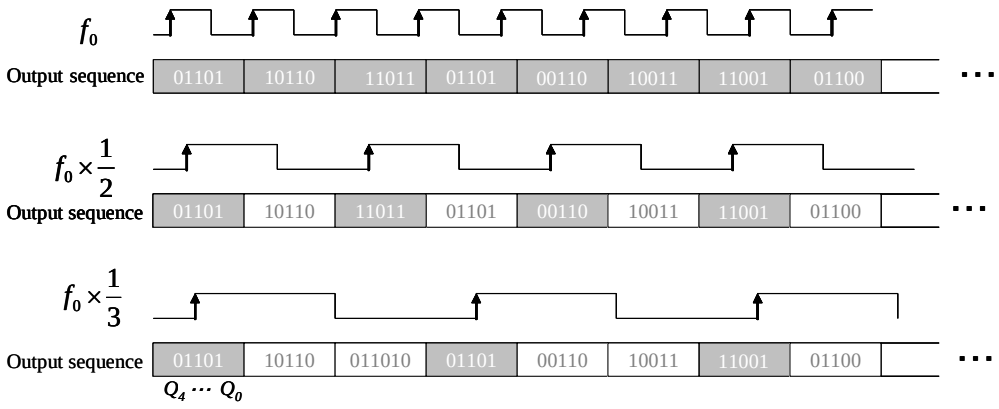

Figure 9. Output values of Figure 8 (a).

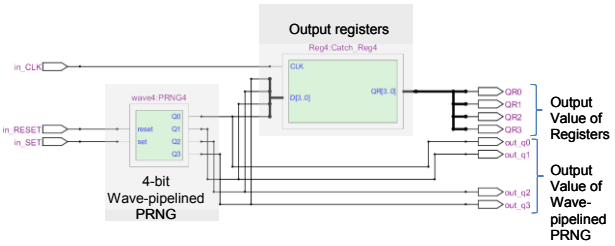

Figure 10. Wave-pipelined PRNG with output registers.

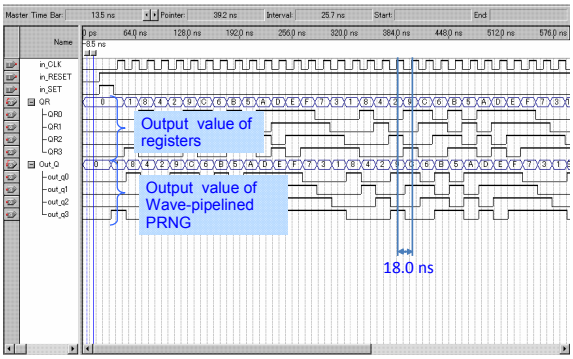
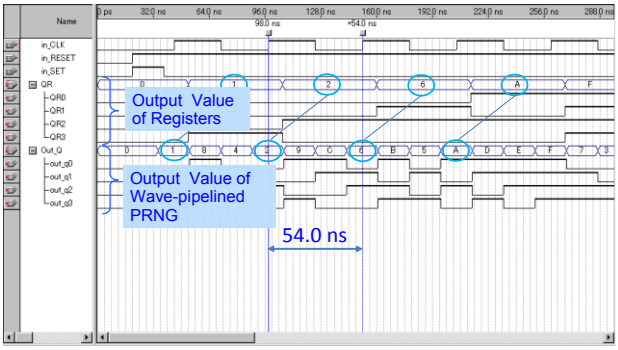


(a)



(b)

Figure 11. The simulation result of Figure 10. (a) 55.6MHz operation. (b) 18.5MHz operation.

conventional PRNG as is explained in Figure 8 (b).

Because we did not add Wave-pipelined PRNG to output registers, we were not able to confirm the operation of Figure 9. Therefore, output registers are added to Wave-pipelined PRNG as shown in Figure 10.

A. Verifying by gate-level simulation

The circuit is evaluated by the gate level simulation using the development environment of Table I. Figure 11 is shown the simulation result of Figure 10. Figure 11 (a) shows that 55.6 MHz operation is the same as the operation speed of Wave-pipelined PRNG. Figure 11 (b) shows that 18.5 MHz operation is 1/3 at the operation speed of Wave-pipelined PRNG. The reason why the circuit of Figure 10 is slower than the result of Figure 6 is to use output registers.

The result of Figure 11 (b) shows Wave-pipelined PRNG generates various random number sequences by controlling the operation clock frequency. When conventional PRNG circuit is used, the generation of various random number sequences needs the circuit that uses a lot of registers.

V. CONCLUDING REMARKS

We have described in this paper generating various number sequences by controlling the operation clock frequency of output registers of wave-pipelined PRNG. The function has been verified by the gate level simulation. Additionally, wave-pipelined PRNG has the feature that operates by high-speed and low-power consumption. Wave-pipelined PRNG makes it possible to design a strong cipher that operates by high-speed and low-power consumption.

***Abstract*- This paper proposes a procedure to enhance an asynchronous system bus. The designed bus is incorporated with synchronizing operation between synchronous components and asynchronous ones. Interrupt and DMA technique are chosen for bus capability enhancement.. The prominent point of this work is to take an interrupt and DMA technique assembled with asynchronous system bus. The designed system bus is described in HDL language. The experiments can show the concurrent processing between asynchronous processor execution and DMA transfer operation.**

I. INTRODUCTION

Asynchronous circuits are well known for last decade because of the clock skew avoided. The clock skew occurs when the global clock used to synchronize their operation which can not be distributed to the entire system at the same frequency [1]. It is a major problem cause the system may malfunction. It is very hard to avoid this problem when high speed circuits' transfer needed. As a result, it limits the speed of synchronous circuits. Asynchronous circuits do not use global clock, circuits respond to signal transitions at any time, and outputs can be sent instantly after the operation completion. More outstanding shot of the asynchronous circuit over synchronous circuits is high speed operation because it is not limited by the slowest part of circuits. Low power consumption due to signal transitions are made only when necessary [2].

Causes of complex circuits' design of asynchronous circuit produce some limitation to the design to be large system. Which operate with asynchrony operation, some asynchronous circuits design like processor, there emerge limitation to enhance the design to be large system. It also serious when propagation needed, like connecting an asynchronous processor with multiple peripherals, because memory and I/O module on a present time operate with clock [6], It's a choice if be able to compromise some element that operate with clock to work together with asynchronous circuits, bus enhancement and communicating between synchronous and asynchronous circuits are main purpose of this paper.

DMA design is splash to five working state, compose of registers to store intermediate data, adder/subtracted to count up and down of write and read addresses, the DMA design is capable to work with our asynchronous system bus as well by add stretchable interfacing [6]between bus and DMA module.

Asynchronous processor architecture, control unit, and instruction has modified for interrupt and DMA capability.

Part of paper start with introduction to background of asynchronous system bus design and explain the design of interrupt and DMA, and follow with full system simulation and provide some future work on the final section.

II. ASYNCHRONOUS SYSTEM BUS OVERVIEW

The bus designs are Multiplex. There are data and address transition on the same lines. 8-bit with dual-rail encoded, transition by 4-phase signaling transition protocol[4]. The processes are start with design each component and group them together.

A. Bus components [8]

a. Bus Interface

Bus interface is design to interface with asynchronous processor. Due to the multiplex bus design, bus interface also handshake with bus controller to control the sequence of data, address or spacer transition.

b. Bus Driver

Bus Driver act like an on/off switch to enable/disable transition signal on the bus. Design with tri-state buffer and C-element (the element that produce output 1 when all of input are 1, produce out 0 when all of input are 0, Otherwise its hold previous state)

c. Bus lines

On account of high impedance state of Tri-state buffer, there were making some problem for asynchronous circuits. Need to improve to be zero value when it's high impedance by added weak inverter to each line on the bus.

d. Bus Receiver

This component use to receive data from bus signal and catch all signals before transfer to the destination, Design with C-element

e. Bus Controller

Design with STG (Signal Transition Graph), use to control the synchronization on the bus, due to multiplexing, its responsible to control the sequence of data, address, and spacer transition.

III. INTERRUPT DESIGN

The processor instruction that use in this system has 16-bit length instruction set, by load instruction from ROM to IR register. When 16-bit instruction load in to IR register, IR register response to separate instruction in to two types, *opcode* and *operand*, opcode is load to control unit section, the operand is load to general purpose register or accumulator follow on instruction type [5, 7]. The modification, benefit to generate ***virtual instruction*** that occur during interrupt even, When interrupt instruction has occurred, a virtual instruction has generate by external signal and load to IR register.

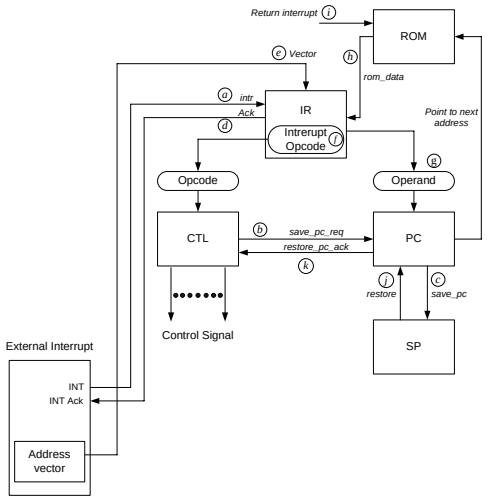

Figure 1. Interrupt Instruction in Asynchronous Processor design

From figure 1 illustrate transaction sequence of an interrupt operation.

a. Interrupt signal asserted
b. Control unit tell pc register to save current pointer
c. Save PC to SP register
d. Interrupt acknowledge asserted
e. Address vector load to IR register
f. Interrupt opcode is generated
g. Load new PC value
h. PC point to interrupt service routine, ROM data load to IR
i. Instruction meets RETI command (return interrupt).
j. RETI command produces SP register to restore value to PC.
k. PC restore acknowledge to control unit
l. Process normal instruction

The processor work on following sequences, First step load instruction that point by PC to IR register, and process base on type of instruction. When EI flags is disable, interrupt is not respond until finish instruction execution of previous instruction EI is enable, if interrupt signal occur by assert *intr* signal by external device, the IR register release ROM connection and produce it self instruction call *virtual instruction* , this instruction is valid for interrupt instruction and separate instruction to two piece, opcode and operand. Opcode is responsible to save / restore signal to pc register , operand is first address that keep an interrupt service routine, when PC register receive save signal from control unit it save current pointer to SP register and jump to next address that produce by virtual opcode.

IV. DMA DESIGN

The Asynchronous processor is a master device on the asynchronous system bus, that it is able to initiate read and write transfers to all devices on the bus. The DMA controller is slave device, which is only able to response to read or write requests. The DMA controller is required to initiate read and write transfers to memory and also other I/O on the bus, DMA controller also required to be a master device

As there will be more than on asynchronous bus master in the system, the asynchronous system bus specification required the presence of a bus arbiter. The bus arbiter selects which master is to have right to the bus at any one instant in time. An arbiter also exits for the asynchronous processor. Initially the DMA controller is programmed by asynchronous processor. This information is stored in internal DMA registers. Include following information: base address for transfer source, base address in memory to where the data is transferred and size of data transfer. The DMA controller also be slave on the asynchronous system bus in order the asynchronous processor access these registers

A. DMA Function

The DMA controller waits for *dma_req* line to assert and take over the asynchronous system bus from asynchronous processor. It checks its internal registers to obtained details of the transfer. The DMA controller read data from the source, store it in internal buffer, and then write it out to the memory, until the transfer is complete. The DMA controller then release usage of asynchronous system bus and activate the IRQ line in order to indicate the asynchronous processor that transfer was complete. If any time the asynchronous processor requires usage of asynchronous system bus it is able to take priority over the DMA controller. The DMA controller check it has control of the bus at each stage, if it does not the controller wait for the bus become available, the asynchronous processor has finished using the bus

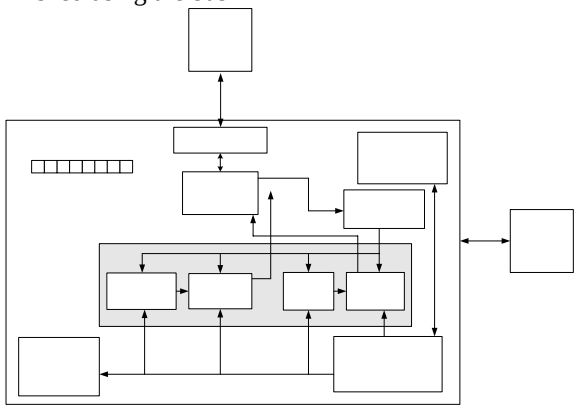

Figure 2. DMA controller architecture

B. DMA Architecture

The internal architecture is very closely based on the classic DMA controller that shown of figure 2, the architecture proposed of the DMA controller split into above functional units. The most complex of these units is timing and control unit, which consist of a large state machine which described in the diagram on the figure 3. The address decoder derives clock enable signal and present 8-bit registers which store details of the transfers.

C. DMA state machine

The most complex part of DMA controller is state machine as shown figure 3

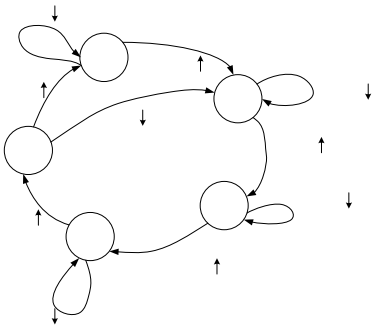

Figure 3. DMA state machine

c. Processor assert *Hold_ack* signal to DMA (processor program base address to DMA base register and count register [ST command]).
d. DMA assert *DMA_ack* signal to I/O Module
e. I/O Module assert Device_ready to DMA (transfer type is set by I/O Module (Read or Write)
f. DMA transfer (read or write transaction occur)
g. DMA assert *TC* signal indicate zero value of count register
h. DMA interrupts to processor for complete transaction

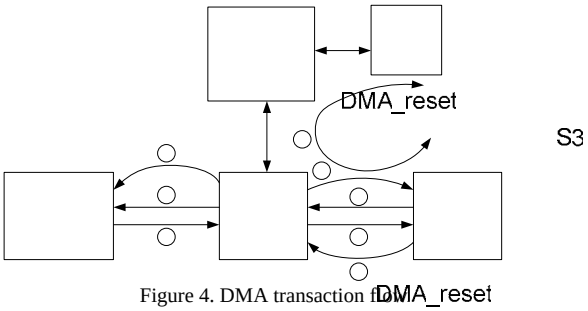

Figure 4. DMA transaction flow

V. SYNCHRONOUS AND ASYNCHRONOUS INTERFACING

This part is design to communicate between synchronous and asynchronous section, design with stretchable clock [6].

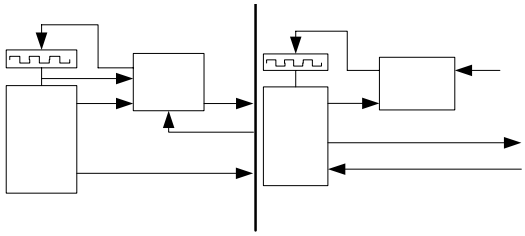

Figure 5. Stretchable clock for read (a) and write (b) interfacing

The clock control is generated using the handshaking signals and the internal state of the synchronous region, a block has either a read port or a write port. Read port provides data for an external element while a write port receive data into the module. In a 4-phase protocol, each module must receive two asynchronous transitions to complete a cycle. Each synchronous module must go through to two clock cycles to allow for two possible stretch signals.

VI. SIMULATION RESULT

The system is design with VHDL description language [3] separately on each component and simulates each component for correct signal behavior and functional. Then combined those together to form a full system as shown on figure 6 .after that experimental simulation are shown.

VII. Conclusion And Future Work

This paper proposes a technique to enhance an asynchronous system bus [8]. Introduce synchronization procedure between synchronous and asynchronous circuits. Interrupt and DMA technique are chosen for bus enhanced, DMA is design with state diagram, and connect with two input/output buffers, I/O arbitration controlled, The system work as follows, interrupt signal from I/O module assert to tell processor release the bus, when processor release it, operation begin by DMA controller concurrently with processor execution. For future work, improve the system to interface with present I/O devices, such as USB, LCD character screen or serial port interfacing, PS/2 mouse/keyboard, VGA and etc. moreover, modify DMA controller to be asynchrony operation.

***Abstract*- Two main parts are necessary to implement a prototype of pH measurement system: pH sensor and interface unit. The pH sensors, based on Ion Sensitive Field Effect Transistor (ISFET), are designed and then fabricated used 6-inch silicon wafers by conventional CMOS process. As ion sensitive membrane, all transistors have 50nm high quality silicon nitride thin film which was deposited on 10nm silicon dioxide. The sensitivity of sensors is found in the range of 40-55 mV/pH. The interface unit supplies the sensor with a constant current and voltage. The pH value is identified from the output voltage of the circuit. From the results, the system can be used for measuring the pH values in the range of 4-10 with a resolution of 0.1 pH.**

I. INTRODUCTION

Monitoring of pH value is beneficial for the agriculture and environment fields. The conventional pH sensors are in a form of the glass electrode. Such sensors have many disadvantages, the size and maintenance of electrode, the reaction time, for examples. An alternative pH sensor was introduced by Bergveld [1]. In stead of glass electrode, the sensor is a solid state device, known as Ion Sensitive Field Effect Transistor (ISFET). Principally the ISFET is very similar to Metal Oxide Semiconductor Field Effect Transistor (MOSFET). Fig.1 shows the schematic of MOSFET compared to ISFET. In stead of the gate on the isolator in case of MOSFET, the gate of ISFET, called reference electrode, float in the electrolyte and the insulator, as know as Ion Sensitive Membrane (ISM), contacts directly to the solution. the surface potential changes with the pH value of the solution, this results in changes of the threshold voltage V_T of the ISFET. In the conventional CMOS process two insulators can be used as ISM: silicon dioxide and silicon nitride. Due to the more stability and shorter response time [2,3], silicon nitride is used in the studies. By combining with CMOS technology process, the sensors can be fabricated in mass production and the membrane dimension can be reduced to an area of a few thousand of square microns.

In the implementation of pH meter, a read out circuit is connected to the sensors. So the accuracy of the system depends not only on the properties of the sensors but also on interface unit. Fig. 2 shows the read out circuit, which is used for the prototype [4]. The circuit is designed to apply constant both drain-source current I_{DS} and drain-source voltage V_{DS} to the sensors. The operation point can be adjusted individually by R_1 and R_2 respectively. From the output voltage V_O the pH value is derived from the calibration in standard buffers.

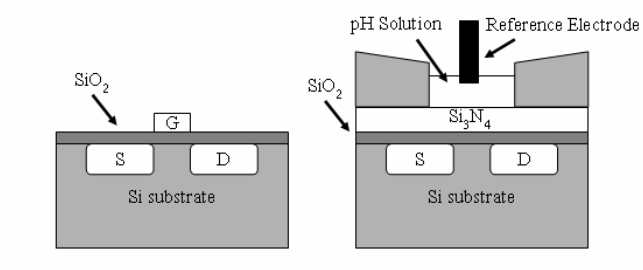

Figure 1. (a) MOSFET has a gate dielectric deposited on top of insulator membrane while (b) ISFEET does not have gate directly deposited on top of the dielectric.

The following parts of the paper will start from the experiments, the electrical characterization and finally the conclusion.

II. EXPERIMENTS

The design and fabrication of ISFET on 6-inch silicon wafers are described in detail elsewhere [5,6]. After the fabrication process is finished, the wafer is diced into individual units. The diced sensor is then glued on a prepared print circuit board and bond wired to metal pads. For encapsulation, negative photoresist SU8-100 is spreaded on the metal parts and the edge of Si substrate. Finally the sensor is cured at 85^{O}C for 30 min and then exposed in UV light 5 min.

The electrical characterization began with the measurement of gate leakage I_G, drain current I_D and source current I_S in the pH7-standard solution using HP 4156B. The purpose of the leakage current measurements is to check the quality of the sensors. By measuring a constant voltage V_{DS} of 0.3 V is applied between source and drain. Between gate and ground the voltage V_G is varied from 0 to 2 V in steps of 0.1 V and the I_S, I_D and I_G are recorded.

Three pH buffers are used for characterization of sensitivity. It begins with the measurement of pH4 solution. Like the leakage current characterization a constant V_{DS} of 0.3 V is applied with variation of V_G from 0 V to 2 V. Before measuring in the next solutions, pH7 and pH10, the sample is then rinsed with deionized water and dried with paper wiper.

The sensitivity is calculated from the shift of V_G at the same I_D with respect to the change in pH values.

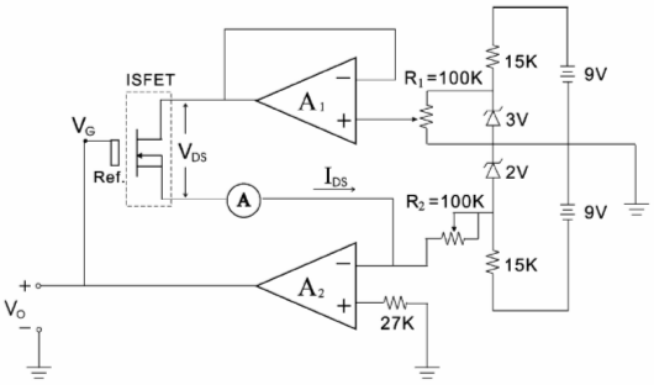

Figure 2. Interface circuit applies both constant V_{DS} and I_{DS} to sensor.

For the implementation of the pH meter, the response time and the memory effect are also studied here. It corresponds to the reliability of the system. In order to characterize the sensor, the sensor is connected with an interface circuit. At the operation point the circuit supplies V_{DS} of 0.3 V and I_{DS} of 10 μA and the V_O were recorded for the period of 3 minutes with the following steps: pH 4, 7, 10, 7 and 4. Furthermore, the sensor is immersed in pH 7 for 10 hours to reveal long time drift behavior.

III. RESULTS AND DISCUSSION

A. Sensors characterization

1. Leakage current measurement

Fig. 3 shows the current response of a sensor with a gate length (L) of 4000 μm and a gate width W of 10 μm by the leakage current measurement. Very low gate leakage current (less than 50 pA at V_G 2 V) is achieved, hence the other curves, I_D and I_S, are not affected from the leakage current and virtually symmetrical about the V_G axis. From the result it indicates that the sample has the ISFET properties, good encapsulated and can be used for the further characterization.

2. Sensitivity

In Fig. 4 the currents of ISFET with L = 10 μm and W = 3200 μm is illustrated. In different buffers, I_{DS} are separated obviously due to the threshold voltage drift. The drift is caused by ion-sensitive of the electrode-liquid-oxide interfaces [7][8]. The sensitivity is specified from the varying of V_G at the same I_{DS} in different pH buffers. From the sample in Fig. 4 the sensitivity varies linearly with 55 mV/pH at 10 μA. Various ISFETs are characterized and the range of sensitivity is 40-50 mV/pH under the same bias condition.

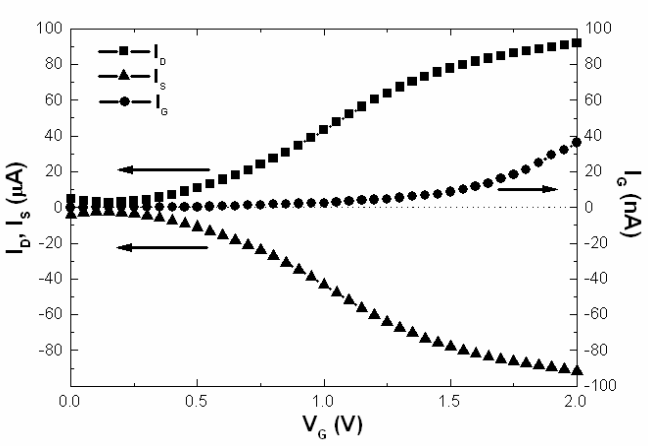

Figure 3 Result of a leakage current measurement at VDS=0.3V, and sweep VG from 0 to 2 V in steps of 100mV.

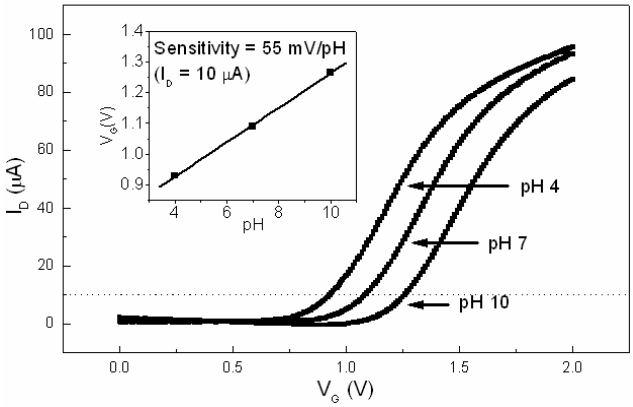

Figure 4 I_D curves in different pH buffers and inset shows the sensitivity of the ISFET.

B. Sensors characterization

1. Memory effect

At operating point, the interface circuit is set to supply a constant current I_{DS} of 10 μA and voltage V_{DS} of 0.3 V. In order to characterize the ISFET, the ISFET is immersed in the following buffers; pH4, 7, 10, 7, and 4, respectively. Fig. 5 illustrates the output voltage V_O of a sample with L = 10 μA and W = 4000 μA. Whatever solution into which the ISFET is immersed , V_O reaches stable value after immersing for a few seconds. This indicates fast response time of the sensors. From the same measurement the accuracy of the sensor can be also defined. The inset of Fig. 5 shows the response of the sensor as function of different pH values. A small voltage drift can be observed only. The discussions of the hysteresis behavior is detailed by Bousse *et al.*[9]. This very small drift corresponds to the high accuracy of the sensors. From the plot the sample shows a voltage drift of 5 mV at pH 4. By the

sensitivity of 50 mV/pH the drift corresponds to the measurement accuracy of 0.1 pH.

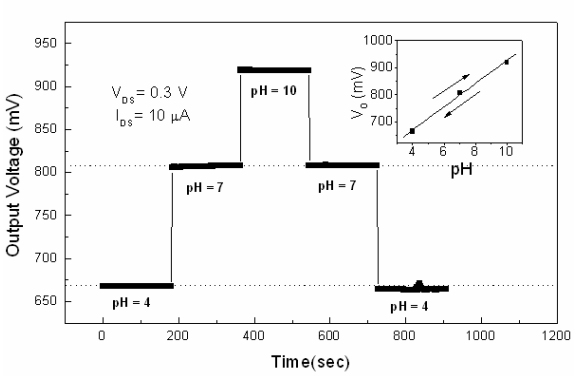

Figure 5 V_O of the interface circuit in different buffers and the inset shows V_O-pH behavior of the ISFET.

2. Drift behavior

Fig. 6 shows the 10 hours record of V_O in pH 7. From the fitting line the voltage drifts with the rate of 1 mV/h. Compared to the accuracy of the sensors, the long time drift behavior can be neglected by the measurement.

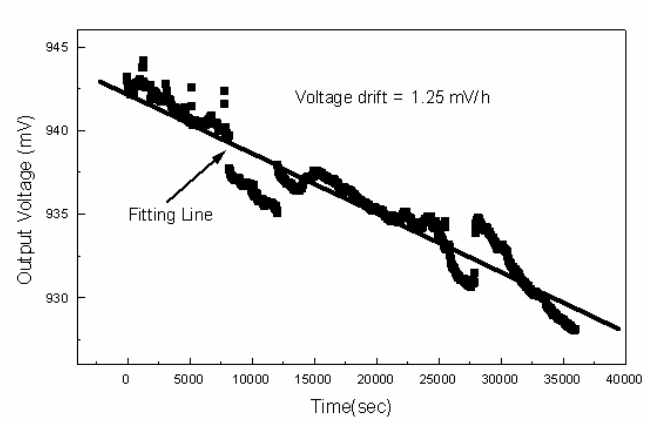

Figure 6 V_O as the function of time in pH7 buffer

IV. Conclusion

The ISFET were fabricated by CMOS compatible process. From the characterization the sensitivity of pH sensors is 40-50 mV/pH. In the prototype implementation, constant I_{DS} of 10 μA and a constant V_{DS} of 0.3 V are supplied to the sensors. The system shows the measurement accuracy of 0.1 pH. The long time drift behavior is negligible.

***Abstract*- An electronically tunable quadrature oscillator using only two current-controlled current differencing buffered amplifiers (CCCDBAs) and two ground capacitors without external passive resistor is proposed. The outputs of two sinusoidal waveforms with 90° phase difference are available from the configuration. The oscillation condition and the oscillation frequency ω_o of the proposed oscillator circuit are tunable by electronically through controlling the external dc bias currents of the CCCDBAs. The simulation results with PSPICE are used to verify the theory.**

I. INTRODUCTION

The quadrature sinusoidal oscillator plays an essential electronic circuit, because it can produce two sinusoidal outputs of identical frequency but of 90° phase shift, as for example in telecommunications for quadrature mixers and single-sideband generators [1] or for measurement purposes in vector generator or selective voltmeters [2]. Therefore, quadrature oscillators are widely used in many communications, signal processing and instrumentation systems. Many quadrature oscillator circuits have been reported in [3]-[11]. Note that these earlier quadrature oscillators in [3]-[7] produced voltage-mode signals, whereas the ones in [8]-[11] generated current-mode signals.

Since an introduction of the current differencing buffered amplifier (CDBA) in 1999, it has been acknowledged to be a versatile active building block in designing analog circuits [12]. The CDBA can be considered as a collection of current-mode and voltage-mode unity gain amplifiers, it thus offers large dynamic range and wide bandwidth similar to its current-mode counterparts such as a second-generation current conveyor (CCII) and a current feedback amplifier (CFA) [13]. Numerous CDBA-based applications have been reported by various researchers [13]-[17]. The CDBA is also useful for sinusoidal oscillator design [18]-[19]. Ozcan *et al.* introduced six CDBA-based sinusoidal oscillator circuits that each consists of one CDBA, three resistors and two floating capacitors. However, the oscillation conditions and oscillation frequencies of these oscillators cannot be independently controllable. Moreover, these sinusoidal oscillators use floating capacitors, which is not suitable for integration [20]. In 2002, Horng proposed a new technique for implementing a quadrature oscillator circuit that consists of two CDBAs, four resistors and two grounded capacitors. Its oscillation condition and oscillation frequency can independently controllable. However, this configuration still uses a large number of passive resistors. On the other hand, by recently introducing the current-controlled current differencing buffered amplifier (CCCDBA) [21], it allows the design of analog circuits with electronically tunable circuit parameters, while offering all the advantages of the conventional CDBA. Also considering the absence of the external resistors in circuit realizations, the CCCDBA-based circuits seem to be good choices to use for the realization of IC oscillator circuits…

In this paper, proposed an electronically tunable quadrature oscillator using only two CCCDBAs and two grounded capacitors without external passive resistor requirement is proposed. The proposed oscillator circuit provides two sinusoidal signals with 90 phase difference. The oscillation condition and the oscillation frequency ω_o of the proposed oscillator circuit are tunable by electronically through controlling the external dc bias current. The circuit also displays low passive and active sensitivities. The employment of only grounded capacitors is a very attractive feature for monolithic integrated circuit technology [20].

II. CURRENT-CONTROLLED CURRENT DIFFERENCING BUFFERED AMPLIFIER (CCCDBA)

The circuit representation and the equivalent circuit of the CCCDBA are shown in Fig.1, where p and n are input and w and z are output terminals. The CCCDBA is defined by the flowing matrix equation [21].

$$\begin{bmatrix} v_p \\ v_n \\ i_z \\ v_w \end{bmatrix} = \begin{bmatrix} 0 & 0 & R_p & 0 \\ 0 & 0 & 0 & R_n \\ 0 & 0 & 1 & -1 \\ 1 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} v_z \\ i_z \\ i_p \\ i_n \end{bmatrix} \quad (1)$$

where R_p and R_n are respectively the parasitic resistances at the terminals p and n of the CCCDBA. A possible bipolar realization of the CCCDBA is shown in Fig.2. In this case, the resistances R_p and R_n can be given by

$$R_p \cong R_n = \frac{V_T}{2I_o} \qquad (2)$$

where V_T is the thermal voltage that is equal to 26 mV at room temperature. Equation (2) shows that it is possible to tune the values of R_p and R_n by means of an external dc bias current I_O.

(a) circuit symbol (b) equivalent circuit

III. PROPOSED CONFIGURATION

Fig.3 shows the proposed electronically tunable quadrature oscillator using CCCDBAs as active elements. The oscillator circuit employs only two CCCDBAs and two grounded capacitors without passive resistor requirement, which is ideal for integration [20]. Circuit analysis yields the characteristic equation of the circuit as follows :

$$s^2 + \left(\frac{1}{R_{p2}} - \frac{1}{R_{p1}}\right)\frac{s}{C_1} + \left(\frac{1}{R_{n1}R_{p2}C_1C_2}\right) = 0 \qquad (3)$$

where R_{pi} and R_{ni} denote the parasitic resistances R_p and R_n of the i-th CCCDBA (i = 1, 2), respectively. Thus, the oscillation condition and the oscillation frequency (ω_o) obtained from the proposed circuit are given by :

$$R_{p1} = R_{p2} \qquad (4)$$

and

$$\omega_o = \frac{1}{\sqrt{R_{n1}R_{p2}C_1C_2}} \qquad (5)$$

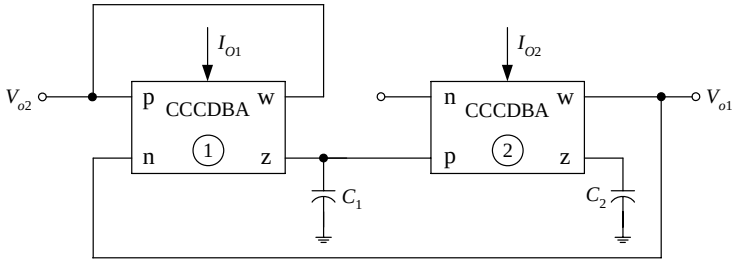

Fig.3 Proposed electronically tunable quadrature oscillator using CCCDBAs.

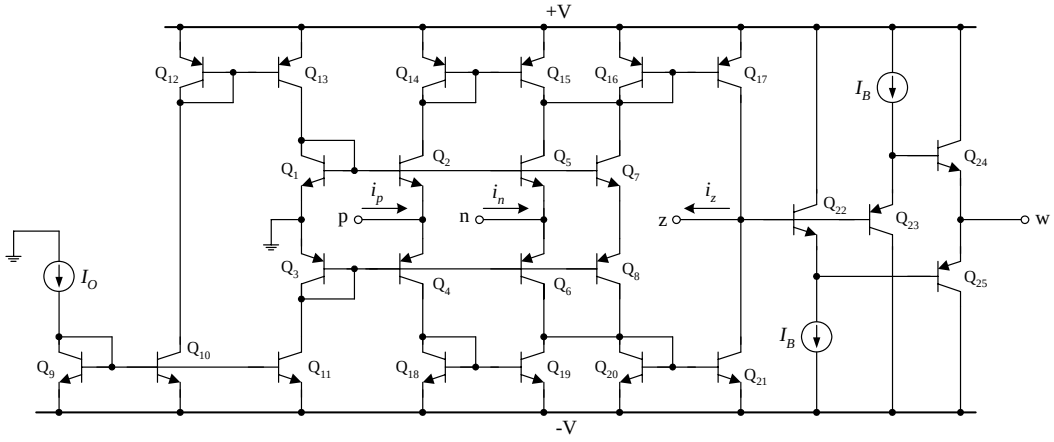

Fig.2 Bipolar realization of the CCCDBA.

Furthermore, if we setting $I_{O1} = I_{O2} = I_O$ and $C_1 = C_2 = C$, then the proposed oscillator circuit of Fig.2 can be controlled to oscillate at the oscillation frequency of

$$f_o = \frac{\omega_o}{2\pi} = \frac{I_O}{\pi V_T C} \tag{6}$$

It is clearly seen from equation (6) that the oscillation frequency of the proposed circuit can be controlled electronically by linearly adjusting the bias current I_O. It is also to be noted that the ω_o is temperature sensitive, the temperature compensation scheme is essential under varying environmental conditions [22]. Moreover, owing to the output impedance at the terminal w of the CCCDBA is very small, the output signal V_{o1} and V_{o2} can be directly connected to the next stage.

From Fig.3, the two quadrature outputs V_{o2} and V_{o1} can be expressed as:

$$\frac{V_{o2}}{V_{o1}} = sC_2R_{p2} \tag{7}$$

Therefore, the phase difference (ϕ) between V_{o2} and V_{o1} is equal to

$$\phi = 90^\circ \tag{8}$$

which guarantees that the voltages V_{o2} and V_{o1} are to be quadrature outputs.

IV. Effects of The CCCDBA Non-idealities

By taking into consideration of the non-ideal CCCDBAs, the relationship of the terminal currents and voltages given with equation (1) can be rewritten as :

$$\begin{bmatrix} v_p \\ v_n \\ i_z \\ v_w \end{bmatrix} = \begin{bmatrix} 0 & 0 & R_p & 0 \\ 0 & 0 & 0 & R_n \\ 0 & 0 & \alpha_p & -\alpha_n \\ \beta & 0 & 0 & 0 \end{bmatrix} \cdot \begin{bmatrix} v_z \\ i_z \\ i_p \\ i_n \end{bmatrix} \tag{9}$$

where $\alpha_p = 1\text{-}\varepsilon_p$, ε_p ($\varepsilon_p << 1$) is the current tracking error from p terminal to z terminal, $\alpha_n = 1\text{-}\varepsilon_n$, ε_n ($\varepsilon_n << 1$) is the current tracking error from n terminal to z terminal, and $\beta = 1\text{-}\varepsilon_v$, ε_v ($\varepsilon_v << 1$) is the voltage tracking error from z terminal to w terminal of the CCCDBA, respectively. Re-analysis the circuit configuration of Fig.3, the non-ideal characteristic equation becomes :

$$s^2 + \left(\frac{1}{R_{p2}} - \frac{\beta_1\alpha_{p1}}{R_{p1}}\right)\frac{s}{C_1} + \left(\frac{\beta_1\beta_2\alpha_{n1}\alpha_{p2}}{R_{n1}R_{p2}C_1C_2}\right) = 0 \tag{10}$$

where α_{pi} , α_{ni} and β_i are the parameters α_p, α_n and β of the i-th CCCDBA, respectively. In this case, the modified oscillation condition and oscillation frequency (ω_{on}) can be rewritten as :

$$R_{p1} = \beta_1\alpha_{p1}R_{p2} \tag{11}$$

and

$$\omega_{on} = \sqrt{\frac{\beta_1\beta_2\alpha_{n1}\alpha_{p2}}{R_{n1}R_{p2}C_1C_2}} \tag{12}$$

It may be pointed out from equations (11) and (12) that the modified oscillation condition and ω_{on} due to the CCCDBA non-idealities will be slightly changed from the ideal case. Moreover, from equation (12), the passive and active sensitivities of this circuit are calculated as :

$$S^{\omega_{on}}_{C_1,C_2} = -\frac{1}{2} \tag{13}$$

$$S^{\omega_{on}}_{R_{n1},R_{p2}} = -\frac{1}{2} \tag{14}$$

and

$$S^{\omega_{on}}_{\beta_1,\beta_2,\alpha_{n1},\alpha_{p2}} = \frac{1}{2} \tag{15}$$

All which are less than 0.5 in magnitude.

V. Simulation Results

The proposed quadrature oscillator in Fig.3 has been simulated by PSPICE to verify the given theoretical analysis. In the simulations, the AT&T ALA400-CBIC-R parameter was used [23]. The power supply voltages were selected as ±V = ±3 V. As an example, the values of capacitors are equal to $C_1 = C_2 = C = 0.01$ μF and bias currents I_B and $I_O = I_{O1} = I_{O2}$ are approximately 500 μA and 200 μA, respectively. This setting was designed to obtain the oscillation frequency f_o at 245 kHz. Fig.4(a) shows the simulated quadrature output waveforms V_{o1} and V_{o2} of the proposed CCCDBA-based quadrature oscillator of Fig.3, where the oscillation frequency f_o is measured to be 216 kHz. Fig.4(b) shows the simulated frequency spectrums of the quadrature outputs V_{o1} and V_{o2}.

The total harmonic distortion (THD) for the designed frequency has been analyzed, and it has also been observed that the THD is approximated to 7.590% for all the quadrature outputs. The results of the total harmonics distortion analysis are summarized in Table 1.

DC component = 1.051418E-02					
Total harmonic distortion = 7.594297E+00 PERCENT					

VI. CONCLUSIONS

A new quadrature sinusoidal oscillator employing only two CCCDBAs and grounded capacitors has also been proposed. The proposed quadrature oscillator circuit offers the following advantages ; (i) two quadrature sinusoidal output waveforms of 90° phase shift are obtained simultaneously; (ii) it provides low output impedance ; (iii) the oscillation condition and the oscillation frequency are controllable electronically; (iv) using only grounded capacitors for its realization, which is suitable for integration; (v) low passive and active sensitivities.

Implementation of a Chua's Chaotic Oscillator Using "Roughly-Cubic-Like" Nonlinearity

Banlue Srisuchinwong and Wimol San-Um
Sirindhorn International Institute of Technology, Thammasat University, Bangkadi Campus,
131 Moo 5, Tiwanont Road, Muang, PaThum Tani, 12000, Thailand, banlue@siit.tu.ac.th

***Abstract*— Implementation of a Chua's chaotic oscillator is proposed using roughly-cubic-like nonlinear resistor. A simple current mirror and a single-ended differential pair shape a grounded nonlinear resistor and exhibit roughly cubic-like voltage-current characteristics. A simulated trajectory of the double-scroll chaotic attractor is demonstrated.**

I. INTRODUCTION

Over the past two decades chaotic oscillators [1-3] have received increasing interest as a useful tool not only for investigation of nonlinear phenomena, bifurcation and chaos, but also for a variety of applications such as synchronizations, control [4] and chaos-based communications systems [5]. Chua's circuit [3] is one of the best-known chaotic oscillators using a nonlinearity known as a (piecewise-linear) "Chua Diode". Several techniques including the "cublic" nonlinearity [6] or "cubic-like" nonlinearity [7, 8] have alternatively been proposed to replace the Chua diode.

In this paper, an implementation of the Chua's chaotic oscillator is presented using roughly-cubic-like nonlinearity. A single-ended differential pair and a simple current mirror are combined to form a compact four-transistor grounded nonlinear resistor that exhibit roughly cubic-like voltage-current characteristics. The circuit develops the double-scroll chaotic attractor.

II. CIRCUIT IMPLEMENTATION

Figure 1 shows the proposed Chua's chaotic oscillator using a roughly-cubic-like nonlinear resistor R_N. Inductor L1, capacitors C1 and C2 form parts of the Chua's circuit. A single-ended differential pair (M1, M2), a simple current mirror (M3, M4) and a current source I1 form the nonlinear resistor R_N. For simplicity, let the effects of the channel length modulation of transistors be neglected. Let v_x and i_x be the input voltage and input current to R_N, i.e. $R_N = v_x / i_x$ at the gate of M1. A routine small-signal analysis suggests that $i_x = -2i_d$ where $i_d \cong g_{m1}v_x / 2$ and g_{m1} is the transconductance of transistor M1 or M2. Consequently, for a small-signal operation, R_N exhibits a negative resistance i.e.

$$R_N \cong -\frac{1}{g_{m1}} \tag{1}$$

For a large signal operation, R_N can be distored in a nonlinear fashion because of the nonlinearity of the MOS transistors or eventually may enter into saturation.

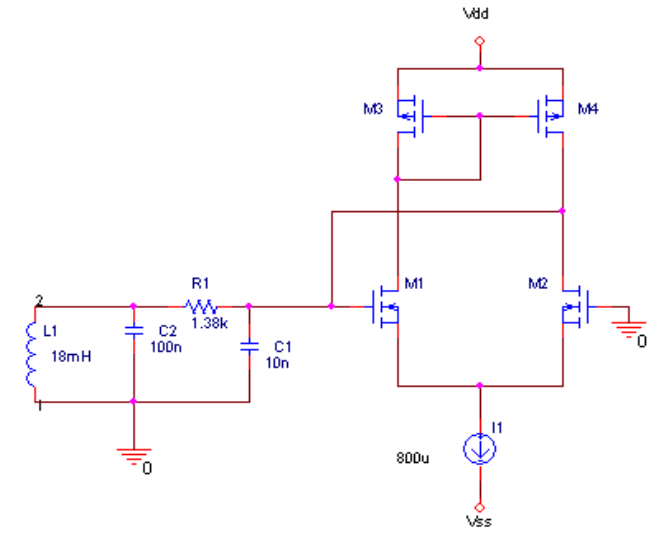

Figure 1 Chua's circuit using roughly-cubic-like nonlinearity.

III. SIMULATION RESULTS

The performances of the circuits shown in Fig. 1 have been simulated through Pspice using models IRF150 and M2N6849 for NMOS and PMOS transistors, respectively. The aspect ratio of all transistors are W/L = (100 μm)/(2 μm) and the threshold voltage of the NMOS V_{TH} = 2.831 V. The values of I1 = 800 μA, L1 = 18 mH, C1 = 10 nF, C2 = 100 nF, R1 = 1.38 kΩ. The gate-source DC voltage of M1 and M2 is V_{GS1} = 3.71 V. Consequently, $g_{m1} = I1/(V_{GS1}-V_{TH}) = 910.12\ \mu\Omega^{-1}$ and, for the small-signal analysis, the calculated value of R_N = –1.09 kΩ.

Figure 2 shows the simulated voltage-current characteristics of the nonlinear resistance R_N where v_x in the x axis is between -5 V to 5 V and i_x in the y axis is between -800 μA to 800 μA. For the small-signal analysis, the measured value of $R_N = v_x / i_x$ = (–40 mV)/(35 μA) = –1.14 kΩ and is consistent with the calculated value. It can be seen from Fig. 2 that, for the small signal operation, the negative resistance R_N is evident through the negative slope whilst, for the large signal operation, R_N exhibits nonlinearity. The curve of R_N shown in Fig. 2 looks like a roughly coarse version of a "cubic-like" voltage-current characteristics and hence the name "roughly-

cubic-like" nonlinearity. For purposes of comparison, a simulated example of a "cubic-like" voltage-current characteristics is shown in Fig. 3. Fig. 4 depicts the simulated trajectory of the double-scroll chaotic attractor developed in Fig. 1 in the $V_{C1} - V_{C2}$ plane where V_{C1} and V_{C2} are the voltages across the capacitors C1 and C2, repectively.

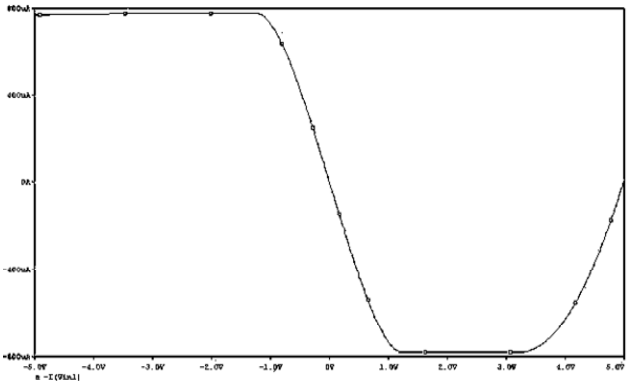

Figure 2 Voltage-current characteristics of R_N looks like a roughly coarse version of the "cubic-like" characteristics.

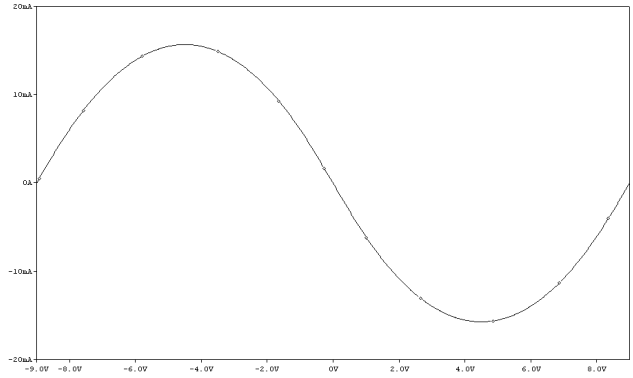

Figure 3 An example of a "cubic-like" voltage-current characteristics

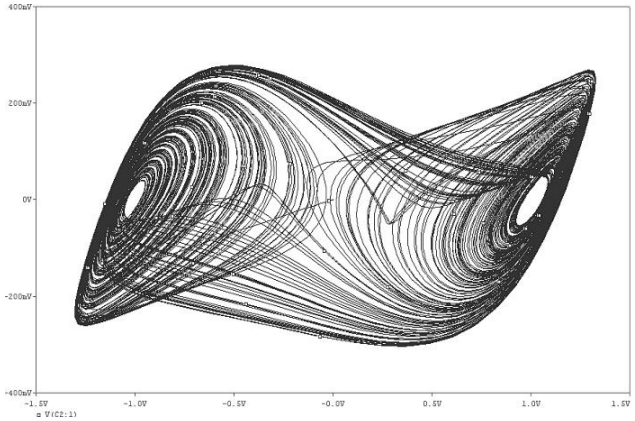

Figure 4 A simulated trajectory of the double-scroll chaotic attractor developed in Fig. 1

IV. CONCLUSIONS

Implementation of a Chua's chaotic oscillator has been presented using the roughly "cubic-like" voltage-current nonlinearity. The combination of a single-ended differential pair and a simple current mirror with a feedback has enabled a roughly cubic-like nonlinear resistor. The simulated double-scroll chaotic attractor has been demonstrated.

Improved Implementation of Sprott's Chaotic Oscillators Based on Current-Feedback Op Amps

Banlue Srisuchinwong and Chun-Hung Liou
Sirindhorn International Institute of Technology, Thammasat University, Bangkadi Campus,

***Abstract*- Improved implementation of Sprott's chaotic oscillators based on current-feedback op amps (CFOAs) is proposed. A Sprott's jerk function and four different types of nonlinear components are implemented using the attractively high-frequency features of the CFOAs operating in both voltage and current modes. Four trajectories of the chaotic attractors are demonstrated. The chaotic spectrums are easily scaled and extended to higher frequencies by a factor of 277 to 380**

I. INTRODUCTION

Over the past two decades there has been increasing interest in the study of chaotic oscillators [1-3]. Chaotic oscillators are useful tools not only for investigation of nonlinear phenomena, bifurcation and chaos, but also for a variety of applications such as synchronizations, control [4] and chaos-based communications systems [5]. Chua's circuit [3] is one of the best-known chaotic circuits but is difficult to scale to arbitrary frequencies because of the inductor with its frequency-dependent resistive losses [6] although inductorless versions of Chua's circuit have been possible [7]. Three reactive components (capacitors or inductors) and a nonlinear component are typically required for chaos systems with continuous flows so that the Kirchhoff representation of the circuit contains three first-order ordinary differential equations (ODEs).

Recently, Sprott [6] has alternatively proposed chaotic oscillators based on a single third-order ODE in a simple form of $d^3x/dt^3 = F(d^2x/dt^2, dx/dt, x)$ called a "jerk function" (time derivative of acceleration). One of the Sprott's jerk functions in a general form is [6]

$$\frac{\partial^3 x}{\partial t^3} + A\frac{\partial^2 x}{\partial t^2} + \frac{\partial x}{\partial t} = G(x) \tag{1}$$

where G(x) is a nonlinear function and A = 0.6. The most straightforward implementation involves three successive active integrators to generate d^2x/dt^2, dx/dt and x from d^3x/dt^3 coupled with a nonlinear element G(x) and feeds it back to d^3x/dt^3. Although Sprott's chaotic oscillators [6] based on (1) can be easily constructed using operational amplifiers (op amps) and be easily scaled to different frequencies, the operation has been somewhat delicate and the circuit has exhibited hysteresis because of the finite gain-bandwidth product and slew rates of the op amps [6, 8]. This problem has been circumvented by operating at a lower frequency of around 1.59 kHz [6, 8].

In this paper, high frequency implementation of Sprott's chaotic oscillators is presented using current-feedback op amps (CFOAs). The CFOAs are currently recognized as versatile alternatives to the traditional op amps for their excellent performance in bandwidth and slew rates [9].

II. CIRCUIT IMPLEMENTATION

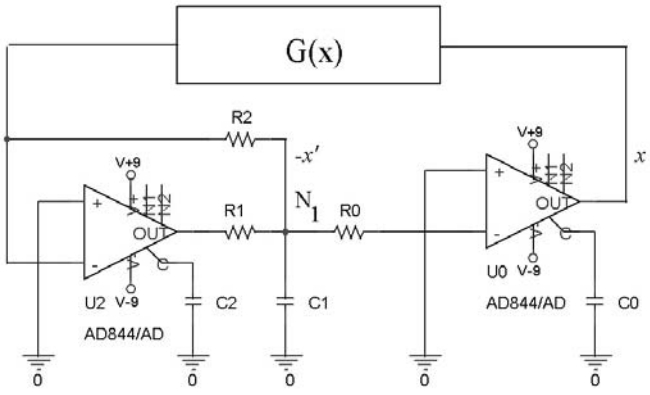

Figure 1. High frequency implementation of Sprott's chaotic oscillator using CFOAs and each of G(x) shown in Figure. 2.

Fig. 1, shows the high frequency implementation of the Sprott's chaotic oscillator based on CFOAs. The nonlinear components G(x) [6] can be implemented using CFOAs as shown in each of the system in Figs. 2(a) to 2(d) where related parameters are also listed. In Fig. 1, the CFOA U_0 forms an integrator U_0 where the zero-dB crossing (ZdB) frequency $\omega_0 = 1/\tau_0$ and $\tau_0 = R_0C_0$. The CFOA U_2 forms another integrator U_2 where the ZdB frequency $\omega_2 = 1/\tau_2$ and $\tau_2 = R_2C_2$. An expected integrator between U_0 and U_1 is replaced by a simpler passive RC filter. A routine analysis in Fig. 1 reveals that the resulting jerk function at node N_1 is

$$\begin{aligned} K_3\frac{\partial^3 x}{\partial t^3} + K_2\frac{\partial^2 x}{\partial t^2} + K_1\frac{\partial x}{\partial t} &= G(x) \\ K_3 &= \frac{\tau_0\tau_X\tau_2 R_1}{R_X R_2} \\ K_2 &= \frac{\tau_0\tau_2}{R_2}\left(1+\frac{R_1}{R_X}\right) \\ K_1 &= \frac{\tau_0}{R_2} \end{aligned} \tag{2}$$

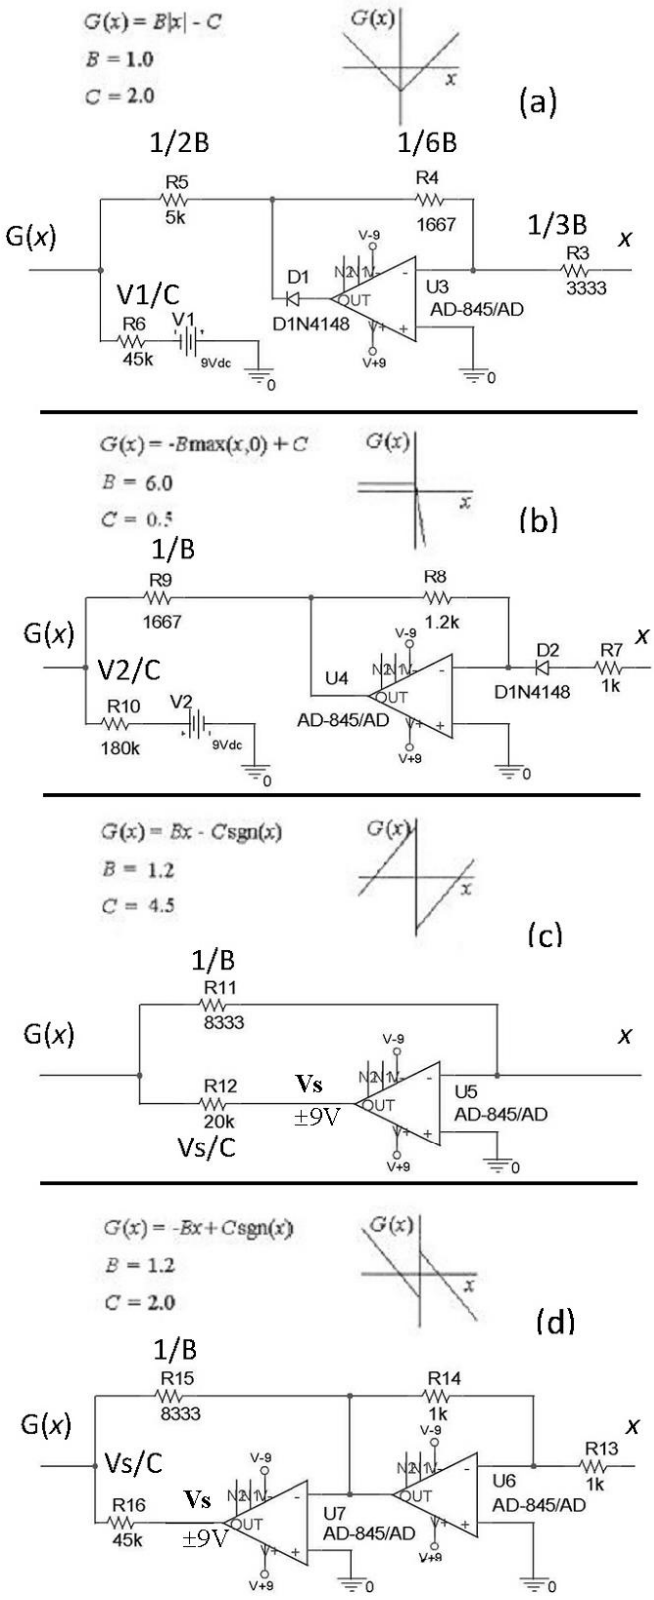

Figure 2. Nonlinear components G(*x*) using CFOAs.

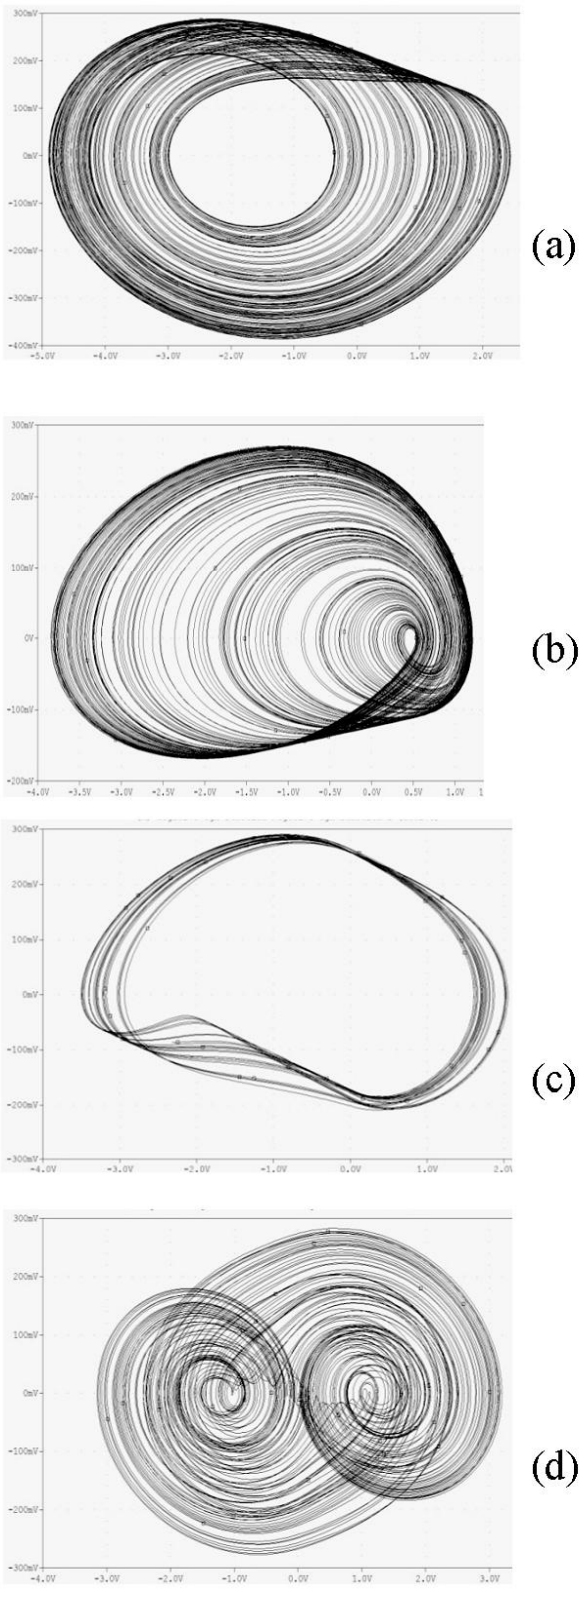

Figure 3. Chaotic attractors produced by Fig.1 using each of the nonlinear components G(x) shown in Fig. 2.

where $\tau_1 = R_1C_1$, $R_X = (R_0R_2)/(R_0+R_2)$, and $\tau_X = R_XC_1$. As (1) = (2), therefore $K_1 = 1$, $K_2 = A = 0.6$ and $K_3 = 1$. For simplicity, let $R_2 = R_1 = R_0 = R_T$. Consequently, $C_2 = A/(3R_T)$, $C_1 = 3/(AR_T)$ and $C_0 = R_2/R_0 = 1$. Table I summarizes the calculated values of the capacitors for $R_T = 1\ \Omega$ and also, with slight modification or scaling, the practical values of the capacitors for $R_T = 1\ k\Omega$.

TABLE I
Calculated and practical values of resistors and capacitors.

Components (Fig. 1)	Calculated Values	Practical Values	
		G(x) in Figs. 2(a), (b), (d)	G(x) in Fig. 2(c)
C_0	1	0.01 µF	0.5 µF
C_1	3/A	0.50 µF	25.0 µF
C_2	A/3	0.02 µF	1.00 µF
R_0	1	1 kΩ	1 kΩ
R_1	1	1 kΩ	1 kΩ
R_2	1	1 kΩ	1 kΩ

III. SIMULATION RESULTS

The performances of the circuits shown in Figs. 1 and 2 have been simulated through Pspice. Models AD844/AD and AD-845/AD are CFOAs with and without current feedback terminal, respectively. By using the practical values shown in Table I, the simulated trajectories of the chaotic attractors in the x-(dx/dt) plane are shown in Figs. 3(a)-3(d) for each of the nonlinear components G(x) shown in Figs. 2(a)-2(d), respectively. In Table I, the practical values of capacitors C_0, C_1, C_2 may be scaled down until the simulated chaotic attractors shown in Fig. 3 corrupt at which point Table II records the minimum values of such capacitors for each G(x) shown in Fig. 2 whilst maintaining the value of $R_0 = R_1 = R_2 = 1\ k\Omega$. Consequently, the operating frequency f_S where the chaotic spectrum is centered will be maximum as shown in Table II.

Table II
Minimum values of capacitors and the corresponding maximum operating frequencies f_S.

As an example in Table II where G(x) is shown in Fig. 2(d), Fig. 4 shows the corresponding output voltage waveform x and the chaotic frequency spectrum (dBm) centered around f_S = 1.21 MHz. The latter is obtained through the fast fourier transform of x. For purposes of comparisons, Table II also includes the minimum values of the capacitors and the resulting frequency f_S for the similar cases using op amps (OAs). It can be seen from Table II that the proposed implementation using CFOAs enables higher f_S by a factor of 277 to 380.

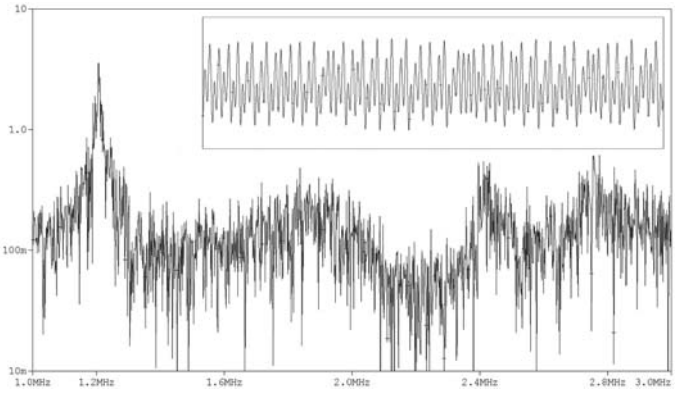

Figure 4. An example of the output voltage waveform and the chaotic spectrum (dBm) centered around 1.21 MHz indicated in Table II.

IV. CONCLUSIONS

High frequency implementation of Sprott's chaotic oscillators has been presented using CFOAs. The Sprott's jerk function and four different types of nonlinear components have been implemented using CFOAs. Four trajectories of the chaotic attractors have been illustrated. The operating frequencies are easily scaled and extended by a factor of 277 to 380.

Whereas, previous CCCII-based MSO scheme is only suitable for bipolar technology and not guarantee generate the sinusoidal at the high frequency. Therefore, the proposed MSO has more flexibility for IC implementation and dealing with the applications than the previous CCCII-based MSO.

II. CIRCUIT DESCRIPTIONS

Fig. 1 shows the symbol of the multiple-output OTA. An ideal OTA is a finite bandwidth voltage-controlled current source, with an infinite input and output impedance. The output currents of the ideal multiple-output OTA is given by

$$I_o = \pm g_m (V_+ - V_-) \tag{1}$$

where g_m is the transconductance gain, I_o the output current, V_+ and V_- is the non-inverting and inverting input voltages, respectively. For the case of OTA implemented with MOS transistors operating in saturation, the transconductance (g_m) is proportional to $(I_{abc})^{1/2}$ and it implemented with bipolar transistors, the g_m is directly proportional to I_{abc}.

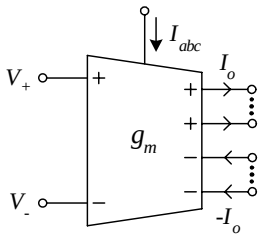

Fig. 1. Circuit symbol of the multiple-output OTA.

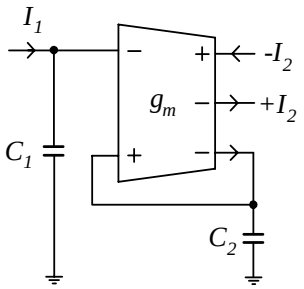

Fig. 2. Basic building block of the proposed multiphase oscillator.

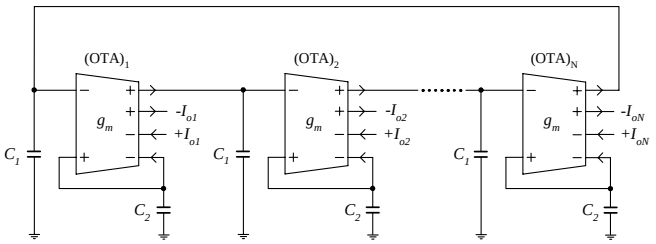

Fig. 3. Generalized circuit for realizing multiphase oscillator.

Fig. 2 shows the basic block of the proposed multiphase oscillator circuit. It consists of a multiple-output OTA and two grounded capacitors. The transfer functions between the output and input terminal of the circuit in Fig. 2 can be given by

$$\frac{I_2}{I_1} = \frac{\pm C_2/C_1}{1 + s(C_2/g_m)} \tag{2}$$

Based on Fig. 2, the generated circuit for realizing an MSO is shown in Fig. 3. Assuming that all OTA in Fig. 3 are identical, by using (1) the loop again can be expressed as

$$L(s) = \left(\frac{-(C_2/C_1)}{1 + s(C_2/g_m)} \right)^N \tag{3}$$

According to the Barkhausen criterion, the condition for the proposed circuit to provide sinusoidal oscillation of frequency is

$$\left(\frac{-(C_2/C_1)}{1 + s(C_2/g_m)} \right)^N_{S=j\omega_o} = 1 \tag{4}$$

or

$$\left(1 + j\omega_o (C_1/g_m)\right)^N + (-1)^{N+1} (C_2/C_1)^N = 0 \tag{5}$$

By expanding (5), it is show that (5) would have a solution only if the value of N is odd ($N \geq 3$). By equating the imaginary and real parts to zero, respectively, the frequency of oscillation (FO) and the condition of oscillation (CO) can be expressed as

FO
$$\omega_o = \frac{g_m}{C_2} \tan\left(\frac{\pi}{n}\right) \tag{6}$$

CO
$$\frac{C_2}{C_1} \geq \left(1 + \tan^2\left(\frac{\pi}{n}\right)\right)^{1/2} \tag{7}$$

From (6) and (7), the FO and CO of a three-phase sinusoidal oscillator (N=3) can be given as

$$\frac{C_2}{C_1} \geq 2 \tag{8}$$

and

$$f_o = \frac{\sqrt{3} g_m}{2\pi C_2} \tag{9}$$

The frequency of oscillation and the condition of oscillation for realizing N-phase sinusoidal oscillator, equal in amplitude and equally spaced in phase, are summarized in Table. From Fig. 3, the use of multiple output-OTA provides an inverted of the output current. Thus, there are $2n$=6, 10, 14 even-phase available output currents. Therefore, the MSO circuit of Fig. 3 can generate both odd-number and even-number of phase by a single circuit. From (8) and (9), the frequency of oscillation and the condition of oscillation can be orthogonally controllable. The oscillation condition can be adjusted the capacitor C_1 and the frequency condition can be tuned by electronically the transconductance g_m through the bias current. The high frequency oscillation can be obtained without the effect of OTA bandwidth in term of oscillation condition. Since the output impedance of the OTA is very high, the MSO current

outputs can be directly connected to the next stage without the using additional current followers. The active and passive sensitivities of proposed MSO circuit have low, approximately -1 to 1.

CONDITION AND FREQUENCY OF OSCILLATION OF MULTIPHASE SINUSOIDAL OSCILLATOR.

Number of phase (N)	Condition of oscillation	Frequency of oscillation (ω_o)
3	$C_2=2C_1$	$1.732g_m/C_2$
5	$C_2=1.237C_1$	$0.728g_m/C_2$
7	$C_2=1.11C_1$	$0.482g_m/C_2$
9	$C_2=1.063C_1$	$0.364g_m/C_2$

III. SIMULATION RESULT

To the theoretical analysis of the proposed multiphase sinusoidal oscillator, a CMOS design example has been simulated through PSPICE simulation program. The PSPICE model parameters for NMOS and PMOS transistor are standard 0.5μm CMOS process of MOSIS. The multiple-output plus/minus OTA schematic is modified from well know single-ended OTA structure [19]-[20], as shown in Fig. 4. It consists of a source-coupled pair with identical MOS devices (M1-M2) operating in the saturation region [19] where the output current is replicated using the current mirrors. The MOS transistors aspect ratios are: 20μm/2μm for M1, M2; 40μm/2μm for M3-M6, M9-M10, M13-M14, M17-M18; and 46μm/2μm for M7-M8, M11-M12, M15-M16, M19-M20. The power supply is V_{DD}=-V_{SS} =2.5V. Fig. 5 presents the simulation results of proposed MSO circuit with C_1=10pF, C_2=20.12pF, I_{abc}=250μA (g_m=0.371mS) for N=3 where C_2 was designed to be larger than 2 times of C_1 to ensure the oscillation will start. Fig. 6 shows sinusoidal waveform for six phases.

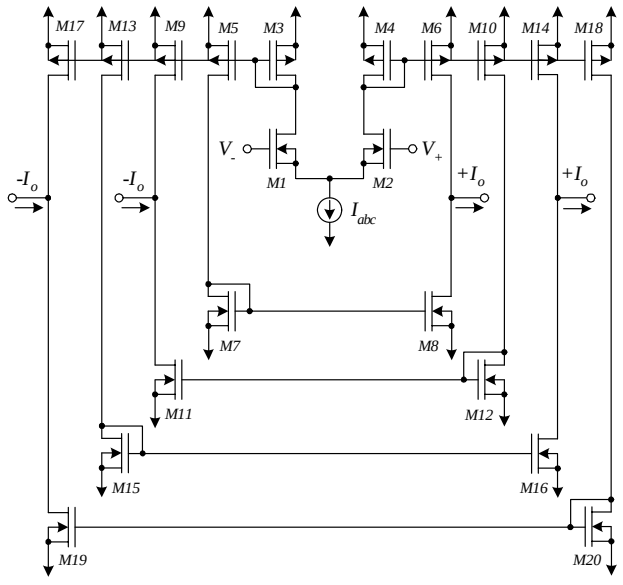

Fig. 4. CMOS multiple-output OTA implementation used in simulation.

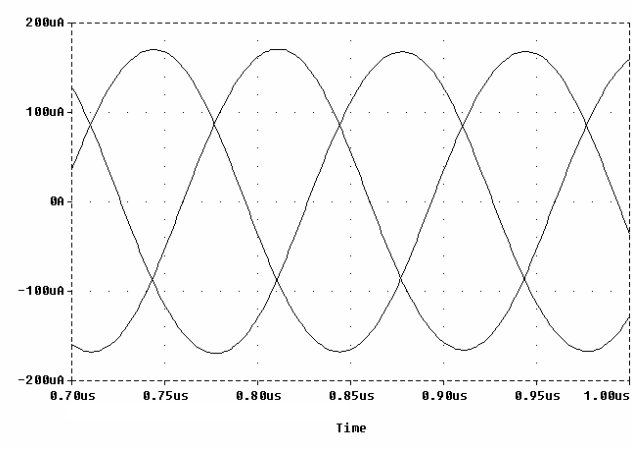

Fig. 5. The simulated output waveform of three phase oscillator of Fig. 3.

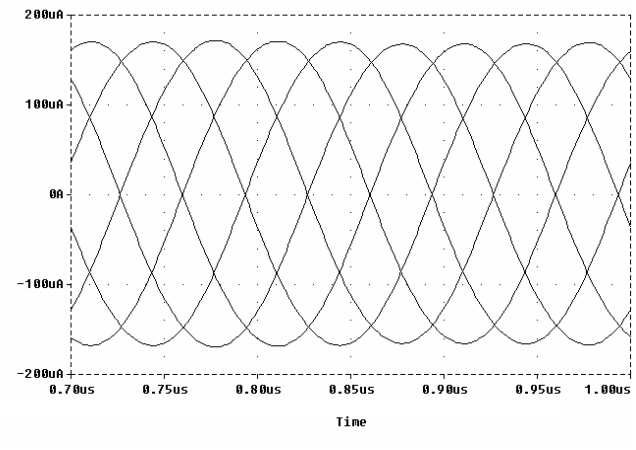

Fig. 6. Simulated output waveform of six phase oscillator of Fig. 3.

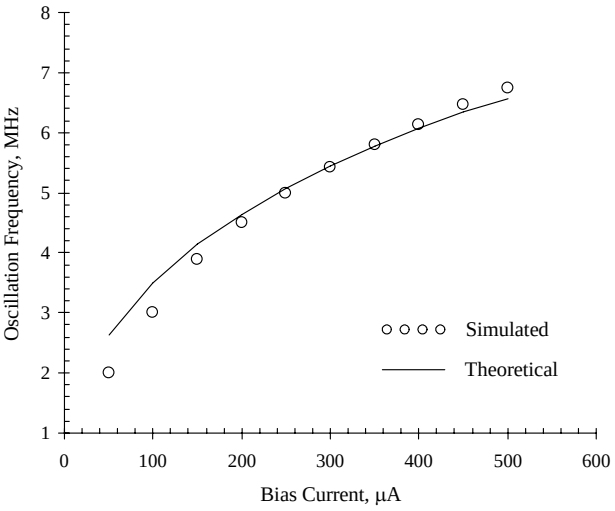

Fig. 7. Variation of the oscillation frequency with the bias current.

Fig. 7 presents the simulation results of oscillation frequency of Fig. 3 by varying the value of the bias current I_{abc} (i.e. 50μA to 500μA or equal g_m from 0.1928mS to 0.48mS) with C_1=10pF and C_2=20.12pF. The relationship between C_2 and oscillation frequency is shown in Fig. 8, which C_1 is varied by C_2 on (8). It shows that the proposed

MSO can be generated the frequency high up to 10MHz according with theoretical. The circuit be generated the frequency higher than 10MHz but the simulation results not confirm with theory, this error cause from the parasitic capacitor of OTA. Finally, Fig. 9 shows the output currents against varied bias current I_{abc}.

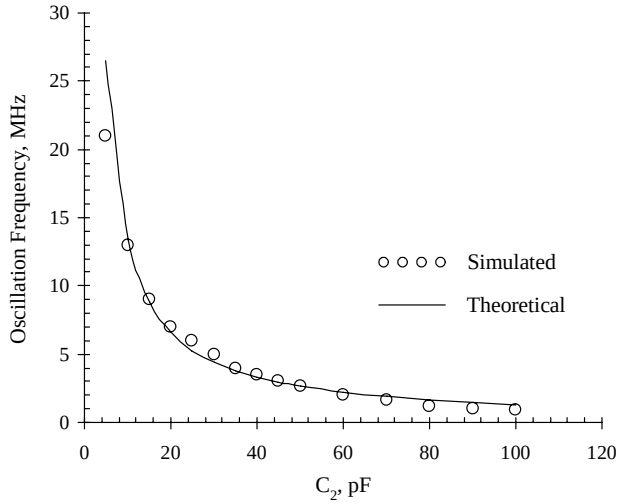

Fig. 8. Variation of the oscillation frequency with capacitor C_2.

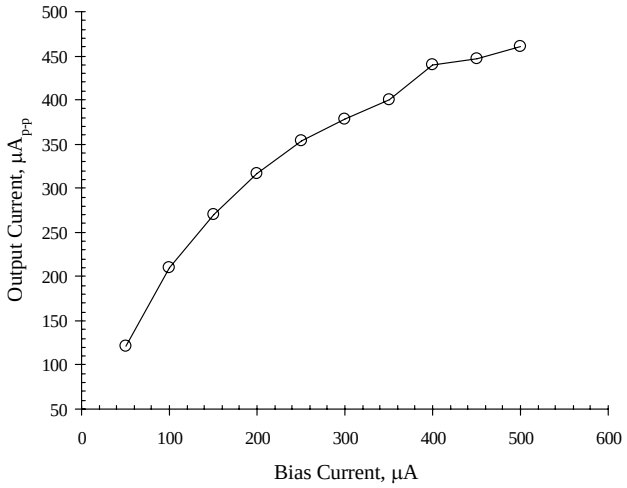

Fig. 9. Output currents of proposed multiphase sinusoidal oscillator again varying bias current with C_1=10pF and C_2=20.12pF.

IV. CONCLUSIONS

In this paper, a new electronically tunable MSO circuit has been presented. The proposed MSO circuit has a simple configuration which uses a multiple-output OTA and two grounded capacitors per section. The MSO circuit can be configured to provide an odd-number of equal-amplitude equally special in-phase output current. The frequency and condition of oscillation are independent controlled. The proposed MSO enjoys simple structure, an electronically tunable and suitable for IC implementation as both CMOS and bipolar technologies. Simulation results, which confirm the theoretical analysis, are obtained.

***Abstract*- This paper describes a multiphase sinusoidal oscillator based on the use of Current Differencing Buffered Amplifiers (CDBAs). The proposed oscillator provides output signals both in voltage and current forms simultaneously. It comprises *N* cascaded lossy integrators and an inverter, and generates *N*+1 sinusoidal signals with 180°/*N* phase difference. The SPICE simulation results obtained using AD844 macro model are given to confirm the theoretical analysis.**

I. INTRODUCTION

The wide use of the multiphase sinusoidal oscillators (MSOs) in power controllers, communication system and signal processing [1-5] have stimulated the development of the MSOs. Voltage-mode operational amplifiers (op-amps) are widely used for realizing the multiphase sinusoidal waveforms [6] due to their commercial availability. However, circuit synthesis techniques in current domain using current conveyors [7], current followers [8] and operational transductance amplifiers [9] have gained substantial interests. The main advantages of processing signal in current form are wide bandwidth, high slew rate and independent gain realization without a constant gain–bandwidth product constraint.

Recently, a new active building block named as a current differencing buffered amplifier (CDBA) has been introduced [10]. Since the CDBA consists of a unity-gain differential amplifier and a unity-gain voltage amplifier, a high frequency operation and less parasitic can be expected. The MSO based on CDBAs has been reported in the literature [11], however it can produce only sinusoidal voltage output. This paper presents a CDBAs based MSO circuit, which is possible to provide output sinusoidal signals in both voltage and current forms simultaneously. The oscillator structure is constructed by cascading of *N* stages current domain lossy integrators and a current inverter. Consequently, the *N*+1 outputs with 180°/*N* phase difference are available.

II. CIRCUIT DESCRIPTION

The circuit symbol of the CDBA is shown in Fig. 1, where *p* and *n* are the input terminals, *z* and *w* are the output terminals. Its current and voltage characteristics can be described by the following relations [1-2]

$$v_p = 0\,,\quad v_n = 0\,,\quad i_z = i_p - i_n \quad \text{and} \quad v_w = v_z \qquad (1)$$

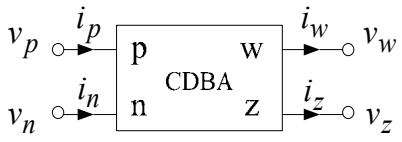

Figure 1. Circuit symbol of CDBA Put units in parentheses.

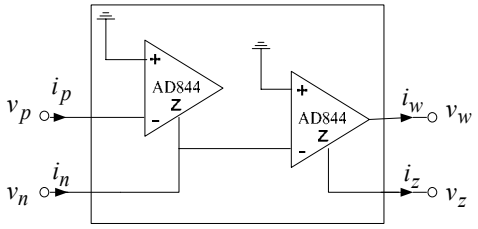

Figure 2. Circuit implementation of CDBA using two CFOAs (AD844).

According to Eq. (1), an output current at the *z*-terminal i_z follows the difference of input currents through the *p*-terminal and n-terminal. Then, the output current is converted into an output voltage v_w through an impedance connected at the terminal *z*. Although there are numerous techniques to realize the CDBAs, a popular one is obtained by using two commercially available CFOAs, AD844 [12], as shown in Fig. 2 [13]. Fig. 3 shows a general block diagram of the MSO for *N*+1 phase sinusoidal oscillator. It is constructed by cascading *N* stages of current domain lossy integrators and a current inverter. The output current $I_{o,N}$ of the last stage is fed back to the first stage through the current inverter. Therefore, the transfer function between I_i and $I_{o,N}$ can be written as:

$$\frac{I_{o,N}}{I_i} = \left(\frac{K}{1+Ts}\right)^N = -1, \qquad (2)$$

where *K* is DC current gain of each stage and system time constant *(T)* is $1/\omega_c$, when ω_c is the internal-pole of the lossy integrator. By expanding Eq. (2), the characteristic equation is obtained as

$$(1+Ts)^N + (-1)^{N+1} K^N = 0 \qquad (3)$$

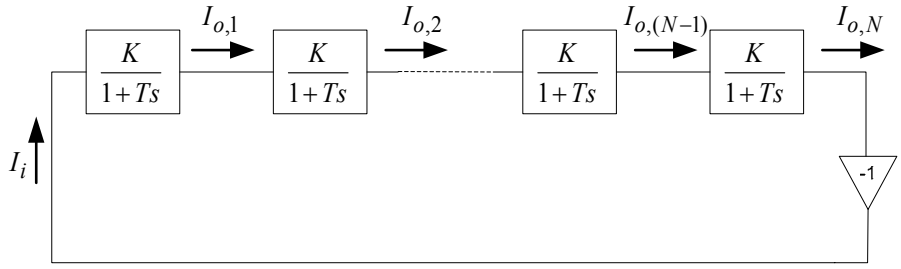

Figure 3. General block diagram of the multiphase oscillator

By replacing $s = j\omega_0$, into Eq. (3), we can find the oscillation frequency and oscillation condition. It can be proved that this equation will give a realistic solution only for $N \geq 3$. To solve for K and ω_0, the real and imaginary parts of Eq. (3) are set to zero. In case of $N = 3$, Eq. (3) yields

$$(1 + j\omega_0 T)^3 + K^3 = 0 , \quad (4)$$

hence,

$$1 - 3\omega_0^2 T^2 + K^3 = 0 , \quad (5)$$

and

$$3j\omega_0 T - j\omega_0^3 T^3 = 0 \quad (6)$$

where ω_0 is the oscillation angular frequency. The oscillation frequency f_0 of this case is obtained by solving equation (6) as

$$f_0 = \frac{\sqrt{3}}{2\pi T} . \quad (7)$$

Substituting Eq. (7) into (5) will give the oscillation condition that is $K = 2$. The conditions of the MSO for the others N can be obtained in a similar way and will result in the MSO with $N + 1$ outputs. Each output is equal in amplitude and has phase shift by 180°/N.

III. Proposed CDBA-Base Multiphase Sinusoidal Oscillator

According to the block diagram representation of the MSO shown in Fig. 3, the system consists of two repeated sub-blocks such: current domain lossy integrator and current inverter. In this work, two new sub-blocks using the CDBA are introduced in Fig. 4. To perform lossy integrator function , the proposed sub-block consisting of one CDBA, three resistors and one capacitor is show in fig. 4(a). The current transfer function I_o/I_i can be written as

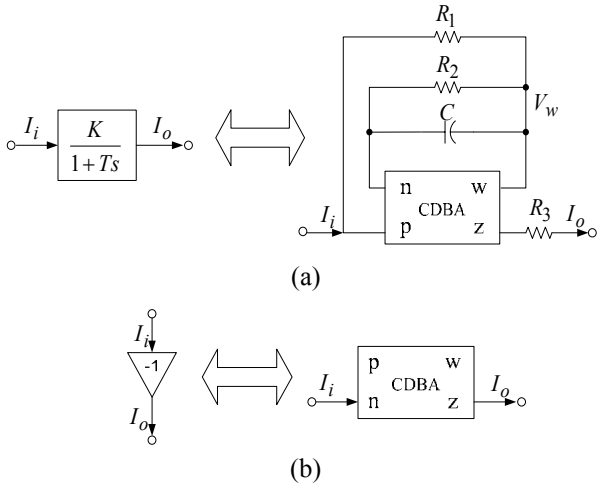

Figure 4. Sub-blocks and their realization using CDBAs
(a) current domain lossy integrator (b) current inverter

$$\frac{I_o}{I_i} = \frac{K}{1+Ts} = \frac{\left(\frac{R_1 R_2}{R_1 R_2 + R_1 R_3 - R_2 R_3}\right)}{1 + sC\left(\frac{R_1 R_2 R_3}{R_1 R_2 + R_1 R_3 - R_2 R_3}\right)} . \quad (8)$$

For simplicity sake, the current inverter is designed using the CDBA as shown in figure 4(b). From Eq. (1), when the input current at terminal p is absent, the current transfer function (I_o/I_i) is obtained equal -1.

By substituting our proposed sub-circuits into the general block diagram of the MSO in fig. 3, the complete circuit of the CDBA-based MSO for $N = 3$, which has 60° phase difference, can be obtained as shown in fig. 5. Since our proposed structure exploits an advantage of having both voltage and current outputs of the CDBA, the resulting MSO will be able to produce the sinusoidal signals in voltage and current forms simultaneously. This gives a potential to apply this circuit in wider range of applications. The current and voltage transfer function between each lossy integrator stage are equivalent and can be directly represented use by Eq. (8). For the sake of

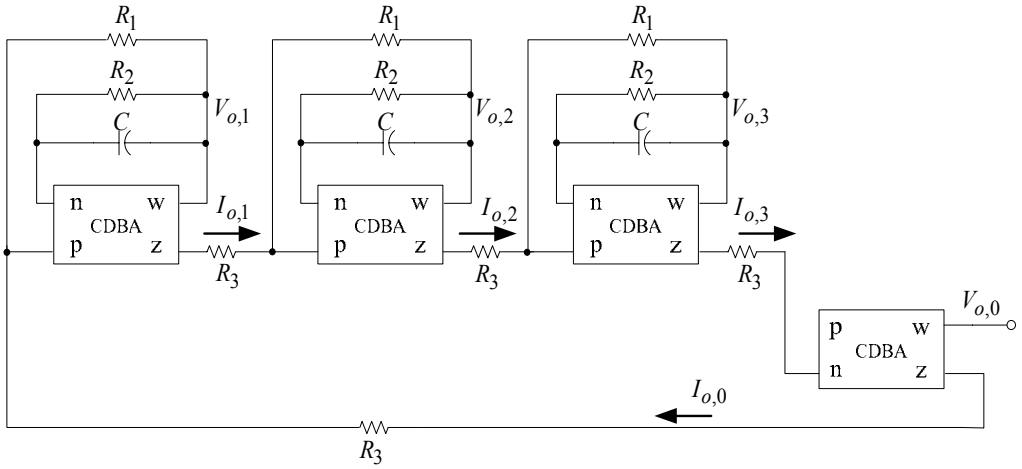

Figure 5. Proposed CDBAs-base multiphase sinusoidal oscillator, which can generate 4 outputs current and 4 outputs voltage different phase sinusoidal both voltage and current signal output each shifted in phase by 60°

design, let us select the circuit components such that $R_1 = R_3$. Therefore, the current and voltage transfer function are

$$\frac{I_{o,N}}{I_{o,N-1}} = \frac{V_{o,N}}{V_{o,N-1}} = \frac{K}{1+Ts} = \frac{(R_2/R_3)}{1+sCR_2} \quad . \quad (9)$$

The oscillation conditions and the oscillation frequency solving from Eq. (4) of this circuit are

$$K = \frac{R_2}{R_3} \quad , \quad (10)$$

$$f_o = \frac{\sqrt{3}}{2\pi R_2 C}. \quad (11)$$

As already determined in the previous section, the oscillation condition is satisfied when $K = 2$ or $R_2 = 2R_3$. It should be noted that, the output voltages are ready to be used since they appear at the voltage output ports of the CDBAs. However, the current outputs need additional ports to duplicate the desired signals to the next stage. This configuration is easily implemented by employing multi-output current mirrors in many customed design CDBAs available both Bipolar and CMOS technology [14 -15].

IV. Simulation Results

Simulation results of the proposed circuit as depicted in Fig. 5 are obtained using the PSPICE circuit simulator with ±18V supply voltage. To verify the proposed circuit, the dual-mode MSO is designed at 27.6 kHz oscillation frequency. Hence, the capacitor and resistors are calculated by using Eq. (10) and (11), that are C = 1nF, $R_1 = R_3$ = 5 kΩ and R_2 = 10 kΩ. The CDBA was constructed using two AD844 as shown in Fig. 2. In fact, there are non-zero impedances at the

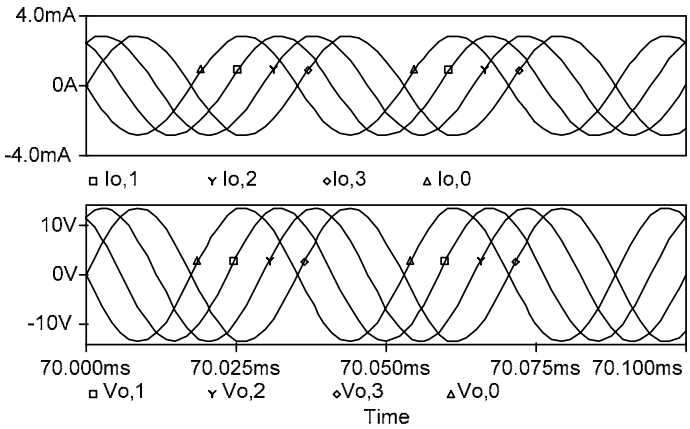

Figure 6. The simulated output voltage ($V_{o,0}$, $V_{o,1}$, $V_{o,2}$, $V_{o,3}$) and output current ($I_{o,0}$, $I_{o,1}$, $I_{o,2}$, $I_{o,3}$) over time at frequency of 28kHz

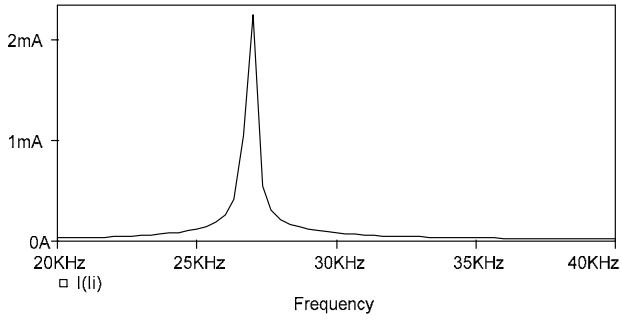

Figure 7. Frequency spectrum of the waveform in Fig. 6.

input ports, p and n, that cause the current transfer error and hence resulting in an oscillation condition violation ($K < 2$). In order to compensate this error, the resistor R_1 and R_3 have to be reduced to satisfy the oscillation condition ($K > 2$). In this case, $R_1 = R_3$ = 4.7 kΩ is selected and K = 2.087 is obtained. The simulated oscillation frequency of 28 kHz is

observed and its output voltages ($V_{o,0}$, $V_{o,1}$, $V_{o,2}$, $V_{o,3}$) and output currents ($I_{o,0}$, $I_{o,1}$, $I_{o,2}$, $I_{o,3}$) over time are shown in Fig. 6. The outputs have equal amplitude of 13.3 V and 2.83 mA for voltage and current signals, respectively. Fig. 7 shows frequency spectrum of the output current signal, which has the total harmonic distortion (THD) about 1.19 %. Note that the oscillation frequency is slightly higher than the calculation. This can be explained by considering Eq. (5). It can be seen that increasing K will also make ω_0 higher.

TABLE I
FREQUENCY, AND CURRENT PHASE WHEN VARYING THE OSCILLATION FREQUENCY

Parameters: C, $f_{expected}$	Oscillation frequency	Phase comparison		
		$I_{o,0}$ - $I_{o,1}$	$I_{o,0}$ - $I_{o,2}$	$I_{o,0}$ - $I_{o,3}$
C = 0.1 nF, f_e = 276 kHz	266 kHz	59.38°	118.13°	179.7°
C = 1 nF, f_e = 27.6 kHz	28 kHz	59.86°	119.98°	179.8°
C = 10 nF, f_e = 2.76 kHz	2.8 kHz	59.66°	119.87°	179.79°
C = 0.1 uF, f_e = 276 Hz	280 Hz	59.68°	120°	180°
C = 1 uF, f_e = 27.6 Hz	28 Hz	59.67°	119.97°	180°

The simulation results when varying the capacitor C to 0.1 nF, 1 nF, 10nF, 0.1uF and 1uF, are summarizable in TABLE I. The expected oscillation frequency, the simulated oscillation frequency and the phase difference of the output currents $I_{o,1}$, $I_{o,2}$, $I_{o,3}$ with respect to $I_{o,0}$ are given. For the frequency of 28 kHz and lower, the frequency error and phase shift error of less than 1.82 % and 1.7 % are observed, respectively. These errors are larger at higher frequency due to the limitation of the employed AD844. Therefore, for the high frequency applications, a high performance CDBAs either implemented in CMOS or Bipolar technology should be properly designed to overcome this problem. Fig. 8 shows simulation results of the MSOs for N = 4 at frequency 28 kHz.

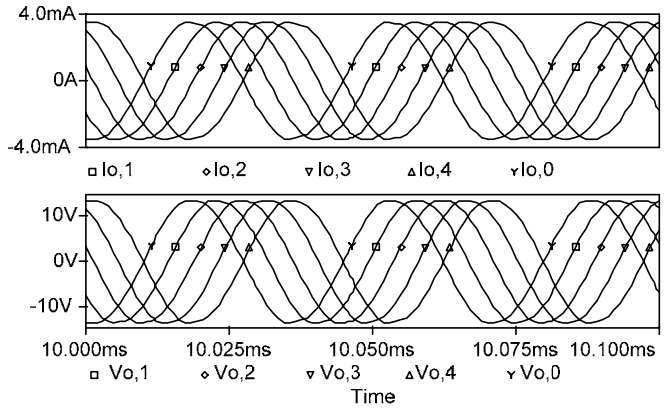

Figure 8. The output voltages ($V_{o,0}$,$V_{o,1}$,$V_{o,2}$,$V_{o,3}$) and output currents ($I_{o,0}$,$I_{o,1}$,$I_{o,2}$,$I_{o,3}$) over time at frequency 28 kHz.

The output voltage ($V_{o,0}$, $V_{o,1}$, $V_{o,2}$, $V_{o,3}$, $V_{o,4}$) and output current ($I_{o,0}$, $I_{o,1}$, $I_{o,2}$, $I_{o,3}$, $I_{o,4}$) have equal amplitude of 13.3 V and 3.5 mA, respectively.

V. CONCLUSION

A new multiphase sinusoidal oscillator based on CDBAs is proposed. The proposed circuit can generate sinusoidal waveforms of both voltage and current signals in the same circuit, so it can be applied in both voltage mode and current mode applications. The circuit can realize N+1 difference phase sinusoidal output signals by using N cascaded lossy integrators and an inverter. This circuit possesses another advantage of that the oscillation condition can be always realized from resistor ratio for every chosen oscillation frequency. The simulation results confirm the theoretical conclusions very well.

A. An Electronically and linearly tunable CMOS OTA (EOTA)

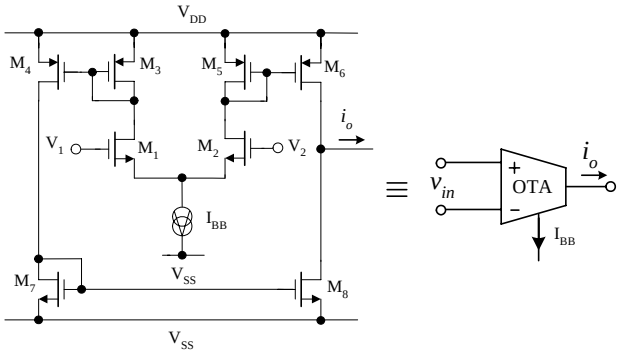

Figure 1 A balanced CMOS OTA

Figure 1 shows a balanced single-output CMOS OTA, which is formed by MOS coupled pair and current mirrors, where V_{in} is the differential input voltage (V_{in}=V_1-V_2), i_o is the output current and I_{BB} is the bias current. Let us assume that M_1 and M_2 are perfectly matched and the current mirrors have unity current gain. By using equation (1), the differential output current of the circuit in Figure 1 can be given by

$$i_o = i_2 - i_1 = \sqrt{2I_{BB}K}\cdot V_{in}\cdot\sqrt{1-\frac{KV_{in}^2}{2I_{BB}}}, \quad for -\sqrt{\frac{I_{BB}}{K}} \le V_{in} \le \sqrt{\frac{I_{BB}}{K}} \qquad (2)$$

The transconductance gain (g_m) of the MOS coupled pair can be derived by taking the derivative of (2) with respect to V_{in}, yielding

$$g_m = \left.\frac{di_o}{dV_{in}}\right|_{V_{in}=0} = \sqrt{2I_{BB}K}, \quad for -\sqrt{\frac{I_{BB}}{K}} \le V_{in} \le \sqrt{\frac{I_{BB}}{K}} \qquad (3)$$

A CMOS-based electronically and linearly tunable OTA, called as an EOTA [10], that realized by using three OTAs the circuit diagram shown in figure 1.

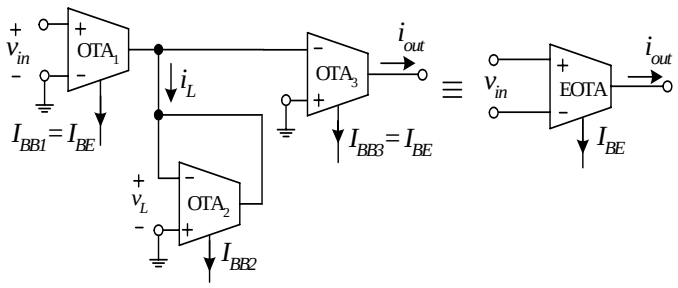

Figure2. An electronically and linearly tunable CMOS OTA (EOTA)

The OTA_1 converts a differential input signal voltage $v_{in} = v_1 - v_2$ into a signal current i_L to flow into an active resistor R_L, formed by the OTA_2, where $Z_L = 1/g_{m2}$ and gm_2 represents the transconductance gain of the OTA_2. Since the current signal $i_L = g_{m1}V_{in}$, the voltage drop across the active resistor (OTA_2) becomes

$$v_L = i_L Z_L = g_{m1}v_{in}\cdot\frac{1}{g_{m2}} \qquad (4)$$

The OTA_3 will convert the voltage v_L, with the transconductance gain of g_{m3}, into the output current i_{out} as

$$i_{out} = g_{m3}v_L \qquad (5)$$

From equations (4) and (5), the current i_{out} can be rewritten as

$$i_{out} = \frac{g_{m1}g_{m3}}{g_{m2}}v_{in} \qquad (6)$$

Since $g_{m1} = \sqrt{2I_{BB1}K_1}$, $g_{m2} = \sqrt{2I_{BB2}K_2}$ and $g_{m3} = \sqrt{2I_{BB3}K_3}$, if we set I_{BB1}=I_{BB3}=I_{BE}, then from equation (6) we obtain

$$i_{out} = \frac{2I_{BE}\sqrt{K_1K_3}}{\sqrt{2I_{BB2}K_2}}V_{in} = g_{mT}v_{in} \qquad (7)$$

where g_{mT} represents the transconductance gain of the proposed EOTA and can be expressed as

$$g_{mT} = 2I_{BE}K_T \qquad (8)$$

and $K_T = \sqrt{K_1K_3/2I_{BB2}K_2}$, which can usually be kept to constant. The equation (8) clearly indicted that the transconductance gain of the proposed EOTA can be electronically and linearly tuned by the bias current I_{BE}.

B. The proposed electronically and linearly tunable sinusoidal quadrature oscillator

The proposed electronically tunable sinusoidal quadrature oscillator is constructed by using EOTAs and OTAs

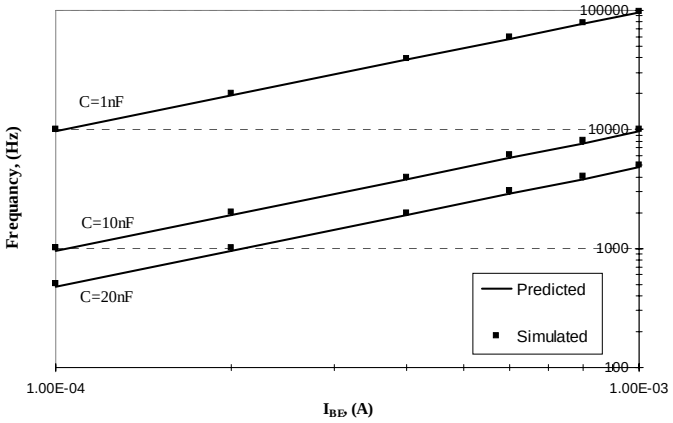

Figure 5. Frequency tunable range of the oscillator

Figure 5 demonstrates the oscillation frequency that tunable with respect to the dc bias-current $I_{BE1}=I_{BE2}=I_{BE}$, where the bias current is varied from 100μA to 1000μA. and for the cases of C= 20nF, C=10nF and C=1nF, respectively. The figure shows that, for the cases of C= 20nF, C=10nF and C=1nF, the oscillation are in the frequency ranges of 500 Hz to 5 kHz, 1 kHz to 10 kHz and 10 kHz to 98 kHz, respectively, with the error of less that 5%. This result demonstrates that the maximum frequencies up to 98 kHz is achieved by reducing the capacitance values ($C_1=C_2=C=1nF$).

IV. CONCLUSIONS

A design of CMOS-based electronically tunable quadrature oscillator has been proposed. The oscillator is realize by using two EOTAs, two OTAs and two grounded capacitors which is suitable for implementing in CMOS integrated form. Its oscillation frequency can be electronically and linearly tuned for a wide range by the transconductance gain without affecting the oscillation condition and the capability of operation at high frequencies. Simulation results have been employed to demonstrate the performances of the proposed oscillator.

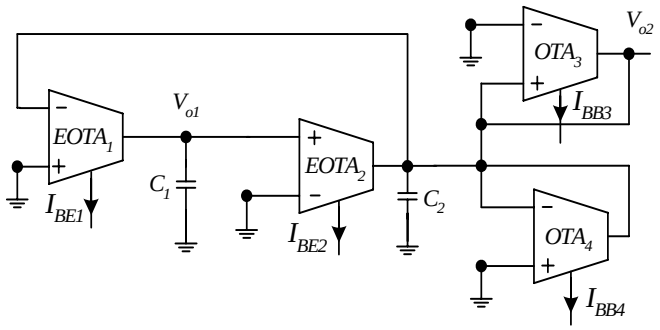

Figure 3. The proposed electronically and linearly tunable sinusoidal quadrature oscillator

The g_m-C quadrature oscillator based on the use of EOTAs is shown in Fig.3. The quadrature oscillator circuit diagram is similar to the bipolar-based quadrature oscillator circuit of the reference 11. The basic building blocks of the oscillators consist of two integrators cascaded in a loop; an inverting integrator (EOTA and C_1) and a non-inverting integrator ($EOTA_2$ and C_2). It should be noted that a regenerative circuit made by the balance CMOS OTA, OTA_3 and OTA_4, are included in order to place the poles in the right-half complex plane so that the circuit is unstable and self-starting, from equation (7), the characteristic equation of the oscillator can be express as

$$s^2 - s\left(\frac{g_{m3} - g_{m4}}{C_2}\right) + \frac{g_{mT1}g_{mT2}}{C_1C_2} = 0 \qquad (9)$$

Therefore, in order to initially locate the poles inside the right-half complex frequency plane to assure self-starting operation, the condition for the oscillation can be start as

$$g_{m3} - g_{m4} \geq \varepsilon \qquad (10)$$

or

$$\sqrt{I_{BB3}} - \sqrt{I_{BB4}} \geq \varepsilon \qquad (11)$$

where ε is a small positive number. The oscillating frequency is

$$\omega_0 = \sqrt{\frac{g_{mT1}g_{mT2}}{C_1C_2}} \qquad (12)$$

Where $g_{mT1}=2I_{BE1}K_T$ and $g_{mT2}=2I_{BE2}K_T$. For simplicity, if we set $C_1=C_2=C$ and $g_{m1}=g_{m2}=2I_{BE}K_T$, the frequency of oscillation can be given by

$$\omega_0 = \frac{g_{mT}}{C} = \frac{2I_BK_T}{C} \qquad (13)$$

It is obvious from (12) and (13) that the oscillation frequency can be tuned without disturbing the oscillation. Moreover, the frequency of oscillation ω_0 can be linearly controlled by adjust the dc bias current $I_{BE1}=I_{BE2}=I_{BE}$.

III. Simulation Results

The performance of the proposed electronically and linearly tunable sinusoidal quadrature oscillator of figure3 was verified through the use of PSPICE simulation results. All the balanced CMOS OTA and EOTAs were simulated by using CMOS transistor parameters of the SCN2 level 2 of MOSIS [12]. The dimensions of transistors M_1 and M_2 are W=50μm and L=10μm. The dimensions of the transistor M_3-M_8 are W=100μm and L=10μm. The power supply voltage were set to V_{DD} = -V_{SS} = ± 5V.

Figure 4 shows the results obtained from the electronically and linearly tunable quadrature oscillator circuit of figure 3 in the case of $C_1=C_2=C$=20nF. $I_{BE1}=I_{BE2}=I_{BE}$=1mA, I_{BE3}=1mA, I_{BE4}=995μA, with $\varepsilon = \sqrt{2I_{BE3}K_3} - \sqrt{2I_{BE4}K_4}$ =1.26μA. The simulated oscillation frequency with quadrature outputs of equal magnitude of about 5 kHz is achieved. The circuit provides the oscillation frequency with the error of less than 5%, since the predicted oscillation frequency from the equation (13) is about 4.8 kHz.

***Abstract*-This paper presents the three-input single-output current-mode universal filter using three current differencing buffered amplifiers (CDBAs), two resistors, and two grounded capacitors. By properly selecting the input signals, the filter can realize five standard biquadratic functions, i.e. lowpass, bandpass, highpass, bandstop and allpass current responses from the same circuit topology. The natural frequency ω_o and the bandwidth *BW* are independently controllable. No critical matching condition is required for realizing all the filter responses, and all the incremental parameter sensitivities are also low. The performances of the proposed circuit are confirmed by PSPICE simulations.**

Keywords:current differencing buffered amplifier (CDBA), universal filter.

I. INTRODUCTION

In recent years, a new active building block, which is called a current differencing buffered amplifier (CDBA), has received much attention. Many applications in active filter design based on CDBA were reported in the literature [1]-[9]. They have been demonstrated that the CDBA is a versatile active building block for voltage- and current-mode signal processing applications. Despite the fact that the current-mode filter with multiple-input and single-output terminals concerning CDBA's is now available. To the best of our knowledges, only one work proposes a current-mode Kerwin-Huelsman-Newcomb (KHN) biquad circuit using three CDBAs and eight passive elements [8]. Actually, the number of the passive elements employed in this filter realization is rather high. Moreover, the filter does not exhibit a high output impedance, which cannot be cascaded to the next stage directly. Although a cascadble CDBA-based current-mode filter has been proposed recently [9], it requires an additional CDBA and component matching conditions for realizing a highpass response. Therefore, a few applications on the cascadable multiple-input single-output (MISO) current-mode universal filter using CDBAs as active components are available.

In this paper, the CDBA-based MISO current-mode universal biquadratic filter is proposed to show versatility of CDBA in current-mode operation. The proposed circuit configuration with three input and single output terminals employs only three CDBAs, two virtually grounded resistors and two grounded capacitors, which provides the advantage of an integrated circuit (IC) implementation [10]-[11]. The filter can realize five standard biquadratic filtering functions, i.e., lowpass (LP), bandpass (BP), highpass (HP), bandstop (BS) and allpass (AP) from the same configuration by properly selecting the input signals. The circuit also provide the low-impedance inputs and high impedance output which is no problem for the input signal current source and easily cascadable to the next stage without needing additional buffers. For the realization of all the filter responses, no critical component matching condition is required, and both active and passive sensitivities are low. PSPICE simulation results are used to verify the performances of the proposed circuit.

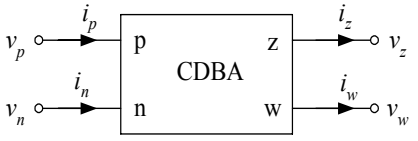

Figure 1. Electrical circuit symbol of the CDBA

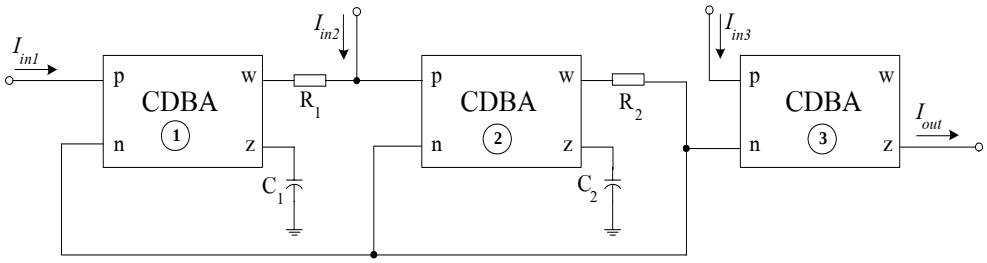

Figure 2. Proposed cascadable TISO current-mode universal filter employing CDBAs

II. CIRCUIT DESCRIPTION

An electrical circuit symbol of the CDBA is shown in Fig.1, where p and n are input terminals, and z and w are output terminals. The characteristic equation of this device can be expressed by the following matrix equation.

$$\begin{bmatrix} i_z \\ v_w \\ v_p \\ v_n \end{bmatrix} = \begin{bmatrix} 0 & 0 & 1 & -1 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \cdot \begin{bmatrix} v_z \\ i_w \\ i_p \\ i_n \end{bmatrix} \qquad (1)$$

According to above equation, the difference of the input currents i_p and i_n at the terminals p and n, respectively, is converted to the output voltage v_w at the terminal w through an impedance connected at the terminal z. It can be further inferred that the terminal impedances of the p and n terminals are internally grounded.

Fig.2 illustrates the proposed three-input single-output (TISO) cascadable current-mode universal filter, which consists of only three CDBA, two resistors and two grounded capacitors. Since all the capacitors are grounded, thus the circuit is beneficial to an IC implementation [10]-[11]. By routine circuit analysis based on equation (1), the current transfer function of the proposed CDBA-based filter can be given by :

$$I_{out} = \frac{D(s)I_{in3} - sR_1C_1I_{in2} - I_{in1}}{D(s)} \qquad (2)$$

where $D(s) = s^2 3R_1R_2C_1C_2 + sR_1C_1 + 1$.

According to equation (2), if the magnitudes of the input current I_{in1}, I_{in2} and I_{in3} are chosen as table I, then all the standard biquad filtering functions can be obtained. This means that the proposed filter can realize five standard types of the biquadratic filtering functions without any component matching condition requirements.

TABLE I
The I_{in1}, I_{in2} and I_{in3} values for each filter function

Function type	I_{in1}	I_{in2}	I_{in3}
LP	I_{in}	0	0
HP	I_{in}	I_{in}	I_{in}
BP	0	I_{in}	0
BS	0	I_{in}	I_{in}
AP	0	$2I_{in}$	I_{in}

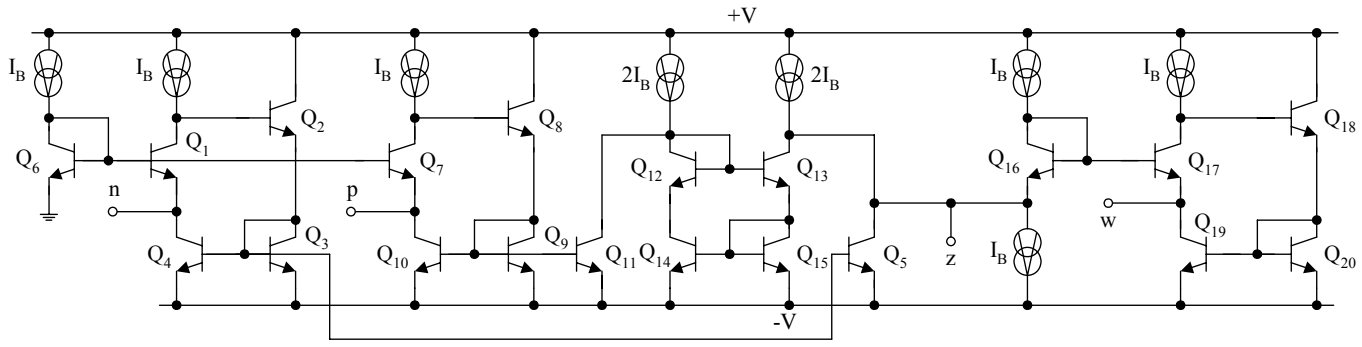

Figure 3. Schematic bipolar implementation of CDBA used in simulations [4].

The natural frequency ω_o and the bandwidth BW of the proposed filter are found to be

$$\omega_0 = \sqrt{\frac{1}{3R_1R_2C_1C_2}} \tag{3}$$

and

$$BW = \frac{1}{3R_2C_2} \tag{4}$$

From equations (3) and (4), it can readily be shown that the ω_o for all the filter responses can be adjusted by controlling the resistor R_1 and/or the capacitor C_1 without disturbing the parameter BW. Therefore, the filter parameters ω_o and BW are independently controllable.

III. Non-Ideal Considerations

The effects of CDBA non-idealities on the filter performance have been now considered in this section. By taking into consideration of the non-ideal CDBAs, the relationship of the terminal currents and voltages given with equation (1) can be rewritten as :

$$\begin{bmatrix} i_z \\ v_w \\ v_p \\ v_n \end{bmatrix} = \begin{bmatrix} 0 & 0 & \alpha_p & -\alpha_n \\ \beta & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \cdot \begin{bmatrix} v_z \\ i_w \\ i_p \\ i_n \end{bmatrix} \tag{5}$$

where α_p = 1 - ε_p and ε_p ($|\varepsilon_p| << 1$) denotes the current-tracking error from p terminal to z terminal, α_n = 1 - ε_n and ε_n ($|\varepsilon_n| << 1$) represents the current-tracking error from n terminal to z terminal, and β = 1 - ε_v and ε_v ($|\varepsilon_v| << 1$) is the voltage-tracking error from z terminal to w terminal of the CDBA. Therefore, considering into account the factors due to the non-idealities of the CDBA given in equation (5), the modified current transfer functions of the proposed filter can be expressed as :

$$I_{out} = \frac{(\alpha_{p3}D_n(s))I_{in3} - (sR_1C_1\alpha_{p2}\alpha_{p3}\beta_2)I_{in2} - (\alpha_{p1}\alpha_{p2}\alpha_{p3}\beta_1\beta_2)I_{in1}}{D_n(s)} \tag{6}$$

where $D_n(s) = s^2 3R_1R_2C_1C_2 + sR_1C_1\alpha_{n2}\beta_2 + \alpha_{n1}\alpha_{p2}\beta_1\beta_2$,

and α_{pi} , α_{ni} and β_i are the parameters α_p, α_n and β of the i-th CDBA (i = 1, 2, 3), respectively. In this case, the modified parameters ω_o and BW are given by :

$$\omega_0 = \sqrt{\frac{\alpha_{n1}\alpha_{p2}\beta_1\beta_2}{3R_1R_2C_1C_2}} \tag{7}$$

and

$$BW = \frac{\alpha_{n2}\beta_2}{3R_2C_2} \tag{8}$$

The incremental passive and active sensitivities are calculated as:

$$S^{\omega_0}_{R_1,R_2,C_1,C_2} = -S^{\omega_0}_{\alpha_{n1},\alpha_{p2},\beta_1,\beta_2} = -\frac{1}{2} \tag{9}$$

$$S^{\omega_0}_{\alpha_{p1},\alpha_{n2},\alpha_{p3},\alpha_{n3}} = 0 \tag{10}$$

$$S^{BW}_{R_2,C_2} = -S^{BW}_{\alpha_{n2},\beta_2} = -1 \tag{11}$$

and

$$S^{BW}_{R_1,C_1} = S^{BW}_{\alpha_{p1},\alpha_{n1},\alpha_{p2},\alpha_{p3},\alpha_{n3},\beta_1} = 0 \tag{12}$$

It is clearly observed from equations (9)-(12) that the absolute value of all ω_o and BW sensitivities with respect to α_{pi}, α_{ni} and β_i are within unity. Thus, the proposed filter exhibits a low sensitivity performance.

IV. Simulation Results

To confirm the theoretical analysis, the characteristics of the proposed filter in Fig.2 have been simulated with PSPICE program. For this purpose, PSPICE circuit simulations were performed with AT&T ALA 400-CBIC-R [12] process parameters for a bipolar CDBA realization shown in Fig.3 [4]. The DC supply voltages were chosen as ±1V and the DC bias current was I_B = 100 μA.

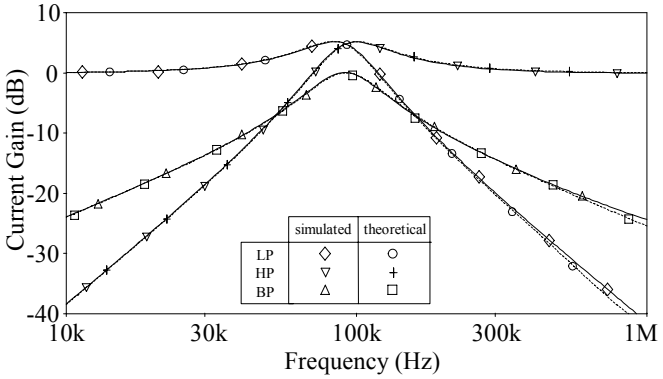

Figure 4. Simulated frequency responses of the proposed CDBA-based universal filter of Figure 2.

Fig.4 shows the simulated frequency responses of the proposed CDBA-based TISO current-mode universal filter with $R_1 = R_2 = 1$ kΩ and $C_1 = C_2 = 1$ nF. This setting leads to obtain the filter responses with $f_o = \omega_o/2\pi \cong$ 91.88 kHz. It was found from the simulation results that the frequency deviation is 0.78%. These results are found to be in good agreement with the critical values. Fig.5 and Fig.6 show the simulated frequency response and the theoretical behavior of the gain and phase characteristics of the AP and BS filters at $f_o \cong$ 91.88 kHz, which agree very well with the presented theory. It can be observed from all figures that the proposed filter performs all the standard biquadratic filtering functions well.

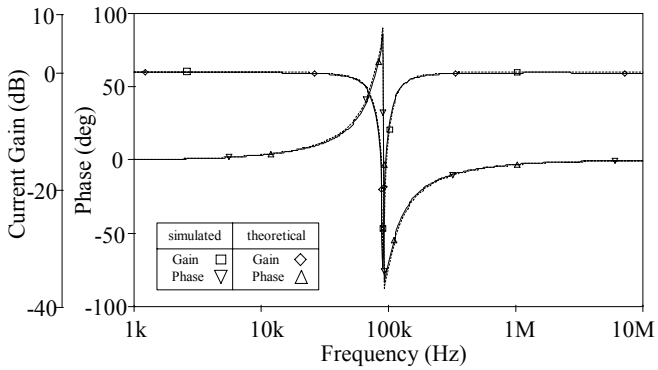

Figure 5. Gain and phase characteristics of the BS filter.

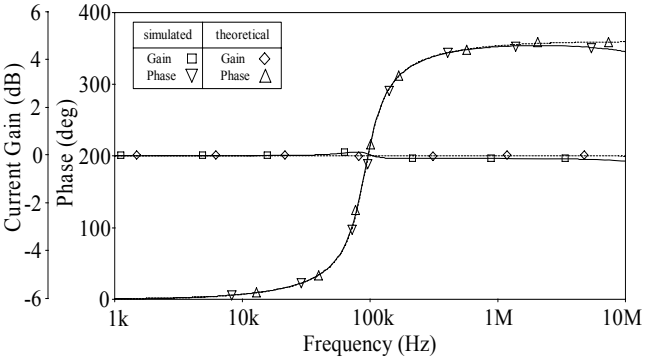

Figure 6. Gain and phase characteristics of the AP filter.

V. CONCLUSION

This paper presents a TISO current-mode multifunction biquadratic filter using only three CDBAs, two resistors and two grounded capacitors, which is very suitable for IC implementation. The proposed filter can realize the LP, HP, BP, BS and AP filter responses all at the high impedance output terminal, which allows easy cascading in current-mode operation. The filter also requires no component matching conditions and has low passive and active sensitivities. An orthogonal control between the natural frequency ω_o and the parameter BW is achieved.

***Abstract*— An active-only devices current-mode universal filter using the biquadratic transfer function is proposed. The proposed circuit is realized focusing on the minimized active-only components count without external passive elements. The different kinds of filter function as low-pass, high-pass, band-pass and band-reject response can be obtained without changing circuit topology. The proposed circuit is realized by using 4 MOS transistors, 2 OTAs, and 2 OPAMPs. The parameters ω_P can be electronically tuned through simply adjusting the transconductance gains of the OTAs or supply voltage of electronic resistors. The Q_P can be tuned in both concepts, changing of their components and the transconductance gain. The simulation results are given by PSpice.**

I. INTRODUCTION

The high performance active filters have been received much attention. In filter circuit design, current-mode filters are becoming popular, since they have many advantages compared with their voltage-mode counterparts. Design of current-mode filters employing active devices such as current followers (CFs) [1], second generation current conveyors (CCIIs) [2] and operational transconductance amplifiers (OTAs) [3,4]. The transfer function biquadratic filter is a basic principle for synthesized is filter circuit to obtain efficiency especially universal filter, and the principle for auxiliary create to filter with integrator based on a synthesized [13]. The open-loop gain of operational amplifier, OA is known well in term of Gain-Bandwidth, GBW. While to obtain using OTA, therefore can be implemented by filter circuit. The same with a high frequency and they have been introduced in the literatures. The current-mode operations were proposed in recent literatures [5-7]. The voltage-mode operations were proposed in recent literatures [8-9]. Although, many active elements are employed but they have very advantages in high-frequency and further integration.

This paper focuses on the synthesized of universal filter using active-only devices. The proposed circuit is realized by using MOS transistors, OAs, and OTAs. The objective on the design is current-mode of evation based on biquadratic function using only active elements without any external passive elements in recent literatures [5-9]. The minimization of active elements and electronically is tunable a core of this paper.

Consider in previous of current-mode active-only filter in recent literatures [5-6], which using 2 OAs and 3 OTAs. The ω_P is tuned by an OTA which in term of square-root function. The linear controlled can not be achieved and complicate in the practical. Another filter [7], the ω_P is tuned with linear controlled has been achieved but the many components are used, 2 OAs, 5 OTAs, that is not suitable for the compactness ICs fabrication. This paper proposed only using 2 OAs, 2 OTAs and 4 MOS transistors for circuit implementation. The achieved circuit can be electronically tuned by either transconductance gains of OTA and electronic resistor for the ω_P parameter. The proposed circuit can be also physically and electronically tuned by changing of transistor aspect ratio for Q_P parameter without effect to the ω_P parameter.

II. THEORY AND PRINCIPLE

The 2 integrators-loop principles have been introduced in recent literatures [12]. The block diagram has been shown in Fig.1 and transfer function can be expressed in (1) as follows

$$\frac{V_2(s)}{V_1(s)} = \frac{sB_2}{s^2 + sB_2k_1 + B_1B_2k_0} \tag{1}$$

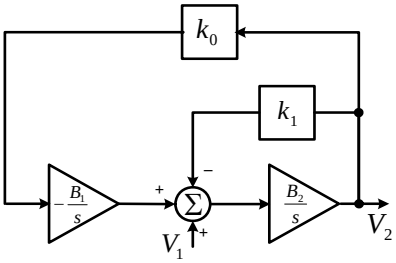

Fig.1 The 2 Integrators-loop block diagram

The comparison of (1) and characteristic equation (2)

$$D(s) = s^2 + s\frac{\omega_P}{Q_P} + \omega_P^2 \tag{2}$$

The parameters ω_P and Q_P can be expressed as

$$\omega_P = \sqrt{B_1B_2k_0} \text{ and } Q_P = \frac{1}{k_1}\sqrt{\frac{B_1B_2k_0}{B_2}} \tag{3}$$

A. Voltage-Gain Circuit

The voltage-gain circuit [10] which used in this paper consists of an OTA and an electronic resistor as show in Fig.2. The transresistance of the electronic resistor circuit can be expressed in (4)

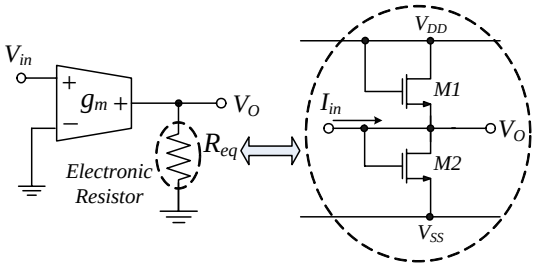

Fig.2 The voltage-gain circuit [10]

$$R_{eq} = \frac{V_O}{I_{in}} = \frac{L}{2\mu C_{OX} W\left(V_{DD} - V_T\right)} \tag{4}$$

The voltage gain of Fig.2 can be obtained to

$$\frac{V_O}{V_{in}} = g_m R_{eq} \tag{5}$$

B. Opamp as a lossless integrator

Consider the open-loop GBW of OA [6], as shown in Fig.3 can be expressed the transfer function as a lossless integrator as (6)

$$A(s) = \frac{B_i}{s} \quad (i = 1, 2) \tag{6}$$

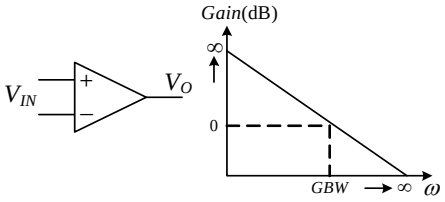

Fig.3 The OA and frequency response, ω_P

C. Current-mode Universal Filter Realization

The proposed filter are realized by using the above methods as shown in Fig.4

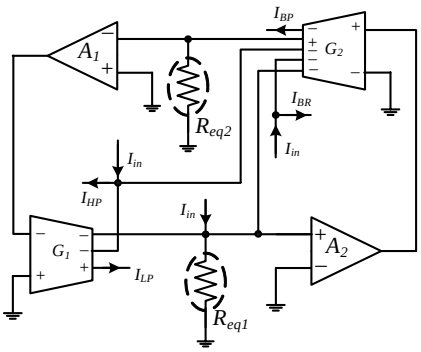

Fig.4-1 The first implementation of proposed current-mode universal filter

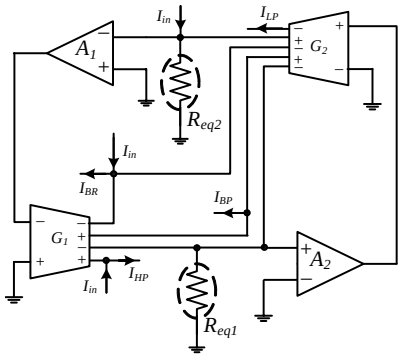

Fig.4-2 The second implementation of proposed current-mode universal filter

From Fig.4-1and 4-2, the different transfer functions are illustrated in (7) – (10)

$$\frac{I_{LP}}{I_{in}} = \frac{R_{eq1}R_{eq2}B_1B_2g_1g_2}{D(s)} \tag{7}$$

$$\frac{I_{HP}}{I_{in}} = \frac{s^2}{D(s)} \tag{8}$$

$$\frac{I_{BR}}{I_{in}} = \frac{s^2 + R_{eq1}R_{eq2}B_1B_2g_1g_2}{D(s)} \tag{9}$$

$$\frac{I_{BPa}}{I_{in}} = \frac{sR_{eq1}B_2g_2}{D(s)} \quad ; \text{ for Fig.4-1} \tag{10a}$$

and

$$\frac{I_{BPb}}{I_{in}} = \frac{sR_{eq2}B_1g_1}{D(s)} \quad ; \text{ for Fig.4-2} \tag{10b}$$

where $D(s) = s^2 + sR_{eq1}B_2g_2 + R_{eq1}R_{eq2}B_1B_2g_1g_2$ (11a)

and $D(s) = s^2 + sR_{eq2}B_1g_1 + R_{eq1}R_{eq2}B_1B_2g_1g_2$ (11b)

Eq.(11a) and (11b) are obtained for Fig.4-1 and 4-2, respectively. The concerning parameters ω_P and Q_P are become

$$\omega_P = \sqrt{R_{eq1}R_{eq2}B_1B_2g_1g_2} \tag{12}$$

$$Q_{Pa} = \sqrt{\frac{R_{eq2}B_1g_1}{R_{eq1}B_2g_2}} \quad ; \text{ for Fig.4-1} \tag{13a}$$

and

$$Q_{Pb} = \sqrt{\frac{R_{eq1}B_2g_2}{R_{eq2}B_1g_1}} \quad ; \text{ for Fig.4-2} \tag{13b}$$

The parameter g_i represents for the transconductance of OTA (i) and R_{eqi} represents for the electronic resistors (i) Generally, B_i is OAs open-loop GBW, are identical suppose that (B_1=B_2=B), the quality factor is unity (Q_P =1), From (12) and (13), the ω_P can be electronically tuned by giving simply parameters as ($g_1 = g_2 = g$) and ($R_{eq1} = R_{eq2} = R_{eq}$). From (12), The frequency response parameter can be will become is also obtained $\omega_P = R_{eq}Bg$.

Therefore, the frequency response can be linearly tuned by 2 approaches, through the transconductance gain of OTA or the electronic resistors from (4) and (13). The parameter Q_P is distinguished for flexible to adjust in electronically and physically.

For $Q_P > 1$, first method the physically tuned can be obtained by ratio adjusting of (R_{eq1}, R_{eq2}) while ($g_1 = g_2 = g$), another method can be tuned by the transconductance gain g_1 and g_2 while ($R_{eq1} = R_{eq2} = R_{eq}$). However, Q_P achievement by ratio adjusting of (R_{eq1}, R_{eq2}) or (g_1, g_2) have to perform in the properly rule otherwise that may effect to the ω_P. The properly adjusting rule of (g_1, g_2) can be described below

$$g_1 g_2 = A \qquad \text{or} \qquad g_1 = \frac{A}{g_2} \tag{14}$$

From (13), the parameters are given as ($R_{eq1} = R_{eq2}$) and ($B_1 = B_2$). The parameter Q_P in (13) can be obtained by setting of g_1 and g_2 as follows

$$Q_{Pa} = \sqrt{\frac{g_1}{A/g_1}} = \frac{g_1}{\sqrt{A}} = \frac{\sqrt{A}}{g_2} \tag{15a}$$

$$Q_{Pb} = \sqrt{\frac{A/g_1}{g_1}} = \frac{\sqrt{A}}{g_1} = \frac{g_2}{\sqrt{A}} \tag{15b}$$

III. SENSITIVITY

The other filter performances can be considered by its sensitivities. The performance with respect to active elements according to the frequency response $S_x^{\omega_P}$ and quality factor $S_x^{Q_P}$, while x is active elements. The achieved sensitivities can be as follows: $S^{\omega_P}_{g_1,g_2,R_{eq1},R_{eq2},B_1,B_2}$ and $S^{Q_P}_{g_1,R_{eq2},B_2}$ are 0.5 and $S^{Q_P}_{g_2,R_{eq1},B_1}$ = -0.5, respectively.

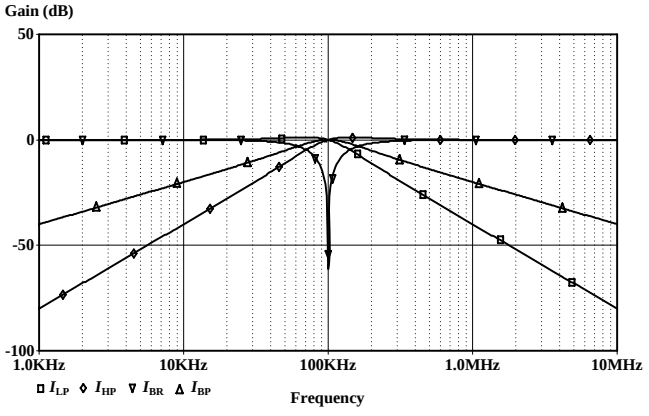

Fig.5 Proposed filter characteristic while power supply of R_{eq} are ± 5 Volt

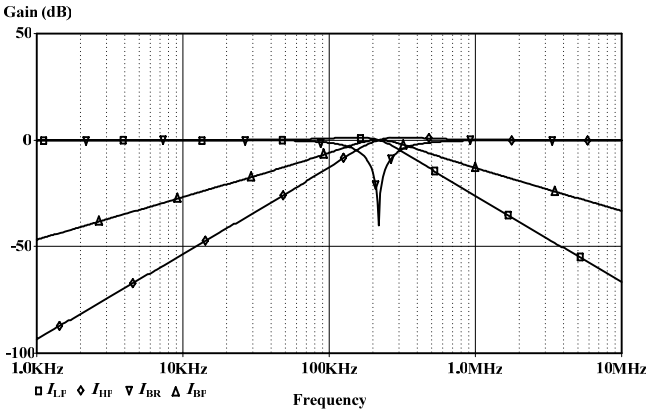

Fig.6 Proposed filter characteristic while power supply of R_{eq} are ± 1 Volt

IV. SIMULATION RESULTS

The proposed universal filter can be confirmed its performances and characteristics by PSpice. The T14Y MOSIS 0.25 μm CMOS model has been employed, V_{TN} = 0.42 volts and $\mu_N C_{OX}$ = 250.1048$\mu A/V^2$ for the electronic resistors. The OA and OTA use the macro model [11] of LF351 and CA3080, respectively. The ± 5 volts power supply is used for the electronic resistors. The transistor aspect ratio (W/L) used for electronic resistors (R_{eq1}, R_{eq2}) are defined for the Q_P adjustment according to (4) and (13).

The electronically controlled ω_P can be confirmed by adjusting power supply of R_{eq} shows in Fig.5 and Fig.6. The characteristic of universal filter as shows in Fig.4 with Q_P = 1. The following equipment parameters can be defined (W/L) = ($1\mu m/1\mu m$) for the electronic resistors $R_{eq1} = R_{eq2}$ = 2.63 $k\Omega$, open-loop GBW of OAs are about 4 MHz or $B_1 = B_2$ = 25.37x10^6 rad/s, power supply of R_{eq} are ± 5 volts and ± 1 volts, respectively. The frequency response ω_P are shown about 100 kHz and 220 kHz. The electronically controlled ω_P by adjusting the supply voltage of electronic resistors or transconductance gain 2 OTAs are confirmed according to the theory above.

TABLE I. THE DIFFERENT Q_P ADJUSTED BY $R_{eq\,1}$, $R_{eq\,2}$ AND g_1, g_2

Q_P	$g_1 = g_2 = 9.42\mu s$		R_{eq1}=R_{eq2}=($1\mu m/1\mu m$)	
	R_{eq1} (W/L)	R_{eq2} (W/L)	g_1	g_2
1	$(1\mu m/1\mu m)$	$(1\mu m/1\mu m)$	$9.42\mu s$	$9.42\mu s$
2	$(2\mu m/1\mu m)$	$(.5\mu m/1\mu m)$	$18.84\mu s$	$4.71\mu s$
4	$(4\mu m/1\mu m)$	$(.25\mu m/1\mu m)$	$37.68\mu s$	$2.35\mu s$
8	$(8\mu m/1\mu m)$	$(.12\mu m/1\mu m)$	$75.36\mu s$	$1.17\mu s$
16	$(16\mu m/1\mu m)$	$(.06\mu m/1\mu m)$	$150.7\mu s$	$0.59\mu s$

Consider (15), the adjusting of Q_P without effect to ω_P by simulation results of universal filter. The ω_P is defined at 100*kHz* while Q_P is varied as 1, 2, 4, 8 and 16, respectively. Firstly, The parameters (g_1=g_2=g) are defined. The adjustment resistor R_{eq1} and R_{eq2} can be adjusting of by (W/L) as table I. The secondly method is based on the setting of (R_{eq1} = R_{eq2} = R_{eq}) and transconductance gain of OTA, g_1, g_2 are adjusted electronically according to table I.

The simulation results in term of BPF and BRF with the different Q_P in table I, are shown in Fig.7 and 8 respectively. The adjusting parameter Q_P without effect to its ω_P can be observed. The frequency response when Q_P increased has a few errors because the error of electronic resistor that is a channel length modulation effects: λ (L=1μm). The ω_P and its magnitude are quite stable while Q_P is varied according to the theory above.

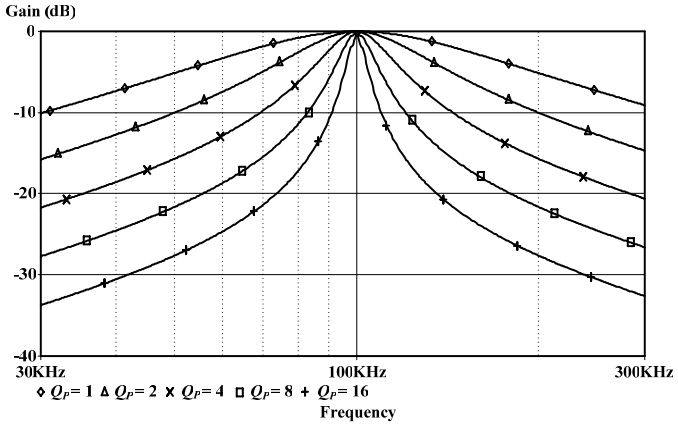

Fig.7 Proposed BPF output with varying Q_P by 1-16

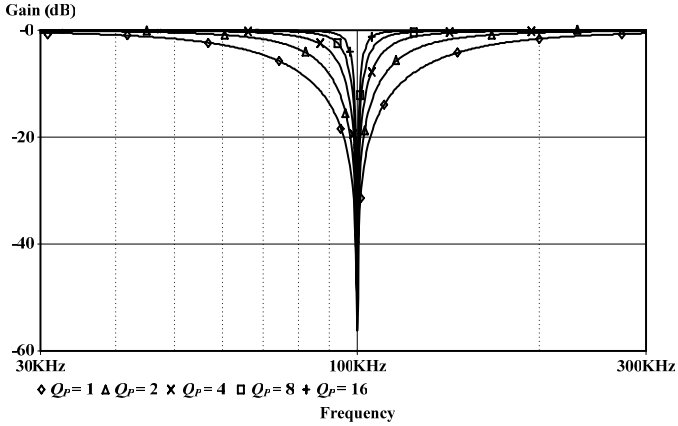

Fig.8 Proposed BRF output with varying Q_P by 1-16

V. CONCLUSION

This paper described a minimum active-only devices current-mode universal filter without external passive elements. In this paper, the high-frequency applications and further ICs technology are suitable. The proposed filter realization is operated based on 2 integrators-loop principles. The ω_P can be electronically tuned through the transconductance or supply of devices. The proposed circuit comprised 2 OTAs, 2 OAs, and 4 MOS transistors that met the minimum devices target. The pole frequency response is given by open-loop GBW of OA corporated with the transconductance gain. The adjustable Q_P can be obtained without effect to ω_P.

***Abstract*-A systematic design of continuous-time current-mode ladder filter using Dual-Output OTAs (DO-OTAs) is resented. The proposed technique is based on leapfrog simulation of RLC ladder filter using only DO-OTAs and grounded capacitors that lead to simple structure, easy to design and suitable for IC fabrication. A fifth-order Chebyshev low-pass filter and a sixth-order Chebyshev band-pass filter which retain a minimum requirement of passive elements and have an advantage of electronically tunable will be introduced. The feasibility of realization strategy is confirmed through PSPICE circuit simulations.**

I. INTRODUCTION

Double terminated passive RLC ladder filters are well known on having an inherent advantage over active filter in terms of their sensitivity to component tolerances. There are several methods to extract this benefit from the prototype passive filter using the opamp-based RC-active and OTA-C-based circuits [1]. The leapfrog structure seems to receive more popular sine it shares the entire low sensitivity characteristic and low component spread of the precedent RLC filter. Traditionally, the simulation is based on modeling all circuit equations as voltage signals [1]. Recently, current-mode signal processing has been received substantial consideration owing to its higher performance properties. Consequently, many suggestions of current-mode leapfrog ladder filter had been published employing OTAs [2] and CCIIs [3] as the active building blocks. However, all of them are established from simulating the operation of the ladder by mean of realizing the transfer function, which require a lot of active and passive elements and sometime the sensitivity may not necessitate being low. The implementation of leapfrog filter using current differential buffered amplifies or CDBAs has been proposed [4], which can perform high frequency and low voltage supply operation. This scheme can simplify the signal flow graph of leapfrog filter and then realize each circuit element one by one, hence the low sensitivity basis is promised. Unfortunately, several floating resistors are required for voltage to current conversion and the utilized frequency is exactly fixed by determined passive elements.

This paper follows the idea of realizing the voltage-current relationships of each element corresponding to the prototype RLC, filters one by one. OTA is chosen to function as a V-to-I converter cell regenerating all voltage parameter into current form because it is a commercially available component. This proposed scheme possesses many advantages. Firstly, the structure is very simple and easy to design. No any external resistor is required, which can save the area in case of fabricating in a silicon chip. Moreover, the center frequency can be tuned electronically by adjusting the bias current of OTAs. This will be useful in redeeming when the values of passive devices are deviated; including changing the system's characteristic is also very comfortable.

This work is organized as follows. Firstly, the Dual-output Operational Transconductance Amplifier will be introduced. The simulated elements, which are grounded resistance simulator, grounded/floating inductance simulators and floating capacitance simulator, are included in Section II. The filter design methodology will be given in Section III. Section IV shows the simulation results. They compare the results of filter synthesis from simulated and ideal elements.

II. PRINCIPLE OF OPERATION

A. The Dual-Output Operational Transconductance Amplifier (DO-OTA)

Since the proposed circuits are based on DO-OTAs, a brief review of the DO-OTA is given in this section. An ideal DO-OTA has infinite input and output impedances. Output current of the DO-OTA is given by

$$I_{O+} = -I_{O-} = g_m(V_1 - V_2)\,. \tag{1}$$

Where g_m is the transconductance parameter of an OTA. For a bipolar OTA, the transconductance gain can be expressed by

$$g_m = \frac{I_B}{2V_T}\,. \tag{2}$$

Where I_B and V_T are bias current and thermal voltage, respectively. The symbol of the DO-OTA is shown in Fig. 1.

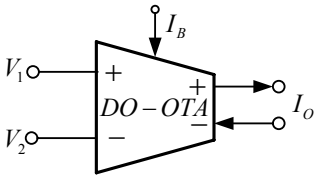

Figure 1. Circuit symbol of DO-OTA

B. Grounded Resistance simulator

The OTA-based grounded resistance simulator is shown in Fig. 2 [5]. From routine analyzing the circuit in Fig. 2, we will get the equivalent grounded resistance as

$$R_{eq} = \frac{1}{g_m} = \frac{2V_T}{I_B}. \quad (3)$$

From Eq. (3), the resistance value is controlled by adjusting I_B.

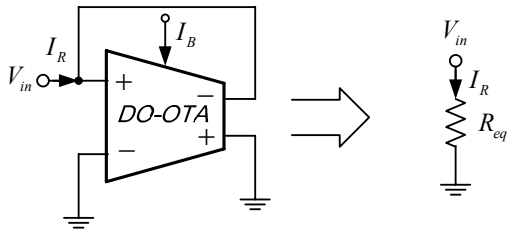

Figure 2. Grounded resistance simulator

C. Grounded Inductance Simulator

Fig. 3 depicts the proposed grounded inductance simulator [6]. Considering the circuit in Fig. 3 and using OTA properties in Section A, we will receive

$$Z_L = \frac{V_{in}}{I_L} = \frac{sC}{g_{m1}g_{m2}}. \quad (4)$$

From Eq. (4), it is obvious that the circuit shown in Fig. 2 simulates a grounded inductance with a value

$$L_{eq} = \frac{C}{g_{m1}g_{m2}} = \frac{4V_T^2 C}{I_{B1}I_{B2}}. \quad (5)$$

It can be clearly seen from Eq. (5) that the inductance value L_{eq} can be adjusted electronically by either I_{B1} or I_{B2}.

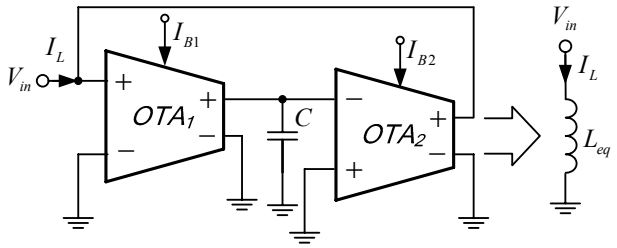

Figure 3. Grounded inductance simulator

D. Floating Inductance Simulator

Fig. 4 depicts the proposed floating inductance simulator, where I_{B1} and I_{B2} are input bias currents of the OTA_1 an OTA_2, respectively.

Considering the circuit in Fig. 4 and using the OTA properties in section A, we will receive

$$Z_L = \frac{V_1 - V_2}{I_L} = \frac{sC}{g_{m1}g_{m2}}. \quad (6)$$

From Eq. (6), it is obvious that the circuit shown in Fig. 4 simulates a floating inductance with a value

$$L_{eq} = \frac{C}{g_{m1}g_{m2}} = \frac{4V_T^2 C}{I_{B1}I_{B2}}. \quad (7)$$

It can be clearly seen from Eq. (7) that the inductance value L_{eq} can be adjusted electronically by either I_{B1} or I_{B2}.

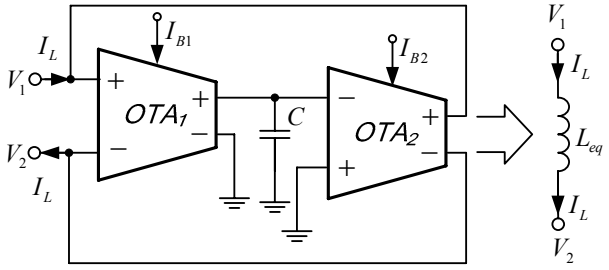

Figure 4. Floating inductance simulator

E. Floating Capacitance Simulator

Fig. 5 depicts the floating capacitance multiplier originated from a grounded capacitor [7]. Considering the circuit in Fig. 5 and using OTA properties in Section A, we will receive the input impedance as

$$Z_C = \frac{V_1 - V_2}{I_C} = \frac{g_{m3}g_{m4}}{sCg_{m1}g_{m2}}. \quad (8)$$

From Eq. (8), it is clearly seen that the circuit can provide the floating capacitor with a value

$$C_{eq} = \frac{I_{B1}I_{B2}}{I_{B3}I_{B4}}C. \quad (9)$$

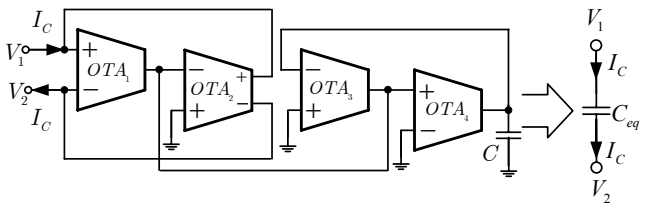

Figure 5. Floating capacitance simulator

From Eq. (9), we found that, if the connected capacitor is free from temperature, the capacitive value is ideally temperature-insensitive and can be adjusted by any input bias

currents. Then the capacitive value, with adjusting by input bias currents, is very widely tuned. For example, the minimum input bias current can be as low as nano-ampere range while the maximum input bias current can be as high as milli-ampere range.

III. Filter Design Methodology

A current-mode fifth-order low-pass RLC ladder filter shown in Fig. 6 is adopted as an example. It comprises the minimum requirement of DO-OTAs and capacitors. There is no obligation of any external resistor, even the terminated resistor, *Rs* and *Ro*; are also implemented using DO-OTA (in Section B). Not only the attempt to eliminate the passive components, it is the necessary for tuning pole frequency feature. Furthermore, this composition has several high impedance outputs, which allow to be easily cascaded without any additional matching circuits.

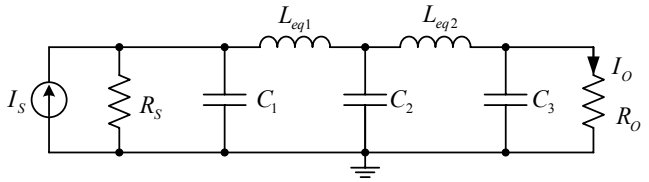

Figure 6. Current-mode fifth-order Chebyshev low-pass RLC ladder filter

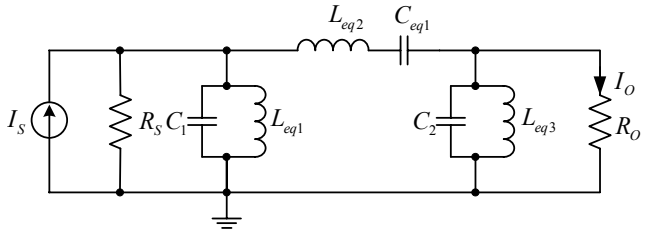

Figure 7. Current-mode sixth-order RLC band-pass filter

In addition, deriving the RLC ladder band-pass filter with this procedure is also possible. Consider a current-mode sixth-order band-pass filter in Fig. 7. In this case, the floating and grounded R, L and C branches can be realized using the basic block as shown in Section II.

IV. Simulation Results

To prove the performances of the proposed principle, the PSPICE simulation program was used for the examination. The PNP and NPN transistors employed in the proposed circuit were simulated by respectively using the parameters of the PR200N and NR200N bipolar transistors of ALA400 transistor array from AT&T [8] with ±2.5V supply voltages and all bias currents I_B were set to be 100μA, except that the I_B of grounded resistances *Rs* and *Ro* were set to be 200μA to obtain resistance value of *276*Ω. Fig. 8 depicts schematic description of the DO-OTA used in the simulations.

To show the frequency domain performance of the current-mode fifth-order Chebyshev low-pass RLC ladder filter in Fig. 6, it was simulated with PSPICE program. $C_1=C_2=C_3=10\mu F$ and $C_{Leq1}= C_{Leq2}=1nF$ are chosen to obtain inductance value of *328μH*. The simulated frequency responses of the ideal and simulated low-pass ladder filter are compared in Fig. 9. The result is very close to ideal filter implemented from the practical passive elements. Tuning ability is also simulated and shown in Fig. 10 by varying bias current to 50μA 100μA and 150μA. It is found that the pole frequency can be tuned by the input bias current.

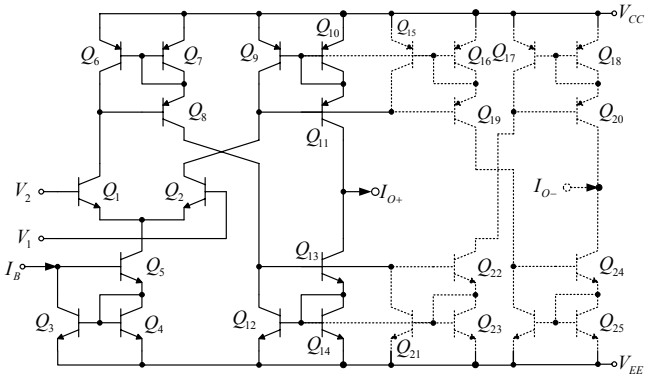

Figure 8. Internal construction of the DO-OTA

Furthermore, $C_1=C_2=10\mu F$, $C_{Leq1}= C_{Leq2}= C_{Leq3}=1nF$ and $C_{Ceq1}=10\mu F$ are taken to obtain inductance and capacitance of *328μH* and *10μF*, respectively. Comparison of the ideal and simulated current-mode sixth-order RLC band-pass filter responses is depicted in Fig. 11. In addition, center frequencies can be adjusted by varying the input bias current of the DO-OTAs, as shown the results in Fig 12.

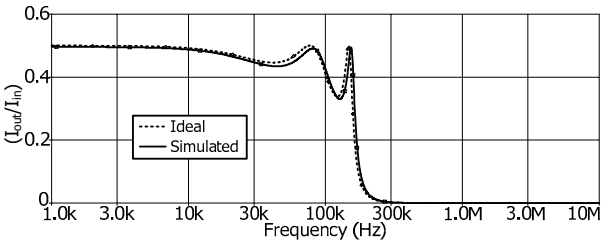

Figure 9. Compared results of current-mode fifth-order Chebyshev low-pass RLC ladder filter

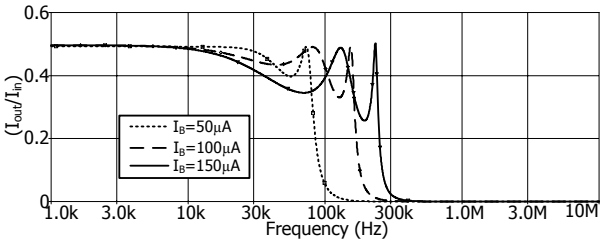

Figure 10. Results for cut-off frequency tunability of the simulated low-pass RLC ladder filter

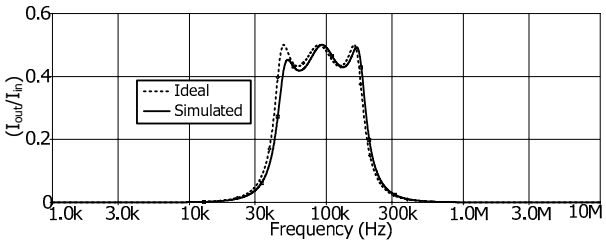

Figure 11. Compared results of current-mode fifth-order Chebyshev band-pass RLC ladder filter

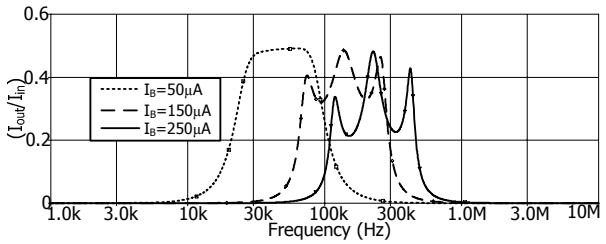

Figure 12. Results for center frequency tunability of the simulated band-pass RLC ladder filter

CONCLUSIONS

A design of RLC ladder filters using simulated elements (resistors, inductors and capacitors) based on the Dual-Output Operational Transconductance Amplifiers (DO-OTAs) has been described. The design strategy is very simple and requires the minimum passive components. The pole or center frequency can be tuned electronically by controlling the bias currents of DO-OTAs, which is very helpful in compensating unmatched components as well as varying the characteristic without changing any device. Fifth-order Chebyshev low-pass filter and sixth-order Chebyshev band-pass filter are derived as examples. Actually, the simulated elements can be applied in any filter functions. The PSPICE simulation results give a good agreement with the theoretical expectations.

***Abstract*- In this article, a new topology which can function both as quadrature oscillator and universal biquad filter is introduced. Working as quadrature oscillator, the oscillation condition and oscillation frequency can be adjusted independently. Functioning as universal biquad filter, it can provide 3 standard functions (Highpass, Lowpass, Bandpass), the quality factor and cutoff frequency can be tuned orthogonally. It comprises 2 voltage to current converters, 2 grounded capacitors, 1 positive grounded and 1 negative grounded resistors. The proposed topology can work as either quadrature oscillator or biquad filter without changing circuit topology. In addition, it can provide output signal both in current-mode and voltage-mode simultaneously. The current-mode universal filter and quadrature oscillator using OTAs being active elements as an example are proposed to shown the usefulness of proposed topology and the PSPICE simulation results are depicted. The given results agree well with the theoretical anticipations.**

***Index Terms*- universal filter, OTA, current-mode, quadrature oscillator, topology**

I. INTRODUCTION

An oscillator and a filter are 2 basic important building blocks which are frequently employed. A quadrature oscillator is widely used because the circuit provides two sinusoids with 90^{o} phase difference, as for example in telecommunications for quadrature mixers and single-sideband generators or for measurement purposes in vector generators or selective voltmeters. Therefore, the quadrature oscillator constitutes an important unit in many communication and instrumentation systems [1-5]. In similar, nowadays, the applications and advantages in the realization of various active transfer functions, called as universal biquad filters, have received considerable attention. A universal filter may be used in phase locked loop FM stereo demodulators, touch tone telephone and crossover networks used in three-way high fidelity loudspeakers [6].

In the last decade, there has been much effort to reduce the supply voltage of analog systems. This is due to the command for portable and battery-powered equipment. Since a low-voltage operating circuit becomes necessary, the current–mode technique is ideally suited for this purpose more than the voltage-mode one. Presently, there is a growing interest in synthesizing the current-mode circuits because of more their potential advantages such as larger dynamic range, higher signal bandwidth, greater linearity, simpler circuitry and lower power consumption [7-8].

The purpose of this paper is to introduce a new topology to implement current-mode universal biquad filter and quadrature oscillator. The features of proposed topology are that:

- It can work as universal filter and quadrature oscillator without changing the circuit topology.
- When it works as universal filter, it can provide 3 functions (lowpass, highpass and bandpass) in the same time. In addition, the natural frequency can be adjusted independently from the quality factor.
- When it works as quadrature oscillator, the proposed topology can provide quadrature sinusoidal signals in both voltage-mode and current-mode simultaneously. Moreover, the oscillation condition can be adjusted independently from the oscillation frequency.
- The topology requires only grounded capacitors (beneficial to an IC implementation [9]).
- It can be implemented by employing any active building blocks to serve as voltage to current converters and positive/negative resistors, such as current conveyor, Operational Transconductance Amplifier (OTA), current feedback op-amp, etc.

Due to commercial availability, the bipolar OTAs are used as the main active elements to be an example and to investigate the performances of proposed topology. The PSPICE simulation results are also shown, which are in correspondence with the theoretical analysis.

II. PROPOSED TOPOLOGY

A. Proposed topology as a current-mode universal filter

The block diagram of the proposed topology is shown in Fig. 1. It consists of inverting/non-inverting voltage-to-current converters, positive/negative grounded resistors and two grounded capacitors. Straightforwardly analyzing the block diagram in Fig.1, the transfer functions at different terminals of this network can be obtained as

$$\frac{I_{HP}}{I_{in}} = \frac{s^2}{s^2 + s\frac{1}{C_1}\left(\frac{1}{R_1} - \frac{1}{R_2}\right) + \frac{K_1K_2}{C_1C_2}}, \quad (1)$$

$$\frac{I_{BP}}{I_{in}} = \frac{sK_1/C_1}{s^2 + s\frac{1}{C_1}\left(\frac{1}{R_1} - \frac{1}{R_2}\right) + \frac{K_1K_2}{C_1C_2}}, \quad (2)$$

$$\frac{I_{LP}}{I_{in}} = \frac{K_1K_2/C_1C_2}{s^2 + s\frac{1}{C_1}\left(\frac{1}{R_1} - \frac{1}{R_2}\right) + \frac{K_1K_2}{C_1C_2}}. \quad (3)$$

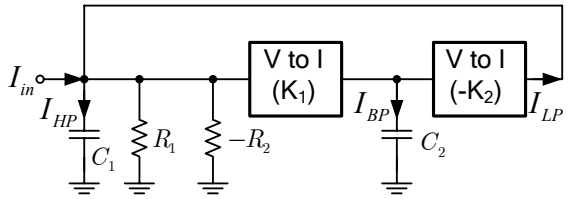

Figure 1. Proposed circuit topology

From Eqns. (1)-(3), the natural frequency ω_0 and quality factor Q_0 of each filter response can be expressed as

$$\omega_0 = \sqrt{\frac{K_1K_2}{C_1C_2}}, \quad (4)$$

and

$$Q_0 = \omega_0 \frac{C_1}{1/R_1 - 1/R_2}. \quad (5)$$

From Eqns. (4) and (5), it can be seen that the quality factor can be adjusted by varying R_1 or R_2 without affecting the natural frequency. On the other hand, the natural frequency can be adjusted by varying K_1, K_2, C_1 or C_2. Thus bandwidth (BW) is given by

$$BW = \frac{\omega_0}{Q_0} = \frac{1/R_1 - 1/R_2}{C_1}. \quad (6)$$

We found that the bandwidth can be controlled by R_1, R_2 or C_1. Moreover, the quality factor can be much high by controlling $1/R_2$ to be much less than $1/R_1$.

B. Topology Sensitivities

The sensitivities of the proposed topology are low and can be found as

$$S_{K_1}^{\omega_0} = S_{K_2}^{\omega_0} = \frac{1}{2};\ S_{C_1}^{\omega_0} = S_{C_2}^{\omega_0} = -\frac{1}{2}, \quad (7)$$

$$S_{K_1}^{Q_0} = S_{K_2}^{Q_0} = \frac{1}{2};\ S_{C_1}^{Q_0} = \frac{1}{2};\ S_{C_2}^{Q_0} = -\frac{1}{2}, \quad (8)$$

$$S_{R_1}^{Q_0} = \frac{1}{1-(R_1/R_2)};\ S_{R_2}^{Q_0} = -\frac{1}{(R_2/R_1)-1}, \quad (9)$$

and

$$S_{R_1}^{BW} = \frac{1}{1-(R_1/R_2)};\ S_{R_2}^{BW} = -\frac{1}{(R_2/R_1)-1}. \quad (10)$$

C. Proposed topology as a quadrature oscillator

If no input current applied to the topology as shown in Fig. 2, system characteristic equation can be expressed as

$$s^2 + s\frac{1}{C_1}\left(\frac{1}{R_1} - \frac{1}{R_2}\right) + \frac{K_1K_2}{C_1C_2} = 0. \quad (11)$$

From Eqn. (11), it can obviously seen that the proposed topology can be set to be an oscillator if

$$R_1 = R_2. \quad (12)$$

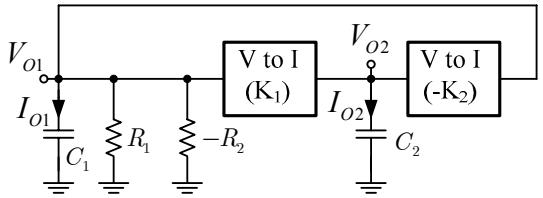

Figure 2. Proposed quadrature oscillator

Eqn. (12) is called as condition of oscillation, then the characteristic equation of the system is changed to

$$s^2 + \frac{K_1K_2}{C_1C_2} = 0. \quad (13)$$

From Eqn. (13), the oscillation frequency of this system can be obtained as

$$\omega_0 = \sqrt{\frac{K_1K_2}{C_1C_2}}. \quad (14)$$

It can be seen, from Eqns. (12) and (14), that the oscillation condition can be adjusted independently from the oscillation frequency by varying R_1 or R_2, while the oscillation frequency can be adjusted by varying K_1, K_2, C_1 or C_2.

Furthermore, the quadrature sinusoidal signals can be obtained both in current-mode and voltage-mode at I_{O1} and I_{O2} or V_{O1} and V_{O2} of Fig. 2, respectively, with the same time.

III. Application Examples

A. Current-Mode Universal Filter Using OTAs

Fig. 3 demonstrates the circuit scheme of the current-mode universal filter using OTAs. The OTAs are employed as voltage to current converters and positive/negative resistance simulators. The depicted bias currents I_{B1}, I_{B2}, I_{B3} and I_{B4} are the input bias currents of OTA1, OTA2, OTA3 and OTA4, respectively. From routine analysis, the following current transfer functions are obtained

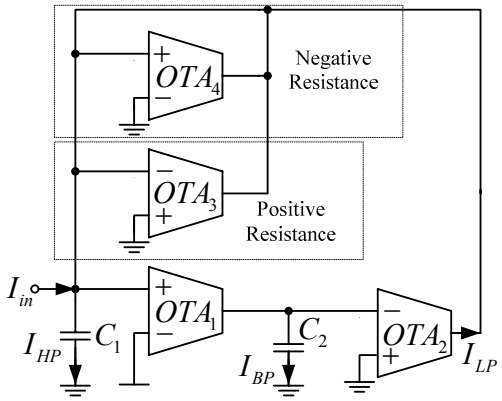

Figure 3. Current-mode universal filter using OTAs

$$\frac{I_{HP}}{I_{in}} = \frac{s^2}{s^2 + s\frac{1}{C_1}(g_{m3} - g_{m4}) + \frac{g_{m1}g_{m2}}{C_1C_2}}, \tag{15}$$

$$\frac{I_{BP}}{I_{in}} = \frac{sg_{m1}/C_1}{s^2 + s\frac{1}{C_1}(g_{m3} - g_{m4}) + \frac{g_{m1}g_{m2}}{C_1C_2}}, \tag{16}$$

$$\frac{I_{LP}}{I_{in}} = \frac{g_{m1}g_{m2}/C_1C_2}{s^2 + s\frac{1}{C_1}(g_{m3} - g_{m4}) + \frac{g_{m1}g_{m2}}{C_1C_2}}. \tag{17}$$

From Eqns. (15), (16) and (17), the parameters ω_0 and Q_0 can be expressed as

$$\omega_0 = \sqrt{\frac{g_{m1}g_{m2}}{C_1C_2}}, \tag{18}$$

and

$$Q_0 = \omega_0 \frac{C_1}{(g_{m3} - g_{m4})}. \tag{19}$$

Where $g_{mi} = I_{Bi} / 2V_T$. V_T is the thermal voltage. For simple consideration, and we assign that $I_{B1} = I_{B2} = I_B$ and $C_1 = C_2 = C$, it yields

$$\omega_0 = \frac{I_B}{2V_TC}, \tag{20}$$

and

$$Q_0 = \frac{I_B}{I_{B3} - I_{B4}}. \tag{21}$$

From Eqns. (20) and (21), it should be observed that the quality factor can be adjusted independently from the natural frequency, as explained in section *II.B*, by varying I_{B3} or I_{B4}. In addition, the natural frequency can be adjusted by I_B or C. Thus bandwidth (BW) is given by

$$BW = \frac{\omega_0}{Q_0} = \frac{I_{B3} - I_{B4}}{2V_TC}. \tag{22}$$

In the same view, the bandwidth can be linearly tuned by I_{B3}. Another advantage of the proposed circuit is that the high Q_0 circuit can be obtained by setting I_{B4} close to I_{B3}, which differs from conventional universal filters in such that the maximum Q_0 is limited by component values.

B. Circuit Sensitivities due to element variations

The sensitivities of the OTAs-based circuit are low and can be found as

$$S_{g_{m1}}^{\omega_0} = S_{g_{m2}}^{\omega_0} = \frac{1}{2};\ S_{C_1}^{\omega_0} = S_{C_2}^{\omega_0} = -\frac{1}{2}, \tag{23}$$

$$S_{g_{m1}}^{Q_0} = S_{g_{m2}}^{Q_0} = \frac{1}{2};\ S_{C_1}^{Q_0} = \frac{1}{2};\ S_{C_2}^{Q_0} = -\frac{1}{2}, \tag{24}$$

$$S_{g_{m3}}^{Q_0} = \frac{1}{1-(g_{m4}/g_{m3})};\ S_{g_{m4}}^{Q_0} = -\frac{1}{(g_{m3}/g_{m4})-1}, \tag{25}$$

and

$$S_{g_{m3}}^{BW} = \frac{1}{1-(g_{m4}/g_{m3})};\ S_{g_{m4}}^{BW} = -\frac{1}{(g_{m3}/g_{m4})-1}. \tag{26}$$

C. Quadrature Oscillator Using OTAs

If no input current applied to the circuit in Fig. 3 as shown in Fig. 4, system characteristic equation can be expressed as

$$s^2 + s\frac{1}{C_1}(g_{m3} - g_{m4}) + \frac{g_{m1}g_{m2}}{C_1C_2} = 0. \tag{27}$$

From Eqn. (27), it can obviously seen that the proposed circuit can be set to be an oscillator if

$$g_{m3} = g_{m4}. \tag{28}$$

Eqn. (28) is called as condition of oscillation, this is achieved by $I_{B3} = I_{B4}$, then the characteristic equation of the system becomes

$$s^2 + \frac{g_{m1}g_{m2}}{C_1C_2} = 0. \tag{29}$$

From Eqn. (29), the oscillation frequency of this system can be obtained as

$$\omega_0 = \sqrt{\frac{g_{m1}g_{m2}}{C_1C_2}}. \tag{30}$$

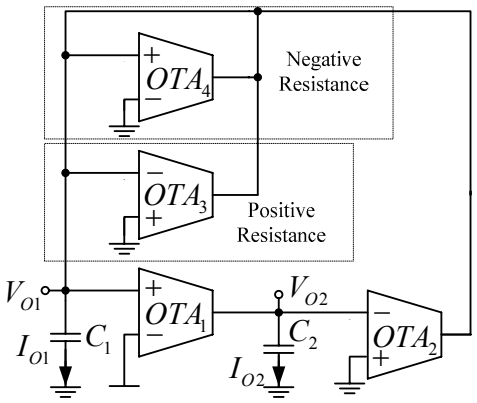

Figure 4. Quadrature oscillator using OTAs

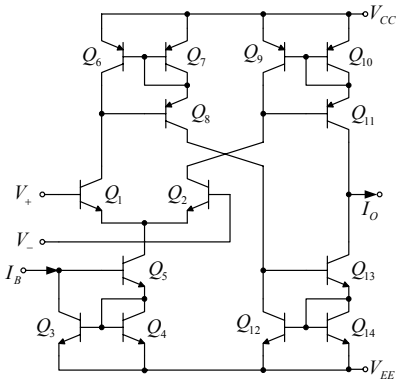

Figure 5. Internal construction of OTA

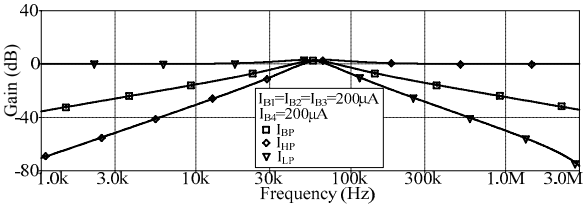

Figure 6. Gain responses of universal filter

D. Simulation Results

To prove the performances of the proposed circuits, the PSPICE simulation program was used for the examination. The PNP and NPN transistors employed in the proposed circuits were simulated by respectively using the parameters of the PR200N and NR200N bipolar transistors of ALA400 transistor array from AT&T [10]. Fig. 5 depicts schematic description of the OTA used in the simulations. All OTAs were biased with ±2V power supplies and $C_1 = C_2 = 10nF$. The results shown in Fig. 6 are the gain responses of the universal filter obtained from Fig. 3. There are clearly seen that the universal filter circuit can provide low-pass, high-pass and band-pass functions, simultaneously.

Fig. 7 display gain responses of bandpass, with different I_{B4} values. They are shown that the quality factor can be adjusted by the input bias current I_{B4} as depicted in Eqn. (21) without affecting the natural frequency. Figs. 8 and 9 show the responses when operation as quadrature oscillator. The maximum oscillation frequency is about 11.23MHz.

IV. CONCLUSIONS

The new circuit topology has been presented. The advantages of the proposed topology are that: it can function both as quadrature oscillator and current-mode universal filter (lowpass, highpass and bandpass) without changing a circuit topology: when it works as the universal filter, the quality factor and the natural frequency can be orthogonally controlled by using input bias currents of the OTAs, this is easily modified to use in control systems using a microcontroller [7]: when it functions as quadrature oscillator, its oscillation condition and oscillation frequency can be adjusted independently. To investigate and verify the performances of proposed topology, the current-mode universal filter and quadrature oscillator based on OTAs have been proposed. The PSPICE simulation results are well agreed with the theoretical anticipations.

***Abstract*- This article presents a three-input two-output current-mode universal biquadratic filter performing completely standard functions: low-pass, high-pass, band-pass, band-reject and all-pass functions, based on Dual-Output Current Controlled Current Differencing Transconductance Amplifier (DO-CCCDTA). The features of the circuit are that: the quality factor and pole frequency can be tuned orthogonally via the input bias currents: the circuit description is very simple, consisting of merely one DO-CCCDTA, one voltage buffer and 2 grounded capacitors. Additionally, each function response can be selected by suitably selecting input signals in digital method. Without any external resistors and using only grounded elements, the proposed circuit is very suitable to further develop into an integrated circuit. The PSPICE simulation results are depicted. The given results agree well with the theoretical anticipation. The maximum power consumption is approximately 1.81mW at ±1.5V power supply voltages.**

***Index Terms*- biquadratic filter, DO-CCCDTA, current-mode**

I. INTRODUCTION

In electrical engineering works, as well-known, an analog filter is an important block and widely used for continuous-time signal processing. It can be found in many fields: for instance, communication, measurement and instrumentation, and control systems [1-2]. One of most popular analog filters is a universal biquadratic filter since it can provide several functions. Nowadays, a universal filter working in current-mode has being been more popular than voltage-mode one. Since the last decade, on the other hand, there has been much effort to reduce the supply voltage of analog systems. This is due to the command for portable and battery-powered equipment. Since a low-voltage operating circuit becomes necessary, the current–mode technique is ideally suited for this purpose. Actually, a circuit using the current-mode technique has many other advantages: for example, larger dynamic range, higher bandwidth, greater linearity, simpler circuitry and lower power consumption [3-4].

The literature surveys show that a large number of circuit realizations for current-mode universal filters have been reported [5-19]. Unfortunately, these reported circuits suffer from one or more of following weaknesses

a) excessive use of the active and/or passive elements and require changing circuit topologies to achieve several functions [5-9]
b) lack of electronic adjustability [6-13], [16]
c) the outputs of the filter responses are not in high output impedance [18-19]
d) use of floating capacitor, which is not convenient to further fabricate in IC [6-13]
e) cannot provide completely standard functions [5, 7-8, 10-12, 15-16]

This work is arranged to propose a new three-input two-output current-mode universal biquadratic filter, emphasizing on use of DO-CCCDTA. The features of proposed circuit are that: the proposed universal filter can provide completely standard functions without changing circuit topology by appropriately selecting the input signals in digital method: the circuit description is very simple, it consists of one DO-CCCDTA and 2 grounded capacitors, which is suitable for fabricating in monolithic chip: the filter does not require any external resistor and passive parameter matching conditions. In addition, the quality factor and pole frequency can be tuned orthogonally via the input bias currents. The performances of proposed circuit are illustrated by PSPICE simulations, they show good agreement as mentioned.

II. PRINCIPLE OF OPERATION

A. The Dual-Output Current Controlled Current Differencing Transconductance Amplifier (DO-CCCDTA)

Since the proposed circuit is based on DO-CCCDTA, a brief review of DO-CCCDTA is given in this section. Basically, the DO-CCCDTA is composed of translinear element, mixed loops and complementary current mirrors. Generally, the DO-CCCDTA properties are similar to the conventional CDTA, except that input voltages of DO-CCCDTA are not zero and the DO-CCCDTA has finite input resistances R_p and R_n at the p and n input terminals, respectively. These parasitic resistances are equal and can be controlled by the bias current I_{B1} as shown in the following equation

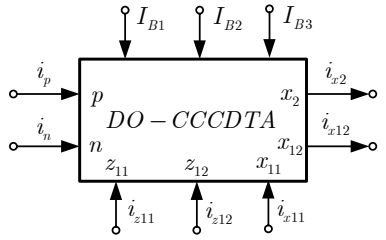
$$\begin{bmatrix} V_p \\ V_n \\ I_{z11,12} \\ I_{x11,12} \\ I_{x2} \end{bmatrix} = \begin{bmatrix} R_p & 0 & 0 & 0 & 0 \\ 0 & R_n & 0 & 0 & 0 \\ 1 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -g_{m1} & 0 \\ 0 & 0 & 0 & 0 & g_{m2} \end{bmatrix} \begin{bmatrix} I_p \\ I_n \\ V_x \\ V_{z1} \\ V_{z1} \end{bmatrix}. \quad (1)$$

Where $$R_p = R_n = \frac{V_T}{2I_{B1}}, \quad (2)$$

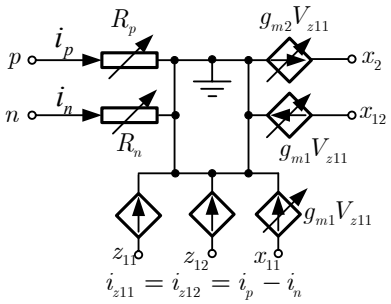
$$g_{m1} = \frac{I_{B2}}{2V_T}, \quad (3)$$

and $$g_{m2} = \frac{I_{B3}}{2V_T}. \quad (4)$$

Where g_m is the transconductance gain of the CCCDTA and V_T is the thermal voltage. The symbol and the equivalent circuit of the CCCDTA are illustrated in Fig. 1(a) and (b), respectively.



(a)



(b)

Figure 1. DO-CCCDTA (a) Symbol (b) Equivalent circuit

B. Proposed universal biquad filter

The proposed current-mode universal biquad filter is shown in Fig. 2. From routine analyzing the circuit in Fig. 2, we will get the output currents as

$$I_{O1} = \frac{1}{D(s)}\left[g_{m1}I_{in1} - sC_2R_pg_{m1}I_{in2} + D(s)I_{in3}\right], \quad (5)$$

and $$I_{O2} = \frac{1}{D(s)}\left(g_{m2}I_{in1} - sC_2R_pg_{m2}I_{in2}\right). \quad (6)$$

Where $D(s) = s^2C_1C_2R_p + sC_2R_pg_{m1} + g_{m2}$. From Eqs. (5) and (6), the magnitudes of input currents; I_{in1}, I_{in2} and I_{in3} are chosen as Table. 1 by digital method to obtain a standard function of the 2nd–order network. From Eq. (5), the pole frequency (ω_0) and quality factor (Q_0) of each filter response can be expressed as

$$\omega_0 = \sqrt{\frac{g_{m2}}{C_1C_2R_p}}, \quad (7)$$

and $$Q_0 = \frac{C_1}{g_{m1}}\sqrt{\frac{g_{m2}}{C_1C_2R_p}}. \quad (8)$$

For simple consideration, if we set $C_1 = C_2 = C$ and $I_{B1} = I_{B3} = I_B$, Eqs. (7) and (8) are subsequently modified to

$$\omega_0 = \frac{I_B}{CV_T}, \quad (9)$$

and $$Q_0 = \frac{2I_B}{I_{B2}}. \quad (10)$$

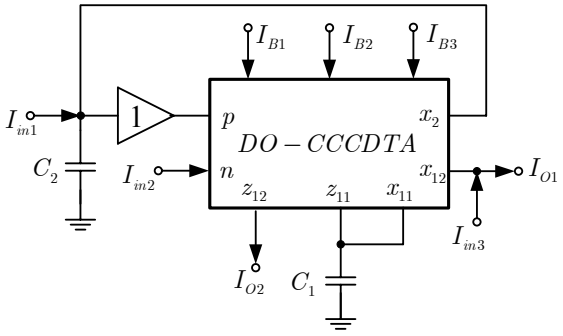


Figure 2. Proposed current-mode universal filter

TABLE I
The I_{in1}, I_{in2} and I_{in3} values for each filter function response

Filter Responses		Input		
I_{O1}	I_{O2}	I_{in1}	I_{in2}	I_{in3}
-	LP	1	0	0
HP	-	-1	1	1
BP	-	0	1	0
BR	-	0	1	1
AP	-	0	2	1

It is obviously found that, from Eqns. (9) and (10), the quality factor can be adjusted by I_{B2} without affecting the pole frequency. Reversely, the pole frequency can be controlled via I_B. In addition, bandwidth (*BW*) of the system can be expressed by

$$BW = \frac{\omega_0}{Q_0} = \frac{I_{B2}}{2CV_T}. \quad (11)$$

We found that the bandwidth can be linearly controlled by I_{B2}. Moreover, the quality factor can be much high by controlling I_{B2} to be much less than I_B. This differs from the conventional current-controlled universal filters in such that they use an input bias current to control the quality factor. However, it has a limited value of current in the circuits, the quality factor is then restricted.

C. Sensitivities

The sensitivities of the proposed circuit are low and can be found as

$$S_{I_B}^{\omega_0} = 1;\ S_C^{\omega_0} = -1, \quad (12)$$

and $$S_{I_B}^{Q_0} = 1;\ S_{I_{B3}}^{Q_0} = -1. \quad (13)$$

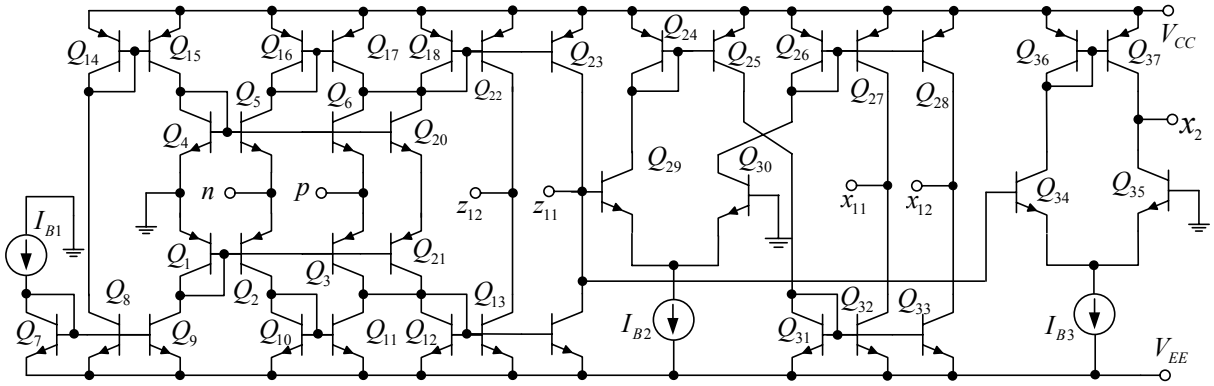

Figure 3. Internal construction of DO-CCCDTA

D. Non-ideal case

For non-ideal case, the I_z and I_x of DO-CCCDTA can be respectively characterized by

$$I_{z11} = \alpha_{p1} I_p - \alpha_{n1} I_n , \quad (14)$$

$$I_{z12} = \alpha_{p2} I_p - \alpha_{n2} I_n , \quad (15)$$

$$I_{x11} = \beta_{11} g_m V_{z11} , \quad (16)$$

$$I_{x12} = \beta_{12} g_m V_{z11} , \quad (16)$$

and

$$I_{x2} = \beta_2 g_m V_{z11} . \quad (18)$$

Where α_p, α_n and β are transferred error values deviated from one. In the case of non-ideal consideration, reanalyzing the proposed filter circuit in Fig. 2 yields the denominator as

$$D(s) = s^2 C_1 C_2 R_p + s C_2 R_p g_{m1} \beta_{11} + g_{m2} \alpha_{p1} \beta_2 . \quad (19)$$

In this case, the ω_0, Q_0 and BW are changed to

$$\omega_0 = \sqrt{\frac{\alpha_{p11} \beta_2 g_{m2}}{C_1 C_2 R_p}} , \quad (20)$$

$$Q_0 = \frac{C_1}{\beta_{12} g_{m1}} \sqrt{\frac{\alpha_{p1} \beta_2 g_{m2}}{C_1 C_2 R_p}} , \quad (21)$$

and

$$BW = \frac{\omega_0}{Q_0} = \frac{\beta_{12} g_{m1}}{C_1} . \quad (22)$$

Eqs. (20)-(22) degrade the performances of proposed filter at high frequency applications in such restricted frequency response and temperature dependence because of the parasitic elements of active device used in the circuit.

Actually, if careful design technique is employed to design the CCCDTA, these deviations are very small and can be ignored**.**

III. SIMULATION RESULTS

To prove the performances of the proposed circuit, the PSPICE simulation program was used for the examination. The PNP and NPN transistors employed in the proposed circuit were simulated by respectively using the parameters of the PR200N and NR200N bipolar transistors of ALA400 transistor array from AT&T [20]. The voltage buffer was used as an ideal voltage buffer. Fig. 3 depicts schematic description of the DO-CCCDTA used in the simulations.

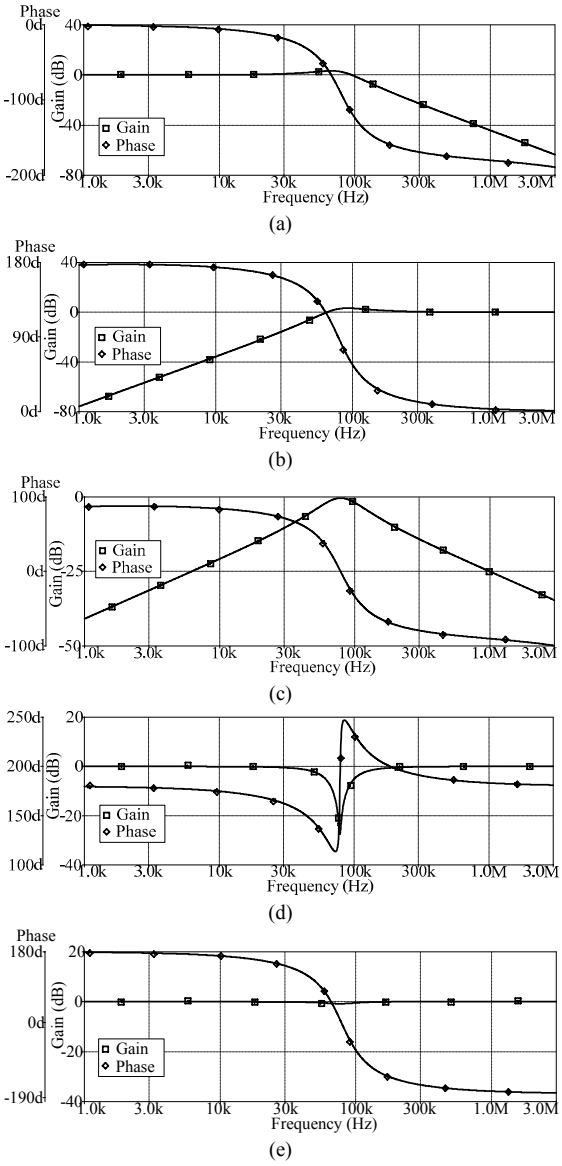

Figure 4. Frequency responses for different functions

The circuit was biased with ±1.5V supply voltages and $C_1 = C_2 = 10nF$. The results shown in Fig. 4 are the gain and phase responses of the proposed biquad filter obtained from Fig. 2 with different functions as shown Table 1, where I_{B1}, I_{B2} and I_{B3} are equal to $50\mu A$, $200\mu A$ and $200\mu A$, respectively. There are clearly seen that the proposed biquad filter can provide low-pass, high-pass, band-pass, band-reject and all-pass functions dependent on selection as shown in Table 1, without modifying major circuit topology.

Fig. 5 displays gain responses of band-pass function with different I_{B2} values. It is obviously shown that the bandwidths of the responses can be linearly adjusted by the input bias current I_{B2} as depicted in Eq. (10) without affecting the pole frequency. Similarly, the results in Fig. 6 are phase responses of all-pass function. It confirms the performances of proposed filter in such controllability of the quality factor via I_{B2} without affecting the pole frequency as well. Maximum power consumption is about 1.81mW.

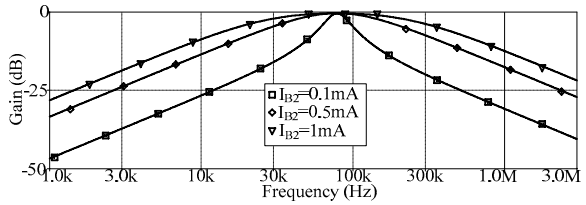

Figure 5. Bandwidth variation of band-pass function for different I_{B2}

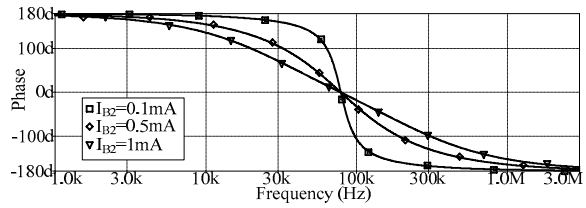

Figure 6. Phase responses of all-pass function for different I_{B2}

IV. CONCLUSIONS

The current-mode universal biquadratic filter based on DO-CCCDTA has been presented. The advantages of the proposed circuit are that: it performs low-pass, high-pass, band-pass, band-reject and all-pass functions with two outputs depending on an appropriately selecting of three input signals: the quality factor and pole frequency can be tuned orthogonally via the input bias currents, this is easily modified to use in control systems using a microcontroller [3]. The circuit description comprises only one DO-CCCDTA and 2 grounded capacitors cooperating with one voltage buffer. With mentioned features, it is very suitable to realize the proposed circuit in a monolithic chip for use in battery-powered, portable electronic equipments such as wireless communication system devices.

Fast Analysis of Analog Design Trade-offs via Geometric Programming

Theerachet Soorapanth
National Electronics and Computer Technology Center, Bangkok, Thailand
Email: theerachet.soorapanth@nectec.or.th

***Abstract*-This paper concerns a method for solving a variety of analog design trade-off problems, which is based on formulating the problem as a geometric program (GP). These nonlinear, constrained optimization problem can be transformed to convex optimization problems, and then solved (globally) very efficiently. Designers can analyze quantitatively trade-offs among different specifications as well as construct trade-off curves very quickly owing to the efficiency of the method.**

I. INTRODUCTION

Most analog design problems deals with how to size a circuit appropriately to achieve a set of specifications subject to various constraints while spending the least amount of resources such as power consumption, for instance. This scenario allows one to formulate such problem as a constrained optimization problem. The variables are often the sizes of transistors and other circuit components as well as biasing conditions. It is also possible to include other design variables such as threshold voltage, supply voltage, and oxide thickness. The choice of design variables determines various top-level circuit objectives, such as the total area of the circuit, the total power it consumes, its bandwidth and other objectives such as noise tolerance, robustness to process and environment parameter variations, and so on. These objectives can be very complex functions of the design variables. In addition, there are many constraints that must be satisfied. There are many approaches to circuit sizing, including heuristics, and methods based on circuit simulation coupled to a generic numerical optimization.

This paper focuses on a particular approach, in which the sizing problem is modeled (at least approximately) as a geometric program (GP), a special type of mathematical optimization. Fortunately, majority of analog circuit sizing problems can be directly (if not, approximately) casted as GP problems. Over the years, the efficient algorithms, such as an interior-point method, to solve such problems have been developed. GPs with tens of thousands of variables and hundreds of thousands of constraints can be reliable solved in minutes, on a personal computer. In addition, since GP is a type of convex optimization, the achieved solution (if feasible) is guaranteed to be globally optimal.

II. GEOMETRIC PROGRAMMING

GP-based circuit optimization is not new; it has been used for digital circuits since the 1980s. In [1], a method was proposed for transistor and wire sizing based on Elmore delay, that was later found to be a GP. Other digital circuit design problems, that can be formulated as GPs, can be found in, e.g. [2,3,4]. Recently, GP has been introduced to solve analog and mixed-signal circuit problems [5,6].

A geometric program is an optimization problem of the form

$$\begin{array}{lll} \text{minimize} & f_0(x) & \\ \text{subject to} & f_i(x) \le 1, & i=1,\ldots,m \\ & g_i(x) = 1, & i=1,\ldots,p \\ & x_i > 0, & i=1,\ldots,n \end{array} \tag{1}$$

where $f_0,\ldots,f_m$ are posynomial functions and $g_1,\ldots,g_p$ are monomial functions. Posynomial function has the form

$$f(x_1,\ldots,x_n) = \sum_{k=1}^{t} c_k x_1^{\alpha_{1k}} x_2^{\alpha_{2k}} \ldots x_n^{\alpha_{nk}} \tag{2}$$

where $c_j \ge 0$ and α_{ij} is real. When there is only one term in the sum, f is called a monomial function. A geometric program can be reformulated as a convex optimization problem by changing variables and considering the logs of the function involved. We define new variables $y_i = \log x_i$ and take the logarithm of a posynomial f to get

$$h(y) = \log f(e^{y_1},\ldots,e^{y_n}) = \log\left(\sum_{k=1}^{t} e^{\alpha_k^T y + b_k}\right) \tag{3}$$

where $\alpha_k^T = [\alpha_{1k} \cdots \alpha_{nk}]$ and $b_k = \log c_k$. It can be shown that h is a convex function of the variable y. Similar transformation can be made to the equality constraint function g. The convexity property guarantees the problem's solution (if feasible) is globally optimal. In addition, the problem can be solved using a very efficient interior-point method [7].

III. CIRCUIT MODELING FOR GP

For circuit problem to be solved by GP, each design equations must be modeled (or approximated) by posynomial/monomial functions. Fortunately, majority of

circuit design equations can be modeled as such. For instance, the following long-channel MOS device equation

$$I_D = \frac{1}{2} K_p W L^{-1} (V_{GS} - V_T)^2 \tag{4}$$

can be considered as a monomial function of transistor width W, transistor length L, and overdrive voltage $V_{GS} - V_T$. Similarly, the transconductance equation can be written in monomial form as

$$g_m(W, L, I_D) = \left(2K_p\right)^{1/2} W^{1/2} L^{-1/2} I_D^{1/2} \tag{5}$$

In addition to device equations, constraint on device operating condition can be modeled by a monomial as well. For instance, the constraint for an MOS to be in saturation, $V_{GS} - V_T \le V_{DS,\min}$, can be written in monomial form as

$$\left(\sqrt{\frac{2}{K_p}} \frac{1}{\left(V_{DS,\min} + V_T\right)}\right) I_D^{1/2} L^{1/2} W^{-1/2} \le 1 \tag{6}$$

Submicron short-channel devices can also be modeled with a posynomial by performing a SPICE-simulation-based posynomial function fitting over large ranges of length, width, and bias currents.

IV. Example: An Op-Amp Design

As an example, we will apply the GP method to the design of a common analog circuit building block, an operational amplifier. There are several op-amp architectures. We will consider a two-stage architecture as shown in Fig. 1. Other op-amp architectures can be applied as well, but this particular architecture is chosen for its design simplicity and good achieved performance.

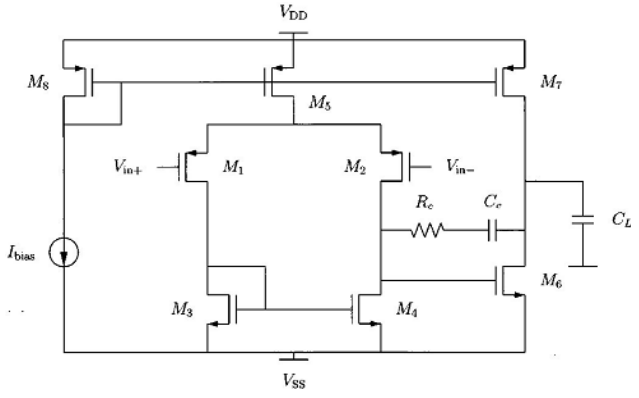

Figure 1. Two-stage op-amp architecture.

To set up the op-amp design problem for GP, we have to consider a variety of performance measures and constraints, which must be formulated in GP-compatible forms. The design variables are the transistor sizes (width and length), the value of the passive components (capacitors and resistors), and the value of the bias currents and bias voltages. For this particular two-stage op-amp, there are nineteen design variables. The constraints in the design of this op-amp are summarized as follows

- Symmetry and matching: $M_1 = M_2$, $M_3 = M_4$
- Limit on device sizes: $W \ge W_{\min}$, $L \ge L_{\min}$
- Limit on chip area: $A \le A_{\max}$
- Systematic input offset voltage
- Current ratio equalities: $I_{M5} \propto I_{M8}$, $I_{M7} \propto I_{M8}$, $I_{M1} \propto I_{M5}$
- Bias conditions: $V_{GS} - V_T \le V_{DS}$
- Gate overdrive voltage: $V_{GS} - V_T \ge V_{OD,\min}$
- Limit on power consumption: $P \le P_{\max}$
- Open-loop DC gain
- Unity-gain bandwidth
- Phase-margin
- Slew-rate
- Common-mode rejection ratio
- Power-supply rejection ratio
- Input-referred noise

In total, there are forty-six constraints, both inequalities and equalities expressed by posynomials and monomials, respectively, according to (1). The objectives of the design can vary depending on the specifications.

V. Design Implementations

The op-amp design has been implemented in C language for GP optimization. We choose a 0.8-μm CMOS technology and specify the design objective to be unity-gain bandwidth maximization. The results are shown in Table 1 and 2.

The first column in Table 1 identifies the performance measures; the second gives the specification. The third column shows the performance of the design obtained from GP optimization. The fourth column shows the value of the specification as simulated by SPECTRE from our optimal design (Fig. 2).

We can see that both GP calculation and SPECTRE simulation achieve or exceed all of the required specifications. Note that some of the constraints are loose, some are tight. Tight constraints include power consumption, phase margin, and input-referred noise, for instance. This suggests that there are some trade-offs among these performance measures, which will be further explored in the next section.

The computer time required for the design is two seconds owing to the efficiency of the interior-point algorithm.

The optimal design parameters found are shown in Table 2.

VI. Trade-Off Analysis

We can consider trade-offs among design specifications by running GP optimization with four different objectives as follows

- Maximizing unity-gain bandwidth
- Maximizing DC gain
- Minimizing input-referred noise
- Minimizing power consumption

Keeping the constraints unchanged, the optimization results are compared in Table 3. The results indicate clear trade-offs among gain, noise, unity-gain bandwidth, and power consumption. For instance, if higher DC gain is desired, the optimal design possesses lower unity-gain bandwidth. If lower input-referred noise is preferred, larger chip area would be required to accommodate larger device sizes. Finally, if low power is favored, the smallest allowed bandwidth and maximum allowed noise level result. Also, it is interesting to note that some constraints, e.g. phase margin specification, remain tight regardless of design objectives. This suggests that all four previously-mentioned performance measures become worsen with higher phase margin requirement.

Since the computation time for each optimization takes merely two seconds, we can explore various design trade-offs very quickly. Besides changing design objectives, we can construct trade-off curves, like Fig. 3, by repeatedly solving the design problem while varying one of the specifications. Within a matter of minutes, we can sweep out the globally optimal trade-off curve between competing objectives (with the others fixed). Designers can determine which specifications are more critical or relaxed.

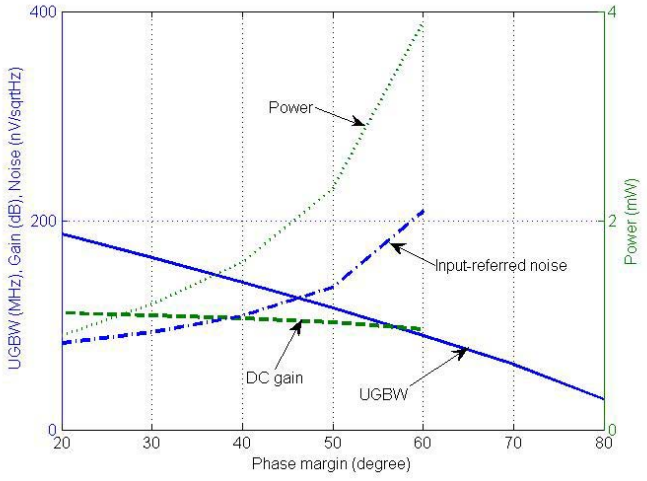

Figure 3. Trade-off curves between optimal unity-gain bandwidth, DC gain, input-referred noise and power consumption, all versus phase margins.

VII. Conclusions

We have shown how geometric programming can be used to design analog circuits such as op-amps. The method is very fast and efficient, can handle a wide variety of constraints and provide *globally optimal* design. This allows designers to spend more time on exploring different circuit architectures rather than wasting time on optimizing a particular design which may end up with a *locally optimal* solution. Trade-off analysis can be performed very quickly thanks to the efficiency of the GP algorithm.

A Current-Mode Square-Rooting Circuit Using Negative Feedback Technique

Ittipong Chaisayun
South-East Asia University
Bangkok 10160,THAILAND, Email:ittipong@sau.ac.th

***Abstact*-In this paper, a square-rooting circuit operating in current mode is proposed. The negative feedback technique is used to realize the proposed circuit. This circuit uses only fourteen CMOS transistors and requests no current source, and moreover it can operate at low voltage supply. Simulation results are carried out by using PSpice. Experimental results by using CD 4007 transistor arrays are shown to confirm the operation.**

I. INTRODUCTION

A square-rooting circuit is a useful building block used in neural networks applications, measurement and instrumentation. For example it can be used to compute the Euclidean distance between two vectors[1], or to calculate the r.m.s. value of an arbitrary waveform[2]. In the past, square-rooting circuit was proposed by using operational amplifiers(op-amp) and bipolar junction transistors[3]. This approach provides the logarithmic principle to realize a square-rooting function. However the frequency performance is limited by the bandwidth of an op-amp. Then, the square-rooting circuit[4] has been proposed by bipolar junction transistors(BJT) in translinear configuration which is suitable for implementing in monolithic integrated circuit form. After that the voltage-mode square-rooting circuits[5-6] and the current-mode square-rooting circuits[7-8] based on CMOS transistors have been reported. In recent years, current-mode analogue signal processing circuit techniques have received wide attention due to the high accuracy, the wide signal bandwidth and the simplicity of implementing signal operations such as addition, subtraction and multiplication[4]. However, the current-mode square-rooting circuit is less involved, so this paper proposes a current-mode square-rooting circuit. The current-mode square-rooting circuit[7] is realized by using the back gate of CMOS biased in weak inversion. Even it uses low voltage supply and only nine transistors, but it has more error about 20%. The current-mode square-rooting circuit[8] is realized by a class AB configuration. Although it achieves a wide dynamic rang and a wide-band capability, but it uses more components (sixteen transistors and three current sources). The novel higher precision current-mode square-root circuit[9] has been reported recently. Although it has high precision, but it uses more devices (twenty-six transistors). In this paper, the current-mode square-rooting circuit is realized by using negative feedback on current squaring circuit. It has low error and uses only fourteen transistors and no current source.

II. PRINCIPLE OF OPERATION

A. *Principle of The Square-Rooting Circuit*

The block diagram in Fig. 1 consists of a squaring circuit, a current-differencing amplifier (CDA) and an NMOS transistor.

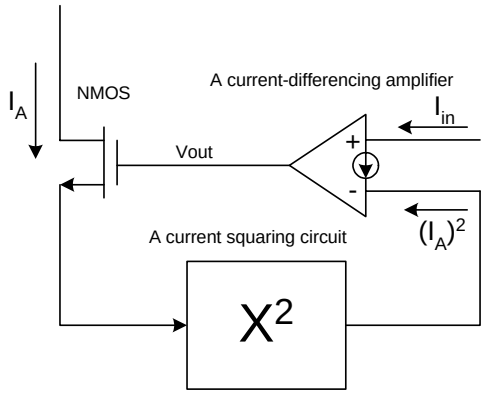

Fig. 1. Block diagram of the proposed circuit

The operation of the block diagram can be explained as: the current-differencing amplifier will convert difference of I_A^2 and I_{in} to be the single ended output voltage V_{out} , and V_{out} will control I_A by the NMOS transistor. Then I_A is fed to the input of the squaring circuit, and its output is I_A^2 which is fed to the inverting input of CDA. Consider feedback loop on the CDA. It is negative feedback. Effect of negative feedback on CDA forces the current at inverting input equating the current at noninverting input or it can be written as $I_A^2 = I_{in}$. In another word, the effect of negative feedback on CDA is that I_A^2 tracks I_{in}. Assume I_A is the output current and I_{in} is the input current. Relationship of I_A to I_{in} can be rewritten

$$I_A = \sqrt{I_{in}} \qquad (1)$$

In this research, all NMOS transistors operate in saturation region, and the drain current can be expressed as follows

$$I_D = \frac{K}{2}(V_{GS} - V_T)^2 ; V_{GS} > V_T, V_{DS} > V_{GS} - V_T \qquad (2)$$

Where $K(= \mu C_{ox} \frac{W}{L})$ is the transconductance, V_T is the threshold voltage, V_{DS} is the drain-to-source voltage, and V_{GS} is the gate-to-source voltage.

B. *Squaring Cell*

The squaring circuit[9] is shown in Fig. 2.

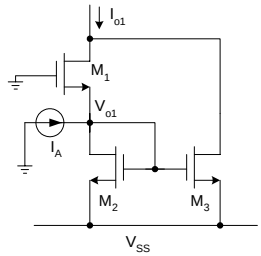

Fig.2. The squaring cell.

In Fig. 2., I_A is the input current, V_{O1} is the input voltage and I_{o1} is the output current. Relation of the drain current to input current can be written as

$$I_A = I_{D2} - I_{D1} \tag{3}$$

Using (2), V_{O1} can be written as

$$V_{O1} = \frac{I_A}{2K(-V_{SS} - 2V_T)} + \frac{V_{SS}}{2} \tag{4}$$

The output current I_{o1} can be written as

$$I_{O1} = I_{D1} + I_{D3} \tag{5}$$

Using (2) and (4), it obtains

$$I_{o1} = 2K\left(\left(\frac{I_A}{2K(-V_{SS} - 2V_T)}\right)^2 + \left(V_T + \frac{V_{SS}}{2}\right)^2\right) \tag{6}$$

It should notice that I_{o1} is squaring of I_A

C. *A Square-Rooting Circuit*

The simple square-rooting circuit can be realized from the current squarer formed by M_1 -M_3 and two current mirrors shown in Fig. 3

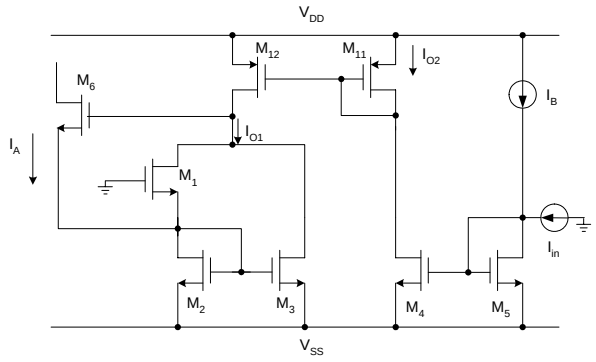

Fig.3. The simple square-rooting circuit.

The basic current-differencing amplifier makes use of a PMOS current mirror. The ratio of the PMOS current mirror consisting M_{11} and M_{12} is equal to 1:1, and The ratio of the NMOS current mirror consisting M_4 and M_5 is also equal to 1:1. I_A is input current of squaring circuit and also is output current of square-rooting circuit, I_{o1} is output current of the squaring circuit, and I_{o2} is sum of I_{in} and I_B. The CDA converts difference of I_{o1} and I_{o2} to be the voltage fed to gate terminal of M_6. The effect of negative feedback on CDA regulates the equilibrium of I_{o1} and I_{o2}

$$I_{o1} = I_{o2} \tag{7}$$

Using (6), it can be rewritten as

$$2K\left(\left(\frac{I_A}{2K(-V_{SS} - 2V_T)}\right)^2 + \left(V_T + \frac{V_{SS}}{2}\right)^2\right) = I_{in} + I_B \tag{8}$$

Define $$I_B = 2K\left(V_T + \frac{V_{SS}}{2}\right)^2 \tag{9}$$

The relation of I_A to I_{in} is

$$I_A = 2K(-V_{SS} - 2V_T)\sqrt{\frac{I_{in}}{2K}} \tag{10}$$

It should notice that I_A is square rooting of I_{in}. To design the circuit with no current sources and no grounded circuit node, the simple square-rooting circuit is improved as Fig. 4. The transistors M_7-M_{10} is used to generate I_B and the ratio of the current mirror consisting M_9 and M_{10} is equal to 1:2. In Fig. 4, the relation of I_o to I_{in} is

$$I_o = 2K(V_A - 2V_T)\sqrt{\frac{I_{in}}{2K}} \tag{11}$$

Where $$V_A = \frac{\left[V_{DD} - |V_{TP}| + V_{TN}\sqrt{\frac{K_N}{K_P}}\right]}{1 + \sqrt{\frac{K_N}{4K_P}}} \tag{12}$$

Defing $K = K_N$ and $V_T = V_{TN}$ are the transconductance and the threshold voltage of NMOS transistor respectively, and K_P and V_{TP} are the transconductance and the threshold voltage of PMOS transistor respectively. Remark M_1 and M_8 should be placed in separate well to eliminate body effect.

D. *Input Range*

Consider the circuit in Fig. 3 when $I_{in} = 0$, it find that $I_{D1} = \frac{I_B}{2}$ and $I_A = 0$. Then when $I_{in} > 0$, it find that

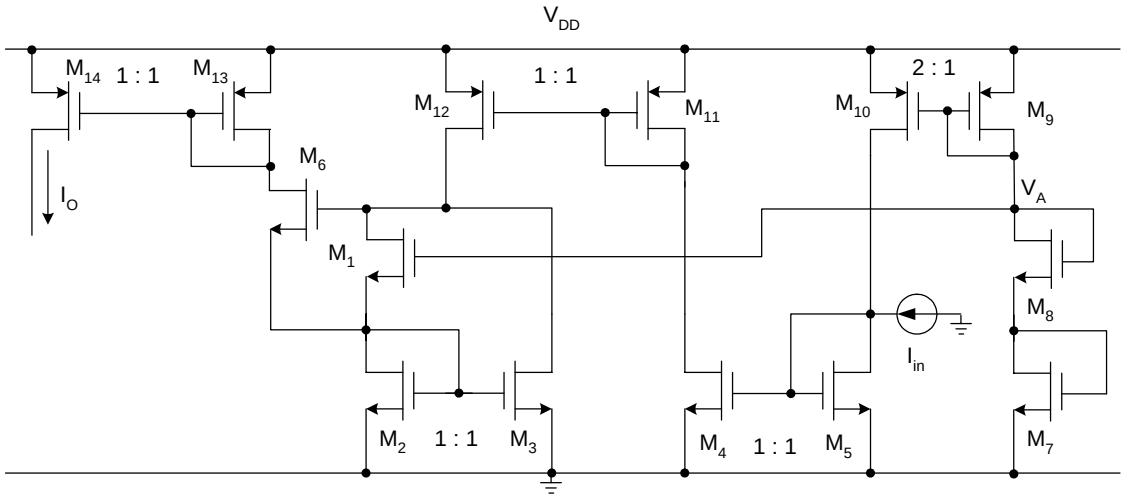

Fig.4. The completed square-rooting circuit.

$I_{D1} < \frac{I_B}{2}$ and $I_A > 0$. Where $I_{in(MAX)}$ or maximum input current, it find that $I_{D1} = 0$ and $I_{A(MAX)}$ or maximum output current is

$$I_{A(MAX)} = \frac{I_B}{2} \tag{13}$$

Using (9) and (10), the input range can be written as

$$0 < I_{in} < \frac{K(2V_T + V_{SS})^2}{8} \tag{14}$$

Consider the circuit in Fig. 4. The input range can be derived by using the same way as the circuit in Fig. 3, and it can be expressed as

$$0 < I_{in} < \frac{K(2V_T - V_A)^2}{8} \tag{15}$$

III. RESULTS

The simulation results have been done by PSpice using transistor model of MOSIS with level 3. The W/L ratio of NMOS transistors M_1 to M_8 is equal to 3μm/3μm, the W/L ratio of PMOS transistor M_9 is equal to 100μm/5μm, and the W/L ratio of others is equal to 200μm/5μm. The voltage supply is set to V_{DD} = 3 volts. The dc transfer characteristics of the proposed circuit is demonstrated in Fig. 5 when i_i is varied from 0_A to 25μA compared to ideal curve($= \frac{\sqrt{V_i}}{135}$). Fig. 6 shows relative error of Fig. 5. (%error=$\left|\frac{X_i - X_s}{X_i}\right| \times 100$ %, X_i is ideal value, X_s is simulated value) Fig. 7 shows the output current when i_i is triangular wave of peak amplitude 20μA.

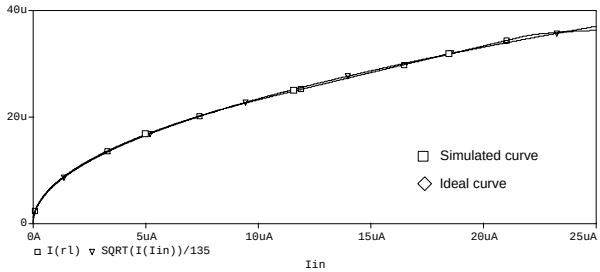

Fig. 5. The dc transfer characteristic of circuit in Fig. 4 compares with ideal curve ($= \frac{\sqrt{I_{in}}}{135}$)

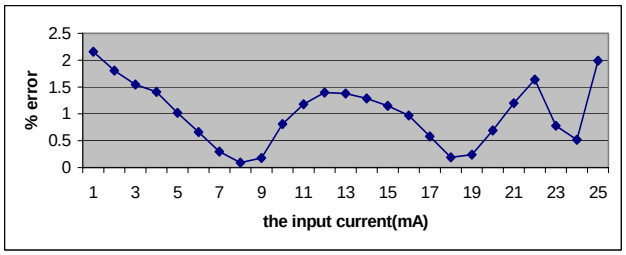

Fig. 6. the relative error of the result in Fig.5 .

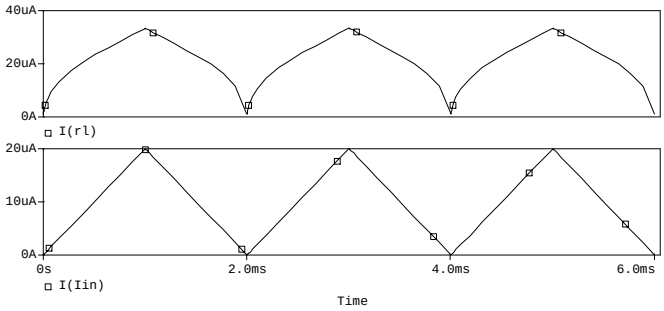

Fig. 7. Triangular wave response of circuit in Fig. 4
Upper trace output, lower trace input

The average of relative error of Fig. 6 is 1.007%. It is important to observe the no circuit node is connected to ground, so this circuit can operate on both a single supply and dual supplies.

The proposed circuit is tested experimentally by using commercial CMOS transistor arrays (CD4007) and the input current is constructed by the linear voltage to current conversion [11]. The voltage supply is set to V_{DD}=6.6 Volts. Fig. 8 shows the dc transfer characteristic when I_i is varied from 0_A to 300μA compared to ideal curve ($=0.2+\frac{\sqrt{i_i}}{1.7}$). Fig. 9 shows the output voltage waveform when I_i is triangular wave of peak amplitude 300μA at 10 kHz frequency and it accords to simulation results in Fig. 7.

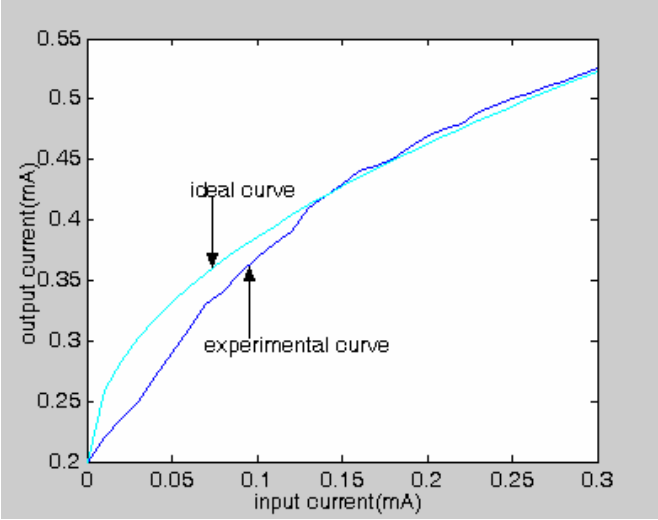

Fig. 8. The dc transfer characteristic

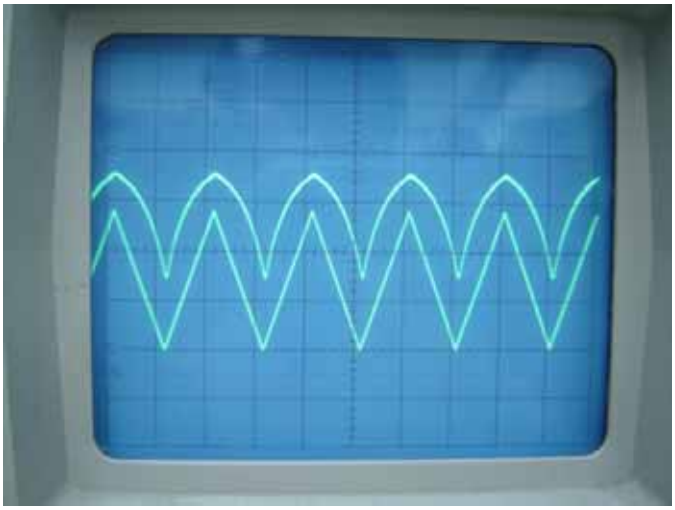

Fig. 9. The output waveform (upper trace) when I_i is triangular wave (lower trace)

Note that the output current of experimental result has dc offset current about 0.2 mA, it may occur from the mismatch problem of devices.

IV. CONCLUSION

A new square-rooting circuit has been presented in this paper. The realization method is based on the principle of negative feedback. This circuit can operate under low voltage supply, so it can be applied widely and is suitable for implementation in CMOS integrated circuit form. Simulation results are carried out by PSpice program. They find that the circuit can operate at 3_V voltage supply, the current input range is 20μA, the relative error is 1.007%, and the current output range is 35μA. Experimental results agree with simulated results.

B. Ultrasonic Signal Simulation

Ultrasonic signal can be modeled by gaussian function in Figure 2 and sine wave in Figure 3. $e(t)$ may be expressed in (2). F_0 is transducer center frequency. t is time. σ^2 is variance of gaussian function. t_0 is position of scatters in time domain. Figure 4 shows $e(t)$ at t_0 =2 μs. $h(t)$ is an impulse response of a scatter function used to convolute with $e(t)$ as described in (3).

$$e(t) = \exp[-2\pi^2\sigma^2(t-t_0)^2]\sin(2\pi F_0 t) \quad (2)$$

$$s(t) = e(t) * h(t) \quad (3)$$

For a medium of scatters, the echo signal $s(t)$ can be modeled in frequency domain as follows:

$$s(t) = e(t) * h(t) = \sum_M e(t) * h_a^2(M,t) * h_d(M,t) \quad (4)$$

where $h(t)$ is impulse response of scatters that relate to (5) and (6) in frequency domain. h_a^2 is the two ways impulse response of attenuation of a scatter in position M and $H_a^2(M,f)$ is frequency domain of h_a^2. $2Z$ is the total distance traveled by the ultrasound wave. $h_d(M,t)$ is a set of impulses in time domain that relate to position M in frequency domain as shown in (8). β is attenuation coefficient, which is estimated from FCS.

$$S(f) = E(f) \cdot H(f) \quad (5)$$

$$S(f) = \sum_M E(f) \cdot H_a^2(M,f) \cdot H_d(M,f) \quad (6)$$

$$H_a^2(M,f) = e^{-2Z\beta f} \quad (7)$$

$$H_d(M,f) = \delta(Z) \quad (8)$$

h_d is the scattering impulse function simulated by Dirac function. The position Z of a scatter is determined with function of object modeled. In this paper, two positions of Dirac function are utilized according to experimental system.

$$h_d(f,Z) = \delta(Z) \quad (9)$$

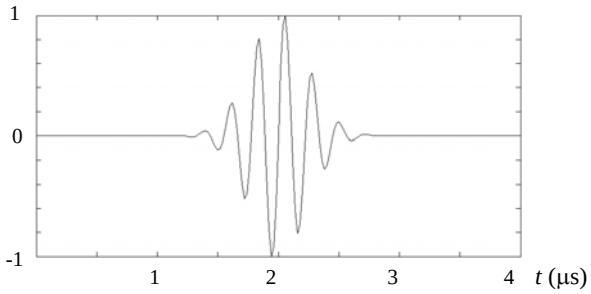

Figure 4. $e(t)$ function

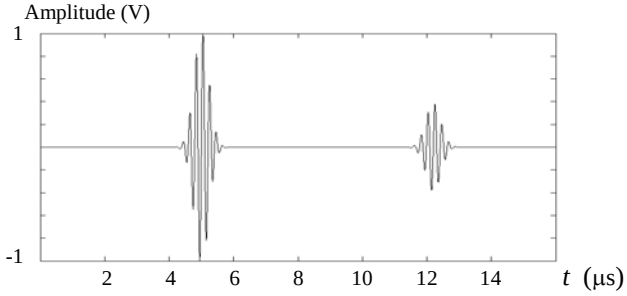

Figure 5. Ultrasonic simulation signal

TABLE II
ATTENUATION OF TISSUE AT 1 MHZ [5]

Tissue	Characteristic Impedance $\rho_0 c$ (10^6Ns/m^3)	Attenuation at 1 MHz (dB/cm)
Blood	1-62	0.2
Spleen	1-6	0.4
Liver	1-65	0.7
Fat	1-38	0.8
Brain	1-60	0.8
Muscle	1.65-1.74	1.5-2.5
Bone	3.2-7.4	11
Lung	0.26-0.46	40
(Water)	1.49	0.002

III. Fourier Centroid Shift Method

FCS is one of strategies in Fourier statistics method that depends on the spectral moment estimation. The spectral centroid $f_c(\tau_i)$ at spectral amplitude $|S(f)|$ as expressed in (10).

$$f_{c(\tau_i)} = \frac{m_1(\tau_i)}{m_0(\tau_i)} \tag{10}$$

m_j is moment of order j defined by (11). τ_i is position of the window on the echo line.

$$m_{j(\tau_i)} = \int_{-\infty}^{+\infty} f^j \cdot S(\tau_i, f) \cdot df \tag{11}$$

With the classical assumption of linear with frequency attenuation, $\alpha(f)$ is attenuation expressed in dB/cm and β is the attenuation coefficient expressed in dB/cmMHz. The relation between $\alpha(f)$ and β can be described in (12).

$$\alpha(f) = \beta \cdot f \tag{12}$$

An estimation of attenuation coefficient can be obtained by (13). σ^2 is variance of spectrum that can be calculated by (14). Additionally, the moment order 0 to 2 is used to obtain σ^2. C is ultrasonic longitudinal velocity. Equation (15) expresses unit conversion from Neper to dB.

$$\beta = \frac{-8.68}{C\sigma^2(\tau)} \cdot \frac{df_c}{d\tau} \tag{13}$$

$$\sigma^2(\tau_i) = \frac{m_2(\tau_i)}{m_0(\tau_i)} - \left(\frac{m_1(\tau_i)}{m_0(\tau_i)}\right)^2 \tag{14}$$

$$\beta\,[\text{dB/cmMHz}] = 8.68 \cdot \beta\,[\text{Neper/cmMHz}] \tag{15}$$

IV. Numerical Simulation

According to ultrasonic transducer, 5 MHz of center frequency is selected to simulate ultrasonic signal with attenuation coefficient of brass = 0.50dB/cmMHz [6] as shown in Figure (6). The difference of time corresponds to Z=2.5 cm at c=4.430 mm/μs as described in Table I.

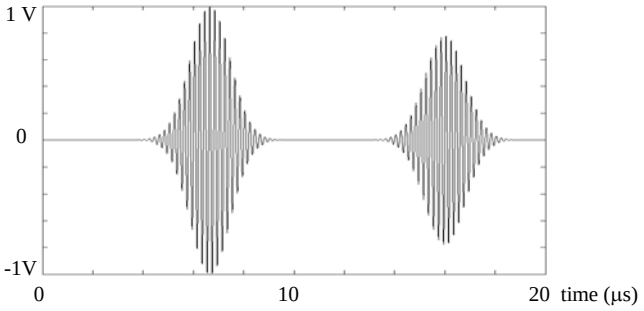

Figure 6. Simulation of Ultrasonic signal at 5 MHz

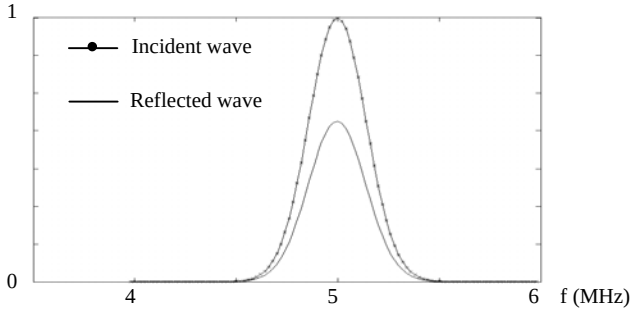

Figure 7. Spectrum of incident wave and reflected wave

From Figure 7, the attenuation coefficient is solved to verify the FCS that described in previous section. The result of β in simulation is 0.50 dB/cmMHz same as [6]. Additionally, other β value at 1 MHz and 5 MHz are tested as shown in Table IV.

TABLE IV

Attenuation Coefficients computed by Simulated Signal

β (dB/cmMHz)	Fourier Centroid Shift Method	
	1 MHz	5 MHz
0.1	0.1124	0.1001
0.3	0.3032	0.2998
0.5	0.5004	0.4997
0.7	0.7000	0.6995
1.0	1.0000	0.9993
1.5	1.5000	1.4989
2.0	2.0000	1.9986
3.0	3.0000	2.9978

TABLE V

Error of Attenuation Coefficients computed by Simulated Signal

β (dB/cmMHz)	Error (%)	
	1 MHz	5 MHz
0.1	12.4000	0.1000
0.3	1.0667	0.0667
0.5	0.0800	0.0600
0.7	0.0000	0.0714

V. Experimental Validation

TABLE III

Instrument and Device used in Experimentation

Instrument/Device	Model
Pulse Generator	Panamatrics: Model500PR
Digital Scope	Tektronix: TDS3012
Ultrasonic Transducer	Panamatrics: Model V309

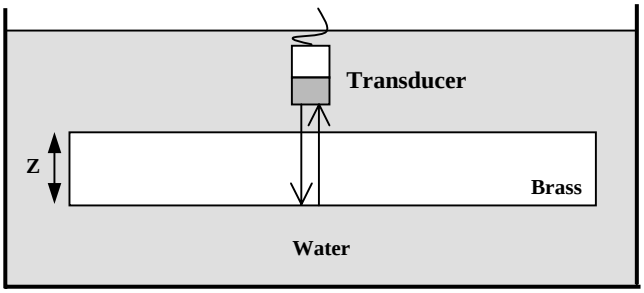

Figure 8. Ultrasonic simulation signal

The experimentation is built up as shown in Figure 8. The metal, brass, is immersed in Plexiglas water tank. Furthermore, the ultrasonic transducer is located at the top of water tank and linked to digital oscilloscope. The instruments and devices as shown in Table III are setup to obtain an ultrasonic signal. Ultrasonic pulse generator and transducer are selected in same manufacturer, Panamatrics. The reflection mode is selected to measure the ultrasonic signal. The echo signal from transducer is digitized with digital oscilloscope and sent as a digital data set to personal computer by GPIB cable. The ultrasonic signal, $s(t)$, is digitized with a sampling interval $\Delta t = 1/F_s$ (F_s is the sampling frequency = 500 MHz), in 10,000 samples. Figure 9 displays a captured signal. The digitized data is computed to obtain β by FCS algorithm. The peaks of spectrum at 5 MHz correspond to transducer center frequency used. The spectrum of measured signal is displayed in Figure 10. So, β of measured signal is 0.4415 dB/cmMHz. The error calculated by (15) of β between simulation and experimentation is approximately 11%.

VI. Conclusion

A FCS method for estimation of ultrasonic attenuation coefficients has been developed. The FCS algorithm is tested by ultrasonic simulation signal. The method has been established on the basis of spectrum in frequency domain that is used to calculate the echoes from the front and back surfaces of the immersed metal. To validate the model, the experimentation has been setup. The 5MHz ultrasonic transducer and brass are selected and immersed in Plexiglas water tank. The data is acquired and computed by FCS algorithm. The result show that β from simulated signal is 0.50 dB/cmMHz while β from experimentation is 0.4415 dB/cmMHz. The error is around 11% because this work omits the ultrasonic diffraction phenomenon. However, the result in simulation and experimentation is satisfied. To reduce an error, the Lommel diffraction correction method [7] will be compensated in future work.

Abstract— **A compact class-AB variable gain amplifier has been proposed. The amplifier structure is based on two-stage architecture comprising a linear transconductor cascaded by a current amplifier-based feedback transimpedance amplifier. The major advantage of such VGA circuit is its ability to offer a good degree of signal linearity without sacrificing the original advantages of its predecessor on both aspects of the power consumption and circuit complexity. Superiority of the proposed VGA has been confirmed by circuit simulation employing 0.18μm standard CMOS technology in designing a 50-MHz VGA under 1V supply voltage draining static power consumption less than 60μW.**

I. INTRODUCTION

Variable gain amplifier (VGA) is an important building block that is used to maximize the dynamic range of the overall system in many applications [1], [2], [3], In communication receiver, VGA is typically employed in a feedback loop to realize an automatic gain control (AGC), to provide constant signal power to baseband analog-to-digital converter (ADC) for unpredictable received signal strengths. The voltage gain of the VGA is controlled by the AGC loop, and a linear-indB gain control characteristic is usually desired to obtain constant settling time of the AGC loop [4]. In addition, VGA is generally required to maintain high linearity and low noise over the entire bandwidth and gain range. It is also important that the bandwidth of the amplifier remains constant when the voltage gain is varied and this can be obtained by employing current-mode techniques [5].

In portable communication devices, VGA, as well as other circuits, are required to operate with low power supply voltage and low power consumption. As the process technologies develop, the maximum allowable supply voltage will scale down. It is inevitable that most low power integrated circuits will have to operate with power supply voltages between 1 V to 1.5 V. It is very challenging to design a VGA with high linearity and wide bandwidth with low supply voltage and low power consumption.

Recently, a compact low supply voltage and low power consumption VGA in [6] has been designed to achieve high linearity and wide bandwidth with acceptable power dissipation. However, since its operation is limited at class-A amplifier, signal swing is small compared to class-AB amplifier. This paper presents an improved VGA to the circuit in [6]. It will be shown that the proposed circuit operates in class-AB manner outperforms its predecessor (class-A), especially, in terms of signal swing and linearity while maintaining the same static power consumption and silicon area.

II. TWO-STAGE CURRENT-MODE VARIABLE GAIN AMPLIFIER

The recently proposed VGA in [6], [7] has shown its versatility and potential to operate at low supply voltage, low power consumption with high bandwidth while maintaining good degree of dynamic range and occupying small silicon area. This VGA's architecture is presented in Fig. 1a, which is a cascade of a linear transconductor cascaded and a linear transimpedance amplifier with shunt-feedback resistors (Rf). This allows constant bandwidth when varying the voltage gain. The voltage gain of the VGA circuit is the product of the transconductance gain (Gm) and the transimpedance gain (R_m). The transimpedance gain is given by

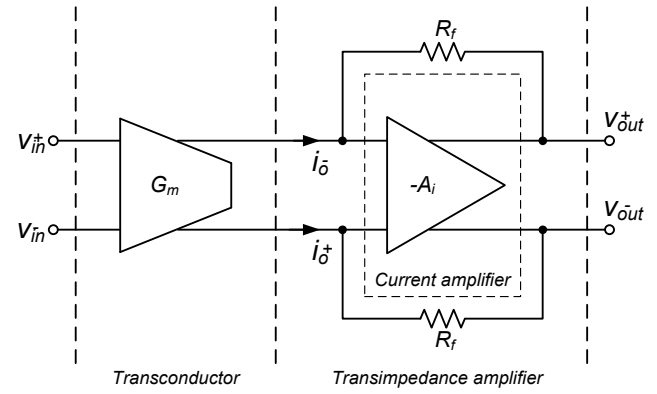
$$R_m = -\left(\frac{R_f A_i - R_{in}}{1 + A_i}\right) \tag{1}$$

where Rin and Ai, respectively, are the input resistance and the current gain of the current amplifier. Note that, when Ai >> 1, we have $R_m \approx -R_f$. There a linear Gm and a high-gain current amplifier are required to realize a high-linearity VGA.

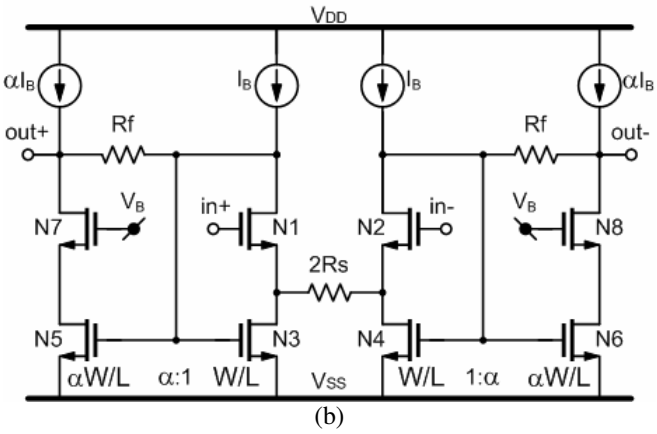
The proposed VGA circuit realization in CMOS is also depicted in Fig. 1b. The circuit is very compact; it however possesses a major limitation at which the output current signal

This work has been financially supported by Thailand Research Fund (under grant no. RSA4680027).

swing is restricted by constant current sources, i.e. the VGA operates in a class-A manner. This would prohibit the VGA to achieve a rail-to-rail output voltage swing.



(a)



(b)

Fig. 1 VGA proposed in [6], [7] (a) architecture (b) circuit realisation with CMOS.

III. PROPOSED CLASS-AB VARIABLE GAIN AMPLIFIER

An improved VGA based on the architecture of Fig. 1a is presented in Fig. 2. The transconductor stage (N1 – N2, Rs) utilizes source degeneration technique without any constant current sources in order to maximum transconductance/bias current efficiency and minimize supply voltage and noise [8]. Despite these advantages, such structure possesses a serious drawback in being unable to reject common-mode signal. The second stage mirror-based current amplifier (P1 – P6, N3 – N6) resolves this problem by employing feedforward technique that allows differential signals to be constructively combined while on the other hand cancel a common-mode signal [9, 10]. This current amplifier combined with feedback resistors Rs form a transimpedance amplifier necessary for current-to-voltage conversion. Moreover, such output stage also provides a class-AB operation allowing larger signal swing compared to its predecessor presented in [6], [7]. Thus the major advantage of such VGA circuit is its ability to offer excellent signal linearity without sacrificing the original advantages on both aspects of the power consumption and circuit complexity.

A small-signal transconductance of the first stage is simply expressed as

$$G_m = \frac{g_m}{1 + g_m R_S + sR_S C_{gs}} \tag{2}$$

where gm and Cgs are respectively transconductance and gate-source capacitance of N1 and N2. The amplifier differential current gain A_i and input resistance R_{in} have been analysed to be

$$A_i = \frac{g_{mx}}{(g_{mi} + sC_x)}\left(1 + \frac{g_{my}}{g_{my} + sC_y}\right) \tag{3}$$

and

$$R_{in} = \frac{1}{g_{mi} + sC_x} \tag{4}$$

where g_{mi}, g_{mx} and g_{my} are transconductance of P1 – P2, P3 – P6 and N3 – N6 respectively. The parameters C_x and C_y are equivalent total capacitance (referred to ground) at gates of P1 (P2) and N3 (N4) whose values are mainly contributed from gate-source capacitance. At low frequency, since $g_{mx} = g_{mi}(\alpha/2)$, thus Ai of Fig. 2 equals to α, which is the same as what obtained from the original circuit in Fig. 1b. Thus, by substituting (3) and (4) into (1), a small-signal transimpedance gain could be obtained to be

$$R_m = -\frac{\alpha\left[2R_f - \frac{1}{g_{mx}} + s\frac{C_y}{g_{my}}\left(R_f - \frac{1}{g_{mx}}\right)\right]}{2\left[1 + \alpha + s\left(\frac{C_y}{g_{my}}\left(1 + \frac{\alpha}{2}\right) + \frac{C_x}{g_{mi}}\right) + s^2\frac{C_x C_y}{g_{mi} g_{my}}\right]} \tag{5}$$

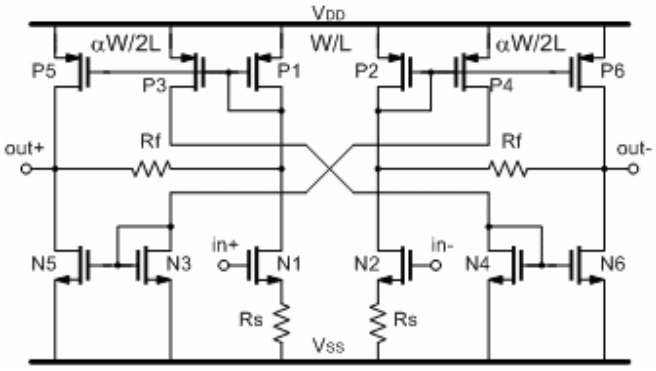


Fig. 2 Improved VGA based on the structure in Fig. 1a with class-AB output stage and signal feedforward topology.

The feedback resistor Rf is selected to set a voltage gain range whereas a source degeneration resistor Rs is tuned to vary the amplifier gain. The minimum value of Rs sets the maximum gain for a specific gain range (as previously set by Rf) and it also defines the maximum static current consumed by the VGA. The similar technique proposed in [8] can be used to tune the grounded resistor Rs.

IV. SIMULATION RESULTS

The improved VGA circuit was designed to operate with a single 1V power supply voltage. The circuit was simulated by using Spectre employing a 0.18-µm standard CMOS technology where device threshold voltages were 0.49V and -0.46V for NMOS and PMOS respectively. With $\alpha = 5$, transistor sizing of the VGA circuit in Fig. 2 is listed in Table I. The minimum value of Rs is chosen to be 500 Ohms to ensure a maximum current consumption not exceeding 60µA for a bandwidth over 50MHz.

Table I: Transistor sizing within the VGA operating under a 1V supply voltage.

Transistors	W/L (um/um)
N1 – N2	1.5/0.18
P1 – P2	10/0.5
P3 – P6	25/0.5
N3 – N6	5/0.5

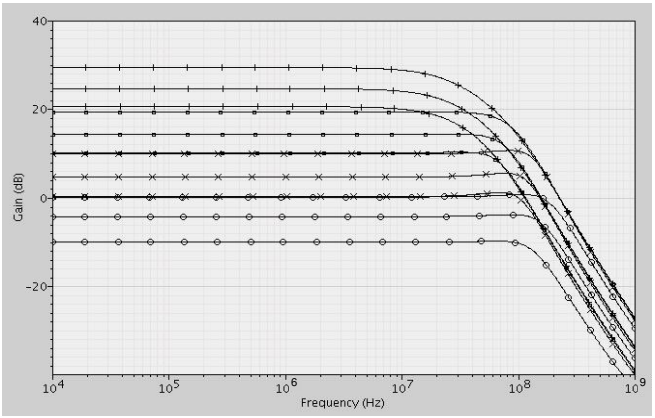

Fig. 3 Frequency response of the VGA where Rf: 500kΩ, 150kΩ, 50kΩ, 15kΩ and Rs: 500Ω – 15kΩ.

It is vital to see how the proposed VGA perform compared to the original VGA circuit of [6], [7] using the same design process. The proposed VGA and its counterpart class-A circuit have been designed under the same power supply voltage of 1V with identical static power and occupy same silicon area. By using a periodic steady-state analysis within Cadence IC design platform, Fig. 4 show simulated output signal swing and total harmonic distortion (THD) compared between two VGA circuits at the same voltage gain of 20dB where we can see that the linearity improvement of over 13dB can be achieved. The THD improvement at various gain values for differential output amplitude of -10dBVp at 1MHz and at other frequencies are depicted in Fig. 5. Other performances are summarized in Table II indicating that the proposed VGA is more superior specifically in terms of linearity.

(b)

Fig. 5 THD improvement vs (a) gain at 1MHz, and (b) frequency for gain = 20dB (for output level at -10dBVp in both cases).

Table II: VGA performance comparison.

Parameters	This work	Circuit in [11]
Supply voltage	1V	
Technology	0.18μm CMOS (V_{TP} = -0.46V, V_{TN} = 0.49V)	
Power consumtion (static)	≤ 60μW	60μW
Bandwidth	~ 50MHz	~ 50MHz
Input-referred noise (gain = 20dB)	8.0×10^{-8} V^2	9.4×10^{-8} V^2
Differential output signal swing for -40dB THD	0.76Vp	0.33Vp
THD improvement	> 13dB	-
Gain range at constant bandwidth	25dB	23dB

V. CONCLUSION

A compact class-AB variable gain amplifier has been proposed. The amplifier structure is based on two-stage architecture comprising a linear transconductor cascaded by a current amplifier-based feedback transimpedance amplifier. The major advantage of such VGA circuit is its ability to offer a good degree of signal linearity without sacrificing the original advantages of its predecessor on both aspects of the power consumption and circuit complexity. Superiority of the proposed VGA has been confirmed by circuit simulation employing 0.18μm standard CMOS technology in designing a 50MHz VGA under 1V supply voltage draining static power consumption less than 60μW.

***Abstract*- A novel circuit for realizing floating inductance, floating capacitance, floating frequency dependent negative resistance (FDNR) and grounded to floating admittance converter depending on the passive component selection is proposed in this paper. The proposed simulator employs second-generation current conveyors (CCIIs), differential voltage current conveyor (DVCC) and only grounded passive elements. The non-ideal current and voltage gains as well as parasitic impedance effects on the proposed circuit are investigated. Also, simulation results using PSPICE program are given for the introduced floating simulator to verify the theory and to exhibit the performances of the circuit.**

***Index Terms*- CCII, Capacitor, DVCC, FDNR, Inductor.**

I. INTRODUCTION

Recently, a simulated immittance has become a standard research topic since it can be applied in areas like oscillator design, active filters and cancellation of parasitic elements [1]. The advent of integrated circuits has encouraged the design of synthetic inductances, which can be used instead of the bulky inductors in passive filters. Although it is difficult to implement inductors and floating capacitors in the integrated circuits, several published circuits [2-15] employing different high-performance active building blocks. The circuits given in [2–7] can realize floating inductor employing a grounded capacitor but the circuits [3–6] can realize floating FDNR employing floating capacitors, at least one of two capacitors is floating, which is not convenient to further fabricate in IC. Also, some circuits introduced in the literature can realize floating FDNR [10–15] and some of the circuits reported in the literature can realize floating capacitor [8-9]. The proposed circuit in [7] needs for passive element matching

As a result, a circuit for the simulation of a floating inductance, capacitance, FDNR and grounded to floating admittance converter depending on the passive element choice is presented. The proposed circuit consists of CCIIs and DVCC as active components. In addition, the proposed circuit employs two to three grounded resistors and one to two grounded capacitors as passive components. The circuit can realize a lossless floating inductance and capacitance, and can convert the grounded admittance into the corresponding floating admittance without changing the original topology. Furthermore, the effects of non-ideal gains on the proposed simulator are considered. The PSPICE simulation results are also shown, which are in correspondence with the theoretical analysis.

II. PRINCIPLE AND OPERATION

A. The Differential Voltage Current Conveyor (DVCC)

The DVCC, whose electrical symbol and equivalent circuit are shown in Fig. 1, is a four-terminal network with the terminal ideal characteristics described by following equation

$$\begin{bmatrix} V_X \\ I_{Y1} \\ I_{Y2} \\ I_Z \end{bmatrix} = \begin{bmatrix} 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} I_X \\ V_{Y1} \\ V_{Y2} \\ V_Z \end{bmatrix}. \quad (1)$$

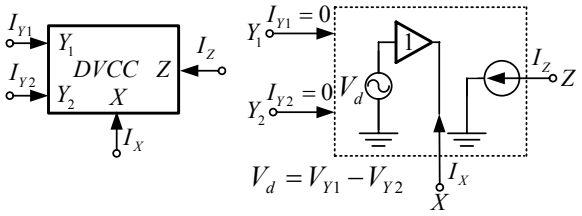

Figure 1. The DVCC (a) Symbol (b) Equivalent circuit

B. The Second Generation Current Conveyor (CCII)

The characteristics of ideal CCII are represented by the following hybrid matrix

$$\begin{bmatrix} I_Y \\ V_X \\ I_Z \end{bmatrix} = \begin{bmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & \pm 1 & 0 \end{bmatrix} \begin{bmatrix} V_Y \\ I_X \\ V_Z \end{bmatrix}. \quad (2)$$

The symbol and the equivalent circuit of the CCCII are illustrated in Fig. 2(a) and (b), respectively.

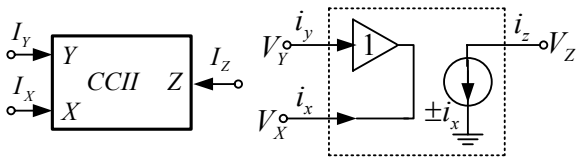

Figure 2. The CCII (a) Symbol (b) Equivalent circuit

C. Proposed floating simulator

The proposed floating simulator is shown in Fig. 3. Straightforwardly analyzing circuit in Fig. 3, it gives the following short circuit admittance matrix

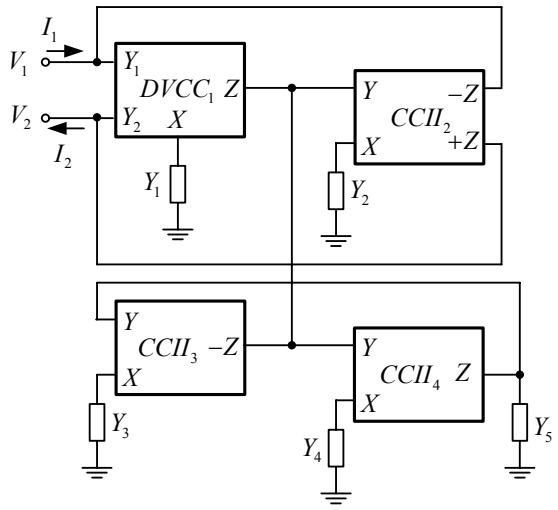

Figure 3. Proposed floating simulator

$$[Y]=\frac{Y_1Y_2Y_5}{Y_3Y_4}\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}. \tag{3}$$

For the proposed circuit, the following passive elements are chosen to achieve floating inductance, capacitance, FDNR and admittance converter, as following explained.

a) If $Y_1=sC_1, Y_2=G_2, Y_3=G_3, Y_4=G_4$ and $Y_5=G_5$ are taken for the circuit in Fig.1, the short circuit admittance matrix of the floating capacitance simulator is obtained as

$$[Y_C]=\frac{sC_1G_2G_5}{G_3G_4}\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}=sC_{eq}\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}. \tag{4}$$

Hence, $C_{eq}=C_1G_2G_5/G_3G_4$.

b) If $Y_1=G_1, Y_2=sC_2, Y_3=G_3, Y_4=G_4$ and $Y_5=G_5$ are chosen, the short circuit admittance matrix of the floating capacitance simulator is found to be

$$[Y_C]=\frac{sC_2G_1G_5}{G_3G_4}\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}=sC_{eq}\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}. \tag{5}$$

Hence, $C_{eq}=C_2G_1G_5/G_3G_4$.

c) If $Y_1=G_1, Y_2=G_2, Y_3=sC_3, Y_4=G_4$ and $Y_5=G_5$ are obtained, the short circuit admittance matrix of the floating inductance simulator is found to be

$$[Y_L]=\frac{G_1G_2G_5}{sC_3G_4}\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}=\frac{1}{sL_{eq}}\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}. \tag{6}$$

Hence, $L_{eq}=C_3G_4/G_1G_2G_5$.

d) If $Y_1=G_1, Y_2=G_2, Y_3=G_3, Y_4=sC_4$ and $Y_5=G_5$ are achieved, the short circuit admittance matrix of the floating inductance simulator is found to be

$$[Y_L]=\frac{G_1G_2G_5}{sC_4G_3}\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}=\frac{1}{sL_{eq}}\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}. \tag{7}$$

Hence, $L_{eq}=C_4G_3/G_1G_2G_5$.

e) If $Y_1=G_1, Y_2=G_2, Y_3=G_3, Y_4=G_4$ and $Y_5=y(s)$ are taken, the short circuit admittance matrix of grounded to floating admittance converter is calculated as

$$[Y_C]=\frac{G_1G_2}{G_3G_4}y(s)\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}=ay(s)\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}. \tag{8}$$

Thus, $a=G_1G_2/G_3G_4$ is defined as a multiplier, and $y(s)$ is the grounded admittance.

f) If $Y_1=sC_1, Y_2=sC_2, Y_3=G_3, Y_4=G_4$ and $Y_5=G_5$ are taken, the short circuit admittance matrix of the FDNR is found to be

$$[Y_D]=\frac{s^2C_1C_2G_5}{G_4G_3}\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}=s^2D_d\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}. \tag{9}$$

Consequently, $D_d=C_1C_2G_5/G_4G_3$ is obtained. As the frequency increases, the absolute value of negative resistance decreases.

g) If $Y_1=G_1, Y_2=G_2, Y_3=sC_3, Y_4=sC_4$ and $Y_5=G_5$ are taken, the short circuit admittance matrix of the FDNR is found to be

$$[Y_D]=\frac{G_1G_2G_5}{s^2C_4C_3}\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}=\frac{D_i}{s^2}\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}. \tag{10}$$

Consequently, $D_i=G_1G_2G_5/C_4C_3$ is obtained. As the frequency increases, the absolute value of negative resistance also increases.

D. Non-ideal case

For non-ideal case, the DVCC can be respectively characterized with the following equations

$$I_{Y11}=I_{Y12}=0, \tag{11a}$$
$$V_X=\beta_{11}V_{Y1}-\beta_{12}V_{Y2}, \tag{11b}$$
$$I_Z=\alpha I_X, \tag{11c}$$

While then non-idea of CCII can be respectively presented with the following equations

$$I_Y=0, \tag{12a}$$
$$V_X=\beta V_Y, \tag{12b}$$
$$I_Z=\alpha I_X, \tag{12c}$$
$$I_{Z-}=-\gamma I_X. \tag{12d}$$

α and γ are the frequency dependent current gains besides β_i is the frequency dependent voltage gain. These gains are ideally equal to unity. In practice, they depend on the frequency of operation, temperature and transistor parameters of the DVCC and CCII.

In the case of non-idea, the short matrix in Eq. (3) is converted to

$$[Y]=\frac{Y_1Y_2Y_5}{Y_3Y_4}\frac{\alpha_1\beta_2}{\alpha_3\alpha_4\beta_3\beta_4}\begin{bmatrix}\gamma_2\beta_{11} & -\gamma_2\beta_{12}\\ -\alpha_2\beta_{11} & \alpha_2\beta_{12}\end{bmatrix}. \quad (13)$$

If parasitic resistances (R_X in series ideally equal to zero, $R_Y=1/G_Y$ and $R_Z=1/G_Z$ in parallel ideally equal to infinity) and parasitic capacitances (C_Y and C_Z in parallel ideally equal to zero) affecting the impedance of the circuit in Fig. 3 are considered, the following equations are obtained

- Second port is grounded

$$Z_{in1}=\frac{V_1}{I_1}=\frac{1}{sC_{Y11}+G_{Y11}}//Z_L. \quad (14)$$

Hence,

$$Z_L=\frac{(sC_A+G_A)+\left(\frac{1}{sC_B+Y_5+G_B}\right)\left(\frac{Y_4}{1+R_{X4}Y_4}\right)\left(\frac{Y_3}{1+R_{X3}Y_3}\right)}{\left(\frac{Y_1}{1+R_{X1}Y_1}\right)\left(\frac{Y_2}{1+R_{X2}Y_2}\right)}. \quad (15)$$

Where $C_A=C_{Y2}+C_{Y4}+C_{Z1}+C_{Z3}$,
$G_A=G_{Y2}+G_{Y4}+G_{Z1}+G_{Z3}$, $C_B=C_{Y3}+C_{Z4}$ and
$G_B=G_{Y3}+G_{Z4}$.

- First port is grounded

$$Z_{in2}=\frac{V_2}{I_2}=\frac{1}{sC_{Y12}+G_{Y12}}//Z_L. \quad (16)$$

Also, if $Z_{P1}=1/(sC_{Y11}+G_{Y11})$ and $Z_{P2}=1/(sC_{Y12}+G_{Y12})$ are defined, the short circuit admittance matrix in Eq. (3) turns to

$$[Y]=\begin{bmatrix}\frac{1}{Z_{p1}//Z_L} & -\frac{1}{Z_L}\\ -\frac{1}{Z_L} & \frac{1}{Z_{p2}//Z_L}\end{bmatrix}. \quad (17)$$

Note that the term $1/(sC_{Y11}+G_{Y11})$ and $1/(sC_{Y12}+G_{Y12})$ in Eqs. (14) and (16) are effected at very high frequency. There are also high and low frequency limitations depending on the passive element selection.

If $Y_1=G_1, Y_2=G_2, Y_3=sC_3, Y_4=sC_4$ and $Y_5=G_5$ are taken for the circuit in Fig.1 as the case d), the first developed circuit has limitations at low frequencies due to terms $1+R_{X3}sC_3$, $1+R_{X4}sC_4$, $s(C_{Y2}+C_{Y4}+C_{Z1}+C_{Z3})+G_{Y2}+G_{Y4}+G_{Z1}+G_{Z3}$ and $s(C_{Y3}+C_{Z4})+G_5+G_{Y3}+G_{Z4}$ as given in Eq.(15) thus the limit at low frequencies is found as

$$f\gg\frac{1}{2\pi}\max\left(\frac{G_{Y2}+G_{Y4}+G_{Z1}+G_{Z3}}{C_{Y2}+C_{Y4}+C_{Z1}+C_{Z3}},\frac{G_5+G_{Y3}+G_{Z4}}{C_{Y3}+C_{Z4}},\frac{1}{C_3R_{X3}},\frac{1}{C_4R_{X4}}\right). \quad (18)$$

As it is seen from Eqn. (18), C_3 and C_4 should be chosen large in order to decrease the limit at low frequencies.

If $Y_1=sC_1, Y_2=sC_2, Y_3=G_3, Y_4=G_4$ and $Y_5=sC_5$ are taken for the circuit in Fig.1, the circuit has limitations at high frequencies due to terms $1+R_{X1}sC_1, 1+R_{X2}sC_2$ $s(C_{Y2}+C_{Y4}+C_{Z1}+C_{Z3})+G_{Y2}+G_{Y4}+G_{Z1}+G_{Z3}$ and $s(C_{Y3}+C_{Z4}+C_5)+G_{Y3}+G_{Z4}$ as given in Eq. (15) thus the limit at high frequencies is found as

$$f\ll\frac{1}{2\pi}\min\left(\frac{G_{Y2}+G_{Y4}+G_{Z1}+G_{Z3}}{C_{Y2}+C_{Y4}+C_{Z1}+C_{Z3}},\frac{G_{Y3}+G_{Z4}}{C_5+C_{Y3}+C_{Z4}},\frac{1}{C_1R_{X1}},\frac{1}{C_2R_{X2}}\right). \quad (19)$$

As seen from Eq. (19), C_1, C_2 and C_5 should be chosen as small as possible in order to increase the high frequency performance.

(b)

Figure 4. Internal construction of (a) CCII (b) DVCC

III. Simulation Results

To prove the performances of the proposed circuit, the PSPICE simulation program was used for the examination. The PNP and NPN transistors employed in the proposed circuit were simulated by respectively using the parameters of the PR200N and NR200N bipolar transistors of ALA400 transistor array from AT&T [16] with ±1.5V supply voltages and $I_B=200\mu A$. Fig. 4 depicts schematic descriptions of the CCII and DVCC used in the simulations. Phase and magnitude responses for the impedances of the proposed circuit in Fig. 3 are given in Fig. 5 where the second port of the floating inductor is grounded. There can be seen that, in case of (a) and (b), the useful frequency ranges are about 1kHz to 3MHz and approximately 10kHz to 1MHz, in case of (c) and (d).

In order to show the frequency domain performance of the proposed circuit, the second-order band-pass filter example in

Fig. 6 was simulated with PSPICE program. $G_1=G_2=G_4=G_5=1mS$ and $C_3=1nF$ are chosen to obtain inductance value of $1mH$. Furthermore, $G_2=G_3=G_4=G_5=1mS$ and $C_1=1nF$ are taken to obtain capacitance of $1nF$. Both of the ideal and simulated bandpass (V_o/V_{in}) filter responses is depicted in Fig. 7. The maximum power dissipation is about 20.09mW.

IV. CONCLUSION

A novel circuit which can simulate floating inductance, floating capacitance, floating admittance and floating FDNR employing CCIIs and DVCC has been proposed. The presented circuit requires no critical component matching constraints, and employs only grounded passive components so it is easy to fabricate the proposed circuit in a fully integrated circuit technology. Under non-ideal considerations, the presented circuit is still lossless synthetic inductor or capacitor. The simulation results agree well with the theoretical calculations.

***Abstract*— This paper presents the application of the active and passive electromagnetic interference (EMI) filters in order to solve practical problems and improve the passive EMI filter performance. First, the basic active filter topologies are discussed and the basis of discussion is based on an equivalent circuit model, which includes the possible combinations of the desirable attributes. Next, a simplified active input EMI filter (AIEF) is proposed, and a large common-mode (CM) inductor of passive EMI filter is replaced by small passive components and an active circuit. A prototype of AIEF verifies the effectiveness and validity with an induction motor drive and ac motor. The CM noise is analyzed using high-frequency (HF) current probe. Finally, the proposed circuit effectiveness is verified by experimental results.**

I. INTRODUCTION

Nowadays, the broader use of power electronic based loads (rectifiers, inverter, motor control systems, etc) has led to a growth of power pollution and conducted electromagnetic emissions also have been produced because of the nonlinear voltage or current characteristics of these loads. So that, there are many researches on passive EMI filters have been done. But the size, cost and performance of EMI filter components are also important considerations in power application. With this reason, there have recently many articles of active common-mode or current ripple cancellation provides alternative approaches to the problem [1-6].

The high-speed switching devices such as IGBT's have enabled to increase a carrier frequency of voltage-source of PWM inverters, thus leading to much better operating characteristics. However, high-speed switching can accompany the serious problems from a steep change in voltage or current such as: ground current escaping to earth through stray capacitors inside motors, conducted and radiated EMI and bearing current and shaft voltage [5, 6]. Consequently, many practical forms of active cancellation circuits have been reported in recently with the same operation. The general topologies of possible active EMI filters have been introduced in [3]. The nullification process was established to classify the basic noise cancellation methods and the insertion loss analysis of active EMI filters are introduced in [4]. They mainly focused on active filters that mitigate the common-mode EMI caused by a switched mode power supply.

In this paper, a simplified active input EMI filter is introduced in order to mitigate the conducted common-mode EMI. It can provide the sufficient attenuation under the limited LC products. The PWM inverter fed ac motor drive system included motors, ac drive system (front-end single-phase diode-bridge rectifier and PWM inverter system) leads, and other possible units that are using to develop a complete motor system. The analysis and experimental results is given, respectively.

II. BASIC ANALYSIS OF ACTIVE FILTER

Generalized topologies are identified by grouping combinations of passive elements with ideal active elements to construct filter varying complexity. A typical passive EMI filter and configuration is shown in Fig. 1 and consisted of CM choke, C_y capacitors, DM choke and C_x capacitor. A good performance filter normally has a CM choke with few mH and CM capacitors are limited by safety considerations for ground leakage current that can calculate by equation (1).

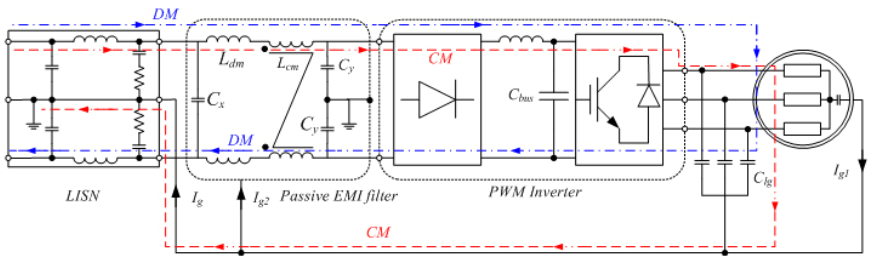

Figure 1. Typical passive EMI filter and PWM inverter system configuration.

The DM choke has lower value (typically < 1 mH) and sometime is used by the few percent leakage inductance of CM choke.

$$C_y = \frac{I_{leakage}}{2\pi \times f \times 115 \times V} \quad (1)$$

where: $I_{leakage}$ is the ground leakage current, V is ac line voltage, f is power line frequency that generally is equal to 50 or 60 Hz [7].

Reference [3] have been analyzed the feedback prototype of active filters as shown in Fig. 2 and their insertion losses (ILs) are summarizes as illustrated in Table I, where internal impedances of detecting and compensating unit are ignored as assumed in ideal case.

As shown in Fig. 2 the noise signal at receiver can be a noise voltage or current, and the compensating signal by active filter can be a voltage or current. Z_s represents the impedance of a noise receiver where one evaluates the noise power due to the noise source i_n. Z_n is an internal impedance of the noise source i_n. The insertion loss is defined as:

$$IL = \frac{v_{s,wo}}{v_{s,w}}. \quad (2)$$

where $v_{s,wo}$ is the receiver's voltage without and any filter installed and $v_{s,w}$ is the receiver's voltage with filter installed.

III. Proposed Active Input EMI Filter Design

The input filter can be an additional passive filter, which gives additional insertion loss as maintained in [2, 4]. So that, a small passive EMI filter is designed to reduce conducted EMI noise where is over the capability of active filter. Fig. 3 illustrates the application of the proposed active EMI filter designed with voltage detecting and voltage compensating (type IV). In the previous active common-mode filter [5, 6], the push-pull amplifier is used the dc voltage, which is supplied to the inverter, to power the active circuit. But in this work, the active input EMI filter is comprised of a common-mode choke with an auxiliary winding, a push-pull type emitter follower circuit using two complementary transistors T_1 (C3230) and T_2 (A1276) as shown in Fig. 3. The emitter follower is supplied from a separate source V_d. The high input impedance is used to minimize the value of C_1, for common-mode voltage detection. The coupling capacitors C_c connected to ac input lines of the system, it is possible to construct a separate input filter stage.

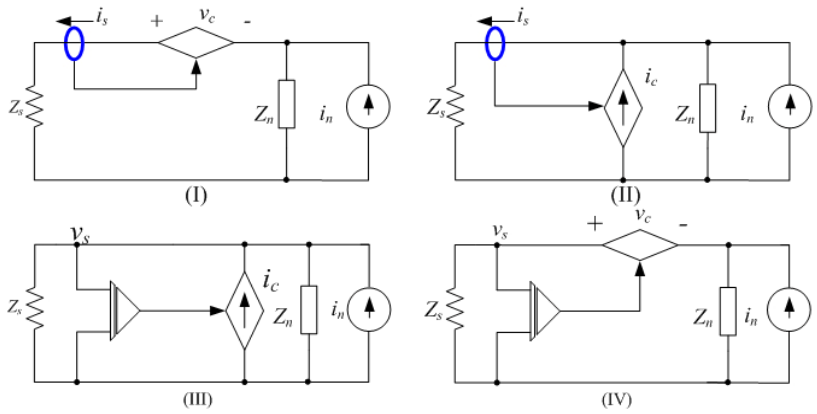

Figure 2. Feedback-type active filters [3]. (I) Current detecting and voltage conpensating, type I. (II) current detecting and current compensating, type II. (III) voltage detecting and current compensating, type III. (IV) voltage detecting and voltage compensating, type IV.

TABLE I
INSERTION LOSS OF FEEDBACK TYPE ACTIVE FILTER IN FIG. 3 [3]

Type	Insertion Loss (IL)	Amplifier gain	Condition for maximum IL
Type I	$1+\frac{A_1}{z_s+z_n}$	Trans-impedance $v_c = -A_1 \cdot i_s$	$A_1 >> z_s + z_n$
Type II	$1+\frac{z_n}{z_s+z_n} \cdot A_2$	Current gain $i_c = -A_2 \cdot i_s$	$z_n >> z_s$
Type III	$1+\frac{A_3}{z_s \parallel z_n}$	Trans-admittance $i_c = -A_3 \cdot v_s$	$A_3 >> z_s \parallel z_n$
Type IV	$1+\frac{z_s}{z_s+z_n} \cdot A_4$	Voltage gain $v_c = -A_4 \cdot v_s$	$z_s >> z_n$

A. *Selection of* C_1

The ceramic capacitors C_1 placed at the inverter input terminals of the inverter. Indeed, the resistors can be used to replace the capacitors C_1. However, there are not attractive because the resistors add more power losses to the system due to the flowing of the normal-mode currents.

The C_1 selection must be based on the maximum current that can be drawn from the main source to the inverter. If a large value of C_1 is chosen, the inverter power devices can be subjected to excessively high current pulse (capacitor charging current). Therefore, these capacitors should be selected as small as possible. The inverter for adjust speed drive is operated with the nominal current 6.4 A, and fed by a single-phase ac input system. Assuming that the inverter's switches are turned on within 500 ns, the maximum value of C_1 for 240 V is expressed:

$$6.4 = \frac{240}{500 \times 10^{-9}} \cdot C_{1,\max} \tag{3}$$

Hence, $C_{1,\max} \approx 15$ nF.

In the test setup, C_1 = 390 pF is selected as shown in Fig. 3 to get high input impedance for CM voltage detection.

B. *Complementary Transistors*

The complementary transistors use in [5, 6] are the high frequency and high voltage devices. It is quite difficult to find and expensive. In this paper, the low voltage complementary transistors are proposed because they are the commercially available for cost optimization. The transistors used in the practical implementation are A1276 and C3230. The characteristic of the both transistors are described in the table II.

TABLE II
THE COMPLEMENTARY TRANSISTORS CHARACTERISTIC

	V_{CBO} [V]	V_{CEO} [V]	I_C(dc) [A]	P_C [W]	H_{FE}
C3230-NPN	30	30	3	10	70
A1276-PNP	-30	-30	-3	10	70

C. *Separated DC Power Supply*

In the test setup, the separate 15 Vdc power supply is realized by a single-phase rectifier supplying the two capacitors C_0 connect in series. This power supply is applied to power the active circuitry. In order to remove the dc components, the capacitors C_0 are connected as illustrated in Fig.3. The small capacitance of C_0 makes the large variation of the neutral point potential V_0 [5]. Thus, C_0 is chosen as a value large enough to reduce the voltage variation. In the practical work, the capacitor of 2.2 µF is selected for C_0.

D. *CM Transformer*

In this case, the CM transformer is the same as a conventional CM choke of passive EMI filter, except for connecting a tightly coupled additional winding (auxiliary winding) to the output of the emitter follower and it applies the detecting CM voltage to the CM transformer. The two primary windings of CM transformer with the same polarity are connected between LISN and inverter input plug. Then the polarity of the compensating voltage V_c is opposite to the CM voltage generated by the inverter. Because of the CM transformer played in role of CM choke of passive EMI filter, so the value of L_{cm} should be a few mH. In the test setup, L_{cm} = 3 mH is selected within 1:1:1 winding ratio.

IV. SYSTEM CONFIGURATION AND EXPERIMENTAL RESULTS

In this section, the conducted EMI measurements have been setup: LISN 10A, high frequency current probe 10 kHz to 250 MHz bandwidth, an inverter motor drive, ac motor and EMC spectrum analyzer.

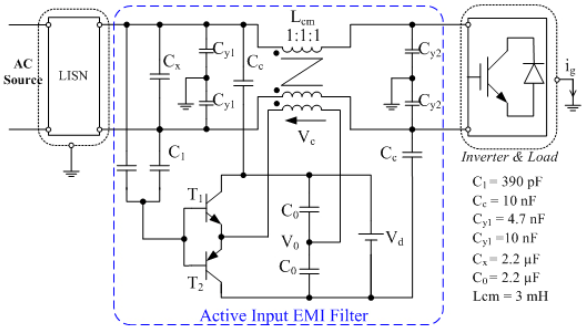

Figure 3. Configuration of experiemental system

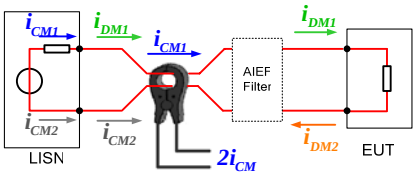

Figure 4. Common-mode EMI measurement.

The operation without load and with load is presented with the completed configuration shown in Fig. 3. An induction motor (1/2 hp, 220/380 V, 2.0/1.15 A, 50/60 Hz) is used as a load of the PWM inverter. The input filter circuit is implemented separate from PWM inverter circuit. A single-phase LISN 10 A is used to provide the stable source impedance at the high frequency while the high frequency current probe is also connected to EMC spectrum analyzer to observe CM noise as shown in Fig. 4. Because of using current probe to measure CM noise, the received results from current probe are equal to $2I_{CM}$ [7]. The CM current or voltage attenuation can be calculated from equations (4) and (5).

$$A_{dB} = \left|2I_{CM}\right|_{dB} - 6\,\text{dB} \tag{4}$$

$$V_{dB} = \left|2V_{CM}\right|_{dB} - 6\,\text{dB}. \tag{5}$$

where $\left|2I_{CM}\right|_{dB}$ and $\left|2V_{CM}\right|_{dB}$ are CM current and voltage measured using high frequency current probe, respectively.

(a)

(b)

Figure 7. Measured CM noise while the proposed AIEF installed in case of operation full load. (a) uninstalled C_{y1}, C_{y2}. (b) installed C_{y1}, C_{y2}.

The conducted EMI noise is composed of CM and DM noise. Both of them are separated, but DM is not discussed in this article with assumption that some appropriate DM components are installed for each design stage. The CM spectrum of the system without any EMI filter of both operations is shown in Fig. 5, and the conducted EMI spectrum of the both operations when the proposed AIEF is installed in the system demonstrated in Fig. 6. The experimental results of both operations are shown in Figs. 6 and 7.

V. Discussion

According to the measuring results above, it can be discussed as follows:

1). In case of the operation without load, the result is given about 35 dB of the IL at 1.5 MHz to 15 MHz when the proposed AIEF is installed, but it cannot comply with the limit-line at low frequency from 150 kHz to 1.5 MHz as shown in Fig. 6(a). When the C_{y1} and C_{y2} is installed, it adds more attenuation at low frequency up to 35 dB of the IL from 150 kHz to 3 MHz and 20 dB from 3 MHz to 20 MHz as shown in Fig. 6(b), respectively.

2). When the motor is run within full load, the result is given about 20 dB of the IL at the high frequency from 600 kHz until 15 MHz as shown in Fig. 7(a). While the C_{y1} and C_{y2} is installed, it gains about 40 dB of the IL at 150 kHz to 4 MHz and 20 dB of the IL from 4 MHz to 8 MHz. It can comply with the limit-line whole the specified frequency range as shown in Fig. 7(b).

As the results, the proposed AIEF can work as active CM voltage canceller and passive EMI filter that can comply with EN 55022 class A conducted.

VI. Conculsion

This paper presents a simplified active input EMI filter based on the CM voltage detecting and voltage compensation technique. This proposed AIEF is reliable to suppress CM voltages generated by PWM inverter using low voltage complementary transistors as the push-pull amplifier. The experimental results of two operated conditions, no load and full load of induction motor, are demonstrated the effectiveness of this AIEF using HF current probe over the frequency range 150 kHz to 30 MHz.

***Abstract*- This paper addresses the comparison of the input impedance measurement between the resonance method and the insertion loss method. The result of the input impedance from the measurement can be used to effectively design the EMI filter or to analyze the stability problem of the system when EMI filter is connected.**

I. INTRODUCTION

The input impedance of the switched mode power supplies (SMPS) is essential in its power line electromagnetic interference (EMI) filter design, and when ignored, the system may be not meet EMI regulation. To meet EMI regulation, the EMI filters are one of the most popular applied by industries to suppress EMI problems. According to, the EMI filter performance depends not only on itself. But the selections of the appropriate EMI filter components are also importance to designs EMI filter. The input impedance characteristic (Z_{in}) of the SMPS is a key parameter to design the EMI filter effectively. However, it should be noted that the transfer function of the system is effected when the EMI filter is inserted into the system. Therefore, the stability issue may be occurred.

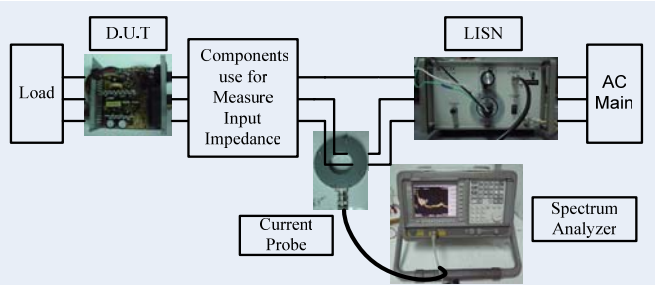

Figure 1. The input impedance measurement setup of SMPS.

There are many paper is presented the method to measure the input impedance of SMPS [1], [2] and [3]. This paper is focused on the measurement of the input impedance of the SMPS and comparison between the resonance method and the insertion loss (IL) method. Two methods to measure the input impedance use the same equipments: the spectrum analyzer and the current probe.The input impedance of SMPS measurement setup is shown in Fig. 1.

Schneider [1] proposed the resonance method to measure the input impedance. This method assumes the SMPS is a Norton circuit with reactive source impedance and employs the quality factor (Q) to solve the input impedance.

Shih [2] proposed the insertion loss method to address the input impedance of SMPS and verified the experimental results by mathmatical expression.

II. THE INPUT IMPEDANCE OF SMPS

The three wires system (line, neutral and ground) can be separated as common mode and differential mode. The impedance between the shorted line-neutral terminals and the ground terminal, is defined as a common mode input impedance. While the differential mode input impedance is the impedance between line terminal and neutral terminal. The common mode input impedance and the differential mode input impedance diagrams of SMPS are showed in Fig. 2 (a) and (b), respectively.

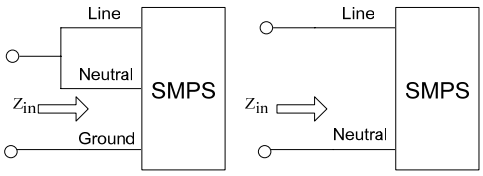

Figure 2. Definition of input impedance
(a) common mode (b) differential mode.

A. *The Input Impedance Measurement Using the Insertion Loss Method*

The input impedance characteristic (Z_{in}) of SMPS can be fined out by insertion loss method. The insertion loss is defined as a ratio of voltages across R_{LISN} before and after the filter element is inserted. The definition of insertion loss is expressed in equation (1).

$$IL = 20 \log \left(\frac{V_{LISN}\ without\ filter}{V_{LISN}\ with\ filter}\right) \quad (1)$$

Figs. 3 - 4 show the conducted emission model and deriving $|Z_{in}|$ by the insertion loss method, respectively.

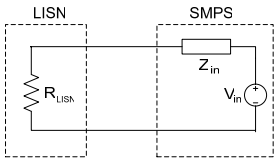

Figure 3. The conducted emission model.

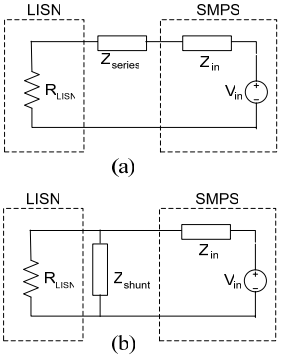

Figure 4. $|Z_{in}|$ by the insertion loss method.

(a) Z_{series} is inserted for common mode input impedance measurement.

(b) Z_{shunt} is inserted for differential mode input impedance measurement.

By the insertion loss method can be separated for two cases. In the first case, the Z_{series} is added with the condition that $|Z_{in}| \gg R_{LISN}$ and $|Z_{series}| \gg |Z_{in}|$. This assumption only uses for measuring common mode input impedance.

$$IL = \frac{\frac{R_{LISN}}{R_{LISN}+Z_{in}} \times V_{in}}{\frac{R_{load}}{R_{LISN}+Z_{in}+Z_{series}} \times V_{in}}$$

$$= 1 + \frac{Z_{series}}{R_{LISN}+Z_{in}}$$

$$\approx 1 + \frac{Z_{series}}{Z_{in}}$$

Since $|IL|$ is normally much greater than 1, then

$$|Z_{in}| \approx \frac{|Z_{series}|}{|IL|} \quad (2)$$

In the case 2, $|Z_{in}| \ll R_{LISN}$ assuming by added a shunt component with $|Z_{shunt}| \ll |Z_{in}|$, the insertion loss can be simplified as follows:

$$IL = \frac{\frac{R_{LISN}}{R_{LISN}+Z_{in}} \times V_{in}}{\frac{R_{LISN} // Z_{shunt}}{R_{LISN} // Z_{shunt}+Z_{in}} \times V_{in}}$$

$$= 1 + \frac{R_{LISN} // Z_{in}}{Z_{shunt}}$$

$$\approx 1 + \frac{Z_{in}}{Z_{shunt}}$$

Similar to the first case $|Z_{in}|$ can be approximated by

$$|Z_{in}| \approx |Z_{shunt}| \times |IL| \quad (3)$$

B. The Input Impedance Measurement Using the Resonance Method

Common mode emission is caused by parasitic capacitance to chassis. The charging and discharging of insulator capacitance are the culprit for common mode electromagnetic interference (EMI). Differential mode emission is generated by diode reverse-recovery phenomena. The resonance of conducted EMI can be determined the input impedance of SMPS by assuming that the SMPS is a Norton circuit with reactive impedance as shown in Fig. 5. First, the Norton current source can be obtained by shorts circuit at the load side. Second, the resistive and capacitive impedance of SMPS can be achieved by resonating the load side with added inductor, and the Q of source may be found at the single frequency. The Q of the circuit is defined as

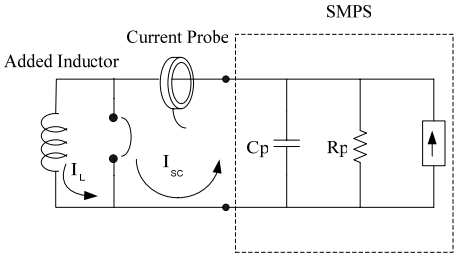

Figure 5. The schematic of resonance method.

$$Q = \frac{I_1}{I_{sc}} \quad (4)$$

Where I_1 is the current when adding the inductor at the load side.

I_{sc} is the short circuit current.

The input resistance of SMPS as shown in equation (5)

$$R = Q\omega L \quad (5)$$

Then, the input capacitance as shown in equation (6)

$$C = \frac{Q}{\omega R} \qquad (6).$$

III. *Test Setup and Experimental Results*

The device under test (DUT) 250 W power supply, input: 200–240 VAC, 3.5 A, output 15 VDC, 3.4 A.

Fig. 6 (a) shows the test setup for common mode input impedance measurement of SMPS by the insertion loss method while Fig. 6 (b) shows the test setup for differential mode input impedance of SMPS by the insertion loss method, respectively [1].

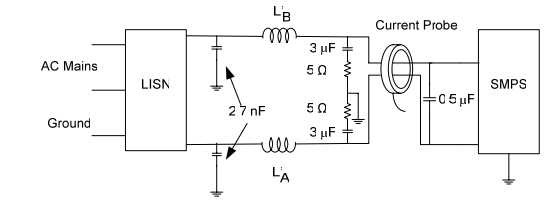
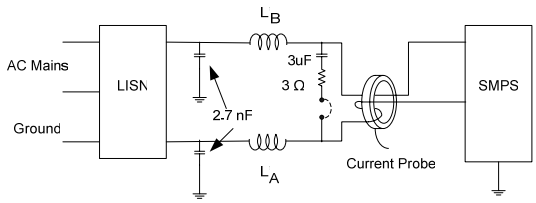
(b) The differential mode input impedance measurement.



(a)



(b)

Figure 7. The setup of the resonance method.
(a) Common mode input impedance measurement.
(b) Differential mode input impedance measurement.

To measure the common mode input impedance of SMPS by the insertion loss method two the common mode choke "Z_{series}" is added two 50 Ω resistors are shown as a equivalent resistor (R_{LISN}) of Line Impedance Stabilization Network (LISN) are paralleled (25 Ω). The common mode input impedance of SMPS are derived by equation (2).

Similarly, the case of the differential mode input impedance of SMPS adds the parallel "Z_{shunt}" to SMPS. The Z_{shunt} is the series combination of a 1 Ω resistor and 1 μF capacitor.

Fig. 7. shows the setup of the resonance method. Fig. 7 (a) shows the common mode setup and Fig. 7 (b) shows the differential mode setup.

The experimental results of C_p and R_p for common mode and differential mode are shown in Figs. 8-9. In Fig. 8 is the derivation of resonance method for common mode input impedance of SMPS (C_p and R_p), by equations (4)-(6). The average of R_{pCM} is 46 kΩ, C_{pCM} is 0.71 nF.

Fig 9 is the derivation of resonance method for differential mode input impedance of SMPS (diode "on") and the average of R_{pDM} and C_{pDM} are 320 kΩ and 0.1 nF, respectively.

The R_p and C_p of the differential mode input impedance is the high source impedance, that is the characteristics of diode reverse-recovery-generated EMI and the low source impedance component is more correctly modeled as a series RL circuit. Its values ranged from 0.5 to 1 μH and 0.5 Ω [4]. Fig. 11 shows the correct differential mode input impedance model.

(b)

Figure 10. The comparison of the input impedance of SMPS.
(a) The common mode comparison.
(b) The differential mode comparison.

The input impedance using the resonance method (R_{pCM}, C_{pCM}, R_{pDM} and C_{pDM}) is plotted as a bold line shown in Fig. 10. For the insertion loss method, the attenuation for each frequency (150 kHz-30 MHz) is measured, then calculating the Z_{in} of the SMPS as a dash line shown in Fig. 10 (a). The differential mode input impedance comparison between the resonance method and the insertion loss method is shown in Fig. 10 (b). The differential mode input impedance of SMPS has the low value both the resonance method and the insertion loss method. The input impedance values are in the same results about 300 kHz-900 kHz and different after 1 MHz. The common mode input impedance of SMPS has the low value both the resonance method and the insertion loss method. The input impedance values are different before 900 kHz and in the same results about 900 kHz–10 MHz.

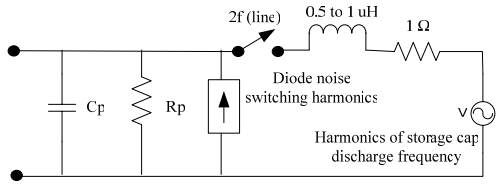

Figure 8. The correct differential mode input impedance model

IV. Conclusion

The insertion loss method and the resonance method are verified to be the simple and effective choice to measure the characteristic of the input impedance of SMPS. The phase of the input impedance can be found by Hilbert transform [5]. For the insertion loss method may be found the input impedance as the voltage source series with input impedance while the resonance method may be found the input impedance as the current source paralleled with the input impedance.

The experimental results are in the same trend in some frequency range of input impedance values, both common mode and differential mode. The insertion loss method, the input impedance values are calculated by attenuation of the EMI of SMPS, which can use these data to calculate the input impedance of SMPS at all frequency range (150 kHz – 30 MHz).

In the other hand, for the resonance method, the input impedance (R_p and C_p) is calculated and averaged the values from 150 kHz-30 MHz. The high source impedance (diode "off") can calculate by equations (4) - (6) However, the low source impedance (diode "on") as the series RL circuit must be selected from 0.5 to 1 µH and roughly 0.5 Ω that makes the error of the differential mode input impedance of SMPS.

Abstract-This paper presents the trade-off between EMI separator and the RF current probe for conducted EMI measurement. EMI toolkit is used as a noise source for investigating effects from differential-mode (DM) and common-mode (CM). Paul-Hardin noise separation network or EMI separator is used as a benchmark to compare with the RF current probe. The conducted electromagnetic interference between RF current probe and EMI separator is compared by the experiment. Finally, the trade-off between two measurement methods is verified by both theoretical and experimental results.

I. INTRODUCTION

Electromagnetic Compatibility (EMC) is an electronic system which is able to function compatibly with other electronic systems and not produce or be susceptible to interference with its environment [1]. The interference can be divided widely into two groups: conducted and radiated interferences. In this paper, the conducted emission is emphasized and mentioned to separate noise components (Differential-Mode: DM and Common-Mode: CM) for electromagnetic environment. It is very useful to know noise components in every interested circuit [2]. Generally, there are two methods, often used for separating noise components. The first method is a classical measurement using radio frequency current probe (RF current probe). The second method is measurement CM and DM by using separating devices such as CM/DM discrimination network [3], Paul-Hardin noise separation network [4] and noise separator [5] etc. However, all separation networks in this paper are called as the EMI separator.

The Equipment Under Test (EUT) in this paper is EMI toolkit, used for conducted EMI studying in terms of theory and practice. Fig. 1 shows outside of EMI toolkit. Boost converter is a main part which generates EMI. In addition, a lot of study functions are combined in the toolkit and it can be selected functional operation such as self-resonant frequency (SRF) of the passive components, reverse recovery time of diodes, switching frequencies, and gate drive control [6].

To understand noise behaviors in a boost converter, Fig. 1 can be rewritten to Fig. 2 which includes Line Impedance Stabilization Network (LISN) schematic and two 50 Ω terminators. These terminators are connected to the RF output ports of LISN when measuring by RF current probe but when using Paul-Hardin network these terminators are input impedance of the network. V_P and V_N stand for phase and neutral voltage signal, respectively. C_S is a parasitic capacitance caused by MOSFET (Q) between drain and frame ground via its heat-sink.

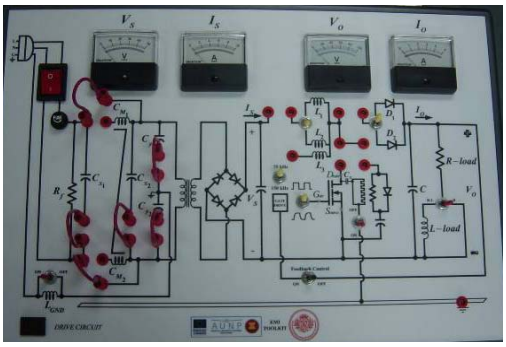

Figure 1. Top view of EMI toolkit configuration.

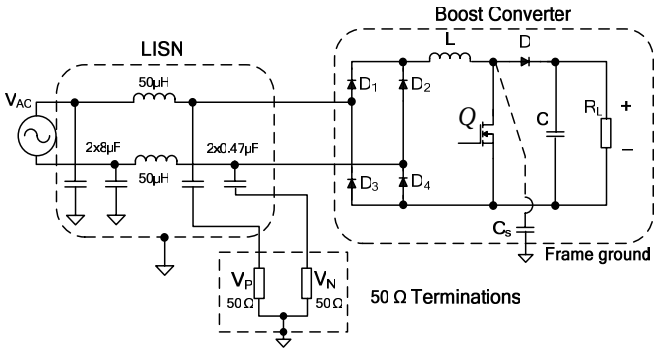

Figure 2. Schematic of LISN and boost converter under consideration.

II. CONDUCTED EMI MEASUREMENTS: RF CURRENT PROBE AND EMI SEPARATOR CONCEPTS

Conducted EMI emission is measured using a LISN as a 50 Ω impedance. The DM noise current (I_{DM}) flows out from line and returns via neutral while the CM noise current (I_{CM}) flows out from line and neutral and returns via ground wire as shown in Fig. 3 Eqns. (1)-(3) are line, neutral and ground current and Eqns. (4)-(5) are line and neutral voltages, respectively [7].

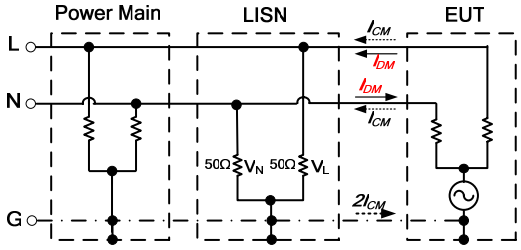

Figure 3. DM and CM currents from LISN.

$$I_{Line} = I_{CM} + I_{DM} \quad (1)$$

$$I_{Neutral} = I_{CM} - I_{DM} \quad (2)$$

$$I_{Ground} = 2 \cdot I_{CM} \quad (3)$$

$$V_{Line} = 50 \cdot (I_{CM} + I_{DM}) \quad (4)$$

$$V_{Neutral} = 50 \cdot (I_{CM} - I_{DM}) \quad (5)$$

A. *RF Current Probe*

RF current probe is a clamp-on RF current transformer designed for use with EMI Test Receivers/Spectrum Analyzers, or with any similar instrument having a 50 Ω input impedance, to determine the intensity of RF current present in an electrical conductor or group of conductors [7]. Fig. 4 shows the RF current probe within bandwidth 10 kHz - 250 MHz. The maximum primary current from DC - 400 Hz is up to 100 A and the transfer impedance (Z_T) is 5 Ω [8]. The performance of the RF current probe may be expressed in terms of sensor transfer impedance: Eqn. (6). Where V_{out} is the voltage developed across a 50 Ω termination on the output and I_{cond} is the current flowing through the conductor being measured. The probe transfer impedance is often expressed in terms of dB which can be calculated the measured current from Eqn. (7) [9].

(a) Top view (b) Side view

Figure 4. Toroidal RF current probe.

$$Z_T = \frac{V_{out}}{I_{cond}} \quad (6)$$

$$I_{cond}(dB\mu A) = V_{out}(dB\mu V) - Z(dB) \quad (7)$$

B. *EMI separator*

Many papers have been discussed and proposed EMI separators [3-5], [10-11]. They can be separated roughly in two groups based on magnitude of output signal, single and double output noise. Moreover, in group of double output [4] has no guarantee that it can be used representative of RF current probe.

Fig. 5 shows the Paul-Hardin noise separation network schematic. There are two important elements; two wideband transformers (1:1 ratio) and single-pole-double-throw (SPDT) switch, which operate simultaneously [7].

The line-ground voltage (V_{LG}) and neutral-ground voltage (V_{NG}) are connected to EMI separator, using Eqns. (8) and (9) for voltage across switch at A and B position respectively.

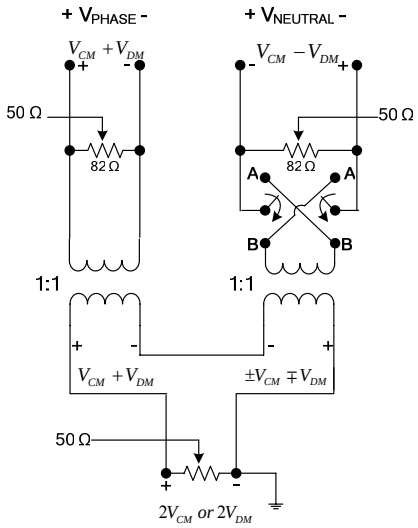

Figure 5. Paul-Hardin noise separation network schematic.

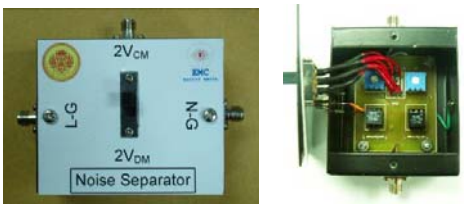
$$|V_{LG} - V_{NG}| = |V_{CM} + V_{DM}| - |V_{CM} - V_{DM}| = |2V_{DM}| \quad (8)$$

$$|V_{LG} + V_{NG}| = |V_{CM} + V_{DM}| + |V_{CM} - V_{DM}| = |2V_{CM}| \quad (9)$$

$$\text{or } |2V_{DM}| = |V_{LG} - V_{NG}| = 50 \cdot |2I_{DM}| \quad (10)$$

$$|2V_{CM}| = |V_{LG} + V_{NG}| = 50 \cdot |2I_{CM}| \quad (11)$$

The output is $|V_{LG} - V_{NG}|$ for $2V_{DM}$ defined by Eqn. (8) and $|V_{LG} + V_{NG}|$ for $2V_{CM}$ defined by Eqn. (9) and lastly, leakage between the DM and CM at the output should be small because noise measurement between the DM and CM must be guaranteed small interference [5]. The impedance of two inputs are 50 Ω within 20 percent tolerance according to CISPR 16-1 standard because both of them have to connected with LISNs. The CM output impedance of network is very closed to 50 Ω (in range 45 Ω – 50 Ω at 150 kHz – 30MHz) but for DM output impedance is nearly 20% tolerance from 50 Ω (35 Ω – 50 Ω) as shown in Fig. 7. The performance of EMI separator can be described in term of rejection attenuation value of both modes; some papers call "CM/DM rejection ratio" [2], [10] as shown in Fig. 8.



(a) Outside (b) Inside

Figure 6. Paul-Hardin noise separation network.

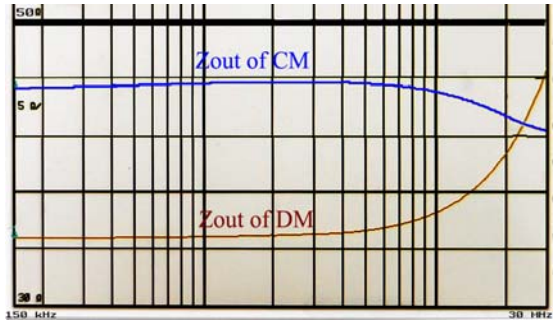


Figure 7. CM and DM output impedance of EMI separator.

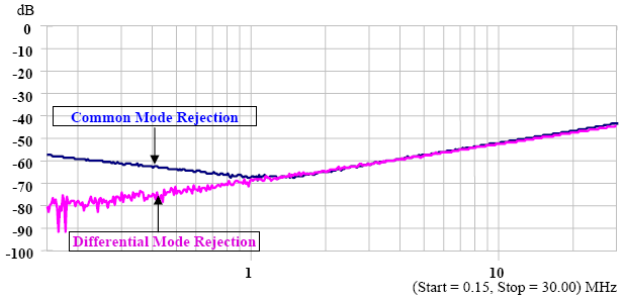

Figure 8. CM and DM rejection.

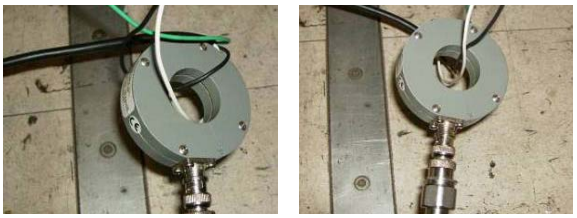
III. Measurement Methods

A. RF Current Probe Measurement

Figs. 9 (a)-(b) show basically method to measure DM and CM noise, respectively. However, the measured results of DM and CM are double ($2I_{DM}$ and $2I_{CM}$) caused by sum of current vectors in same direction. The current probe is usually clamped between the EUT and the LISN as near as possible. In some EMC standard current probes, such as the DEF STAN 59-41 DCE01, have to away 5 cm from the LISN connection on the power lead [7].



(a) Measured 2DM noise (b) Measured 2CM noise

Figure 9. RF Current probe measurement method.

B. EMI separator Measurement

The second method to measure DM and CM noise components are displayed in Fig. 10. LISN-1 couples voltage from line-ground while LISN-2 couples voltage from neutral-ground. Output of separator is connected with 50 Ω terminal of spectrum analyzer. In addition, coaxial cables (50 Ω) with BNC connector are connected with two RF output terminals of LISNs for coupling line-ground and neutral-ground signal simultaneously.

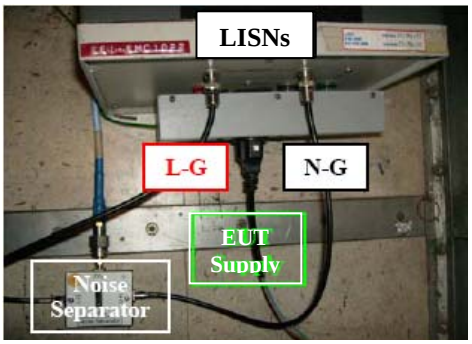


Figure 10. EMI separator measurement method.

IV. Experimental Results

In this section, noise floor between the RF current probe and EMI separator are measured first for using as reference levels. There are three noise floors: RF current probe, CM EMI separation and DM EMI separation which are the same level of noise floors about 25 dB.

Measured results of $2V_{CM}$ and $2V_{DM}$ are divided into three sections by comparison results between RF current probe and EMI separator. Firstly, noise source is measured without filter components this is a full noise condition as shown in Figs. 11-12. Secondly, adding two X-capacitors between line and neutral, 0.47 µF, as shown in Figs. 13-14, which show DM and CM comparing between RF current probe and EMI separator with and without filter components. A dash line prefers to EMI measured result when filter components are added in the circuit. Finally, two Y-capacitors are added across line-ground and neutral-ground, 0.2 µF, as shown in Figs. 15-16.

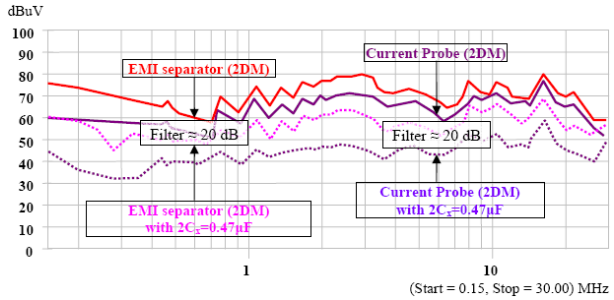

Figure 13. The comparison of $2V_{DM}$ when adding C_x filter between RF current probe and EMI separator.

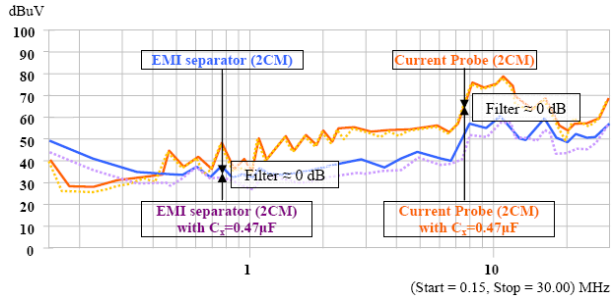

Figure 14. The comparison of $2V_{CM}$ when adding C_x filter between RF current probe and EMI separator.

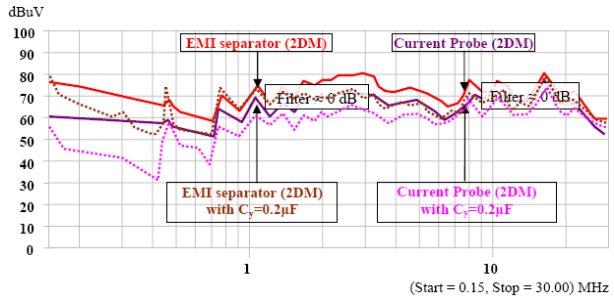

Figure 15 The comparison of $2V_{DM}$ when adding C_y filter results between RF current probe and EMI separator.

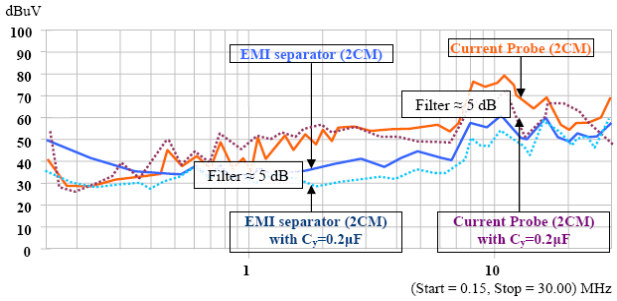

Figure 16 The comparison of $2V_{CM}$ when adding C_y filter results between RF current probe and EMI separator.

V. Analysis

From Eqn. (6), the transfer impedance of the current probe (Z_T) is 5 Ω and the measured current I_{cond} is represented by $2I_{DM}$ or $2I_{CM}$ as follows;

$$V_{out(CM)} = (5)\cdot(2I_{CM}) \text{ and } V_{out(DM)} = (5)\cdot(2I_{DM}) \qquad (12)$$

Where $V_{out(CM)}$ and $V_{out(DM)}$ are common mode and differential mode output voltage measured by RF current probe respectively.

Then, multiplication Eqn. (12) by two to compare with Eqns. (10)-(11) and inverting them to dB values using logarithm function.

The compared results show the different value between using RF current probe and EMI separator about 13.98 dB.

The experimental results as shown in Figs. 11-12, can be realized by the theoretical expression as mention. Fig. 13 shows the performance of X capacitor filters. The DM EMI is decreased about 20 dB while the CM EMI has a little changed as shown in Fig. 14 and the difference between RF current probe and EMI separator still about 14 dB. Figs. 15-16 show EMI results which are mitigated by Y capacitors. The performance of C_y can suppress noise about 5 dB for common mode and nearly 0 dB for differential mode

VI. Conclusions

The separation of conducted EMI measurement, measured by RF current probe and EMI separator, is compared. The attenuation value between RF current probe and EMI separator is about 14 dB, realized by the theoretical and experimental results. The performance of EMI separator has been realized using the convenient EUT as EMI toolkit. However, it should be noted that the EMI separator, which is low cost, can be used at low-medium power level because the saturation of wideband transformer while the RF current probe can be covered the high level.

II. EXPERIMENTAL

Ceramic sample of Gd 1:2:3 were prepared by conventional powder processing from high-purity oxides and carbonates, calcining at 930°C, the powder were pressed into pellets with a pressure of 1 ton/cm^2 .The pellets were sintered at 900°C, 920°C, 925°C, 930°C, 935°C, 940°C, 945°C, 950°C, 955°C, 960°C, 965°C and 970°C for 10 hours.

We had experimentally investigated the following effect of external magnetic field on current-voltage characteristics and magnitude of negative resistances. The current-voltage characteristics were measured by the four probe technique with indium electrodes at 77 K. The magnetic field is applied to samples perpendicular with the direction of current flow.

III. EXPERIMENTAL RESULTS

A. The Optimum condition of critical current for the occurrence of negative resistance

From Fig. 2 shown the relationship between sintering temperature and critical current (I_C). It's found that, the highest I_C is 2.2 A at sintering temperature 930°C. At the highest I_C sample must be applied external magnetic field (B_{EXT}) higher than the low I_C sample, to destroy the superconducting state. However the negative resistance could not be observed at this highest I_C. But negative resistance obviously occurred as I_C is reduced from maximum point.

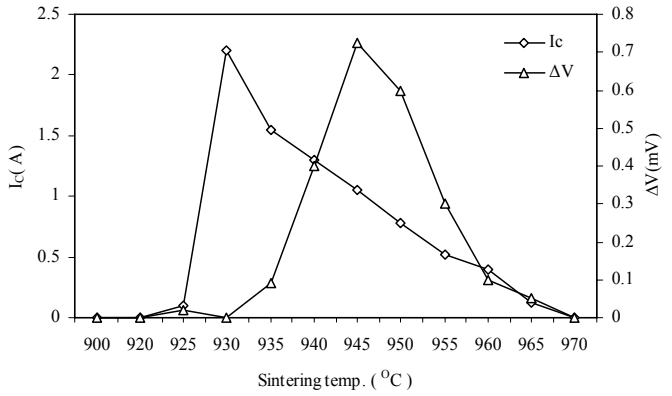

Figure 2. The plot of I_C, ΔV vs sintering temperature

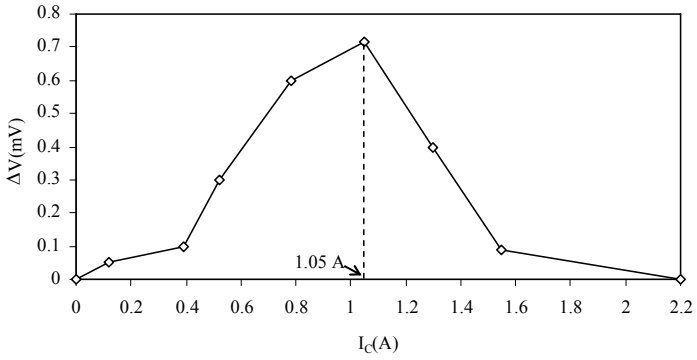

Figure 3. Dependence of ΔV on I_C

The maximum magnitude of difference voltage(ΔV) is obtained at I_C = 1.05 A. ΔV will be to zero while I_C is decreased to zero as shown in Fig. 2 and Fig. 3. Thus, it can be seen that the negative resistance phenomena is apparently found in the range of low I_C.

B. The effect of magnetic field on magnitude of negative resistance

The influences of B_{EXT} on the magnitude of differential voltage (ΔV) are studied. Sample used here show the various values of critical currents which are 1.55A, 1.3A, 1.05A, 0.78A, 0.52A, 0.39A and 0.12A respectively. Current-voltage relations and the dependences of ΔV on B_{EXT} are shown in Fig.4. It's found that the magnitude of ΔV depends on B_{EXT} [4]. For example, for the sample with I_C = 1.05 A, when we applied B_{EXT} from 0 to 0.2 mT, ΔV was increased. However if applied B_{EXT} exceeded 0.2 mT, then ΔV was decreased continuously. The maximum ΔV (ΔV_{MAX}) was obtained at 1.4 mV.

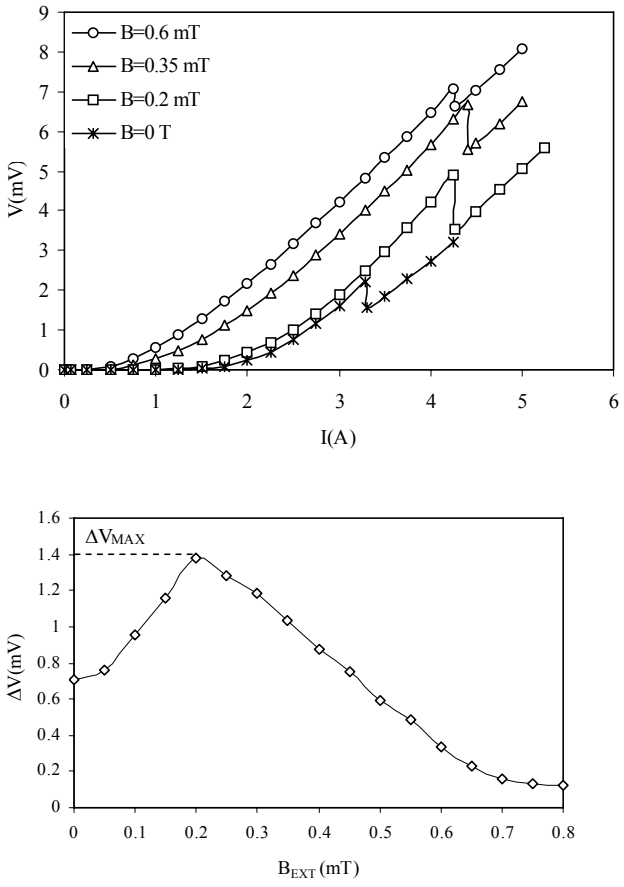

Figure 4. The effect of B_{EXT} on samples with various I_C

Fig. 5 shows ΔV versus B_{EXT} relations obtained from sample with various critical current. It is found from Fig. 6 that the sample with I_C = 1.05 A shows the highest value of ΔV_{MAX} comparing with other I_C samples.

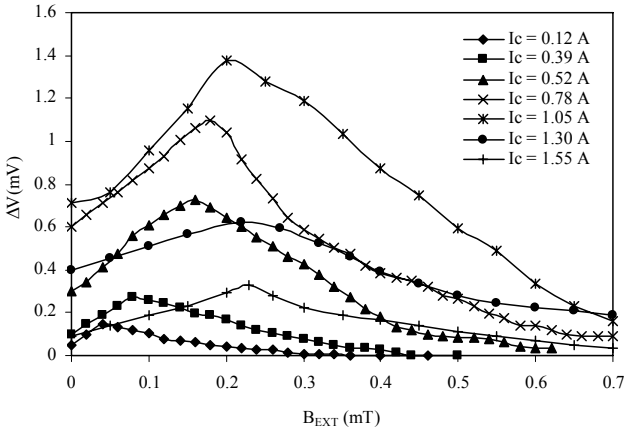

Figure 5. The plot of ΔV vs B_{EXT} at various I_C

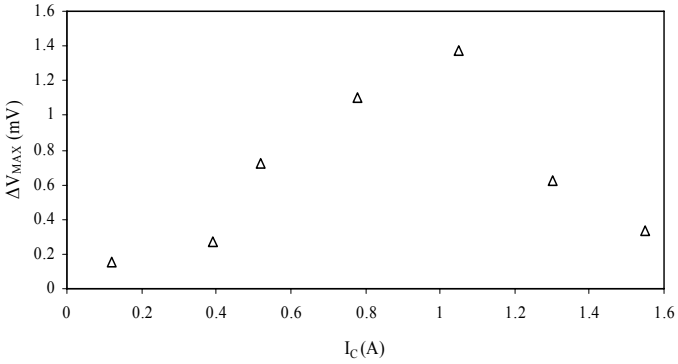

Figure 6. The relationship between ΔV_{MAX} and I_C

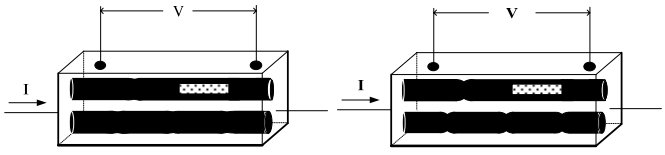
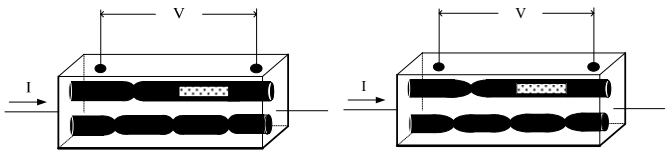
IV. DISCUSSIONS

The experiment al results can be explained by the macrostructure model of Gd-Ba-Cu-O. Since the high-I_C sample exhibits superconducting state more completely than the low-I_C sample, then the connection of weak point region must be stronger than the low-I_C sample as shown in Fig. 7.



a) Sample with I_C = 2.2 A b) Sample with I_C = 1.55 A



c) Sample with I_C = 1.05 A d) Sample with I_C = 0.52 A

Figure 7. Illustration of a macrostructure model at various I_C

From Fig. 8, when the applied current (I) is equal to (or less than) its critical current(I_C) value, both sides of the sample are connected by the superconduction parts. Then, the resistance of sample does not appear. But when $I>I_C$, superconduction part will be cut-off, because weak point region is destroyed. The resistance appears in this condition. Because the volume of upper destroyed parts are less than lower destroyed parts, all current will flow over the upper part only. Then, the small voltage drop will appear across the upper part. When the current reaches I_N, the upper superconduction part, where has magnetic substance, is destroyed. Thus, overall cut-off region of the upper part is more than lower part. The resistance of upper part increases quickly. Then all current flows to lower part, which has low resistance. Therefore, the voltage drop across sample decreases immediately. This phenomenon is called Negative-resistance. The magnitude of differential voltage (ΔV) is about 0.71 mV.

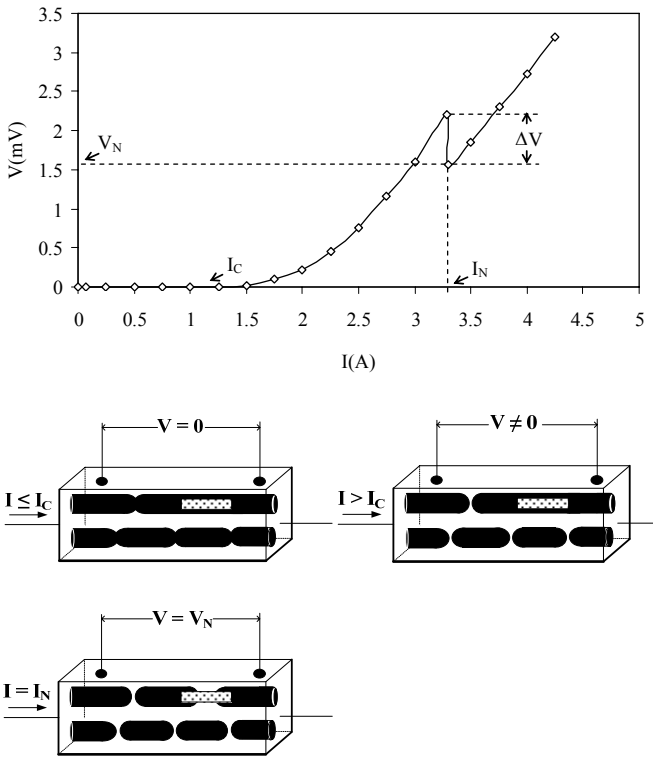


Figure 8. Illustration of current-voltage characteristics of sample with I_C = 1.05 A

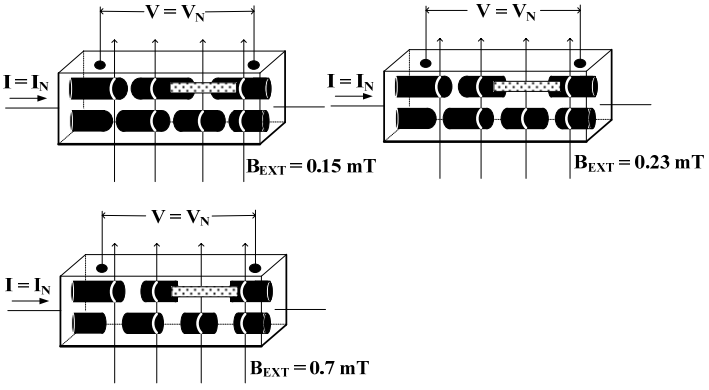
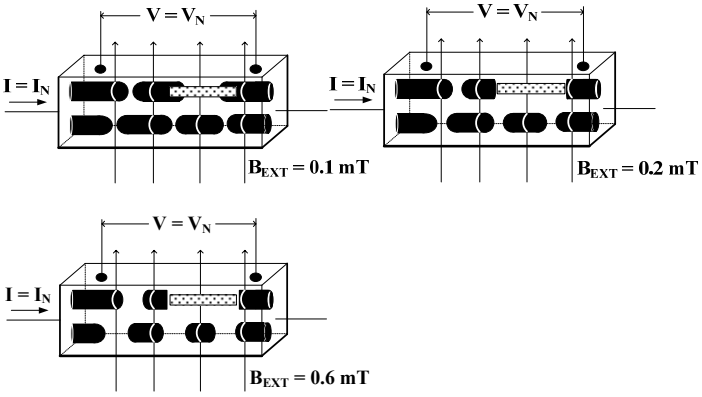
We will consider the effect of B_{EXT} on ΔV as follows. In the case of the sample showing I_C=1.55A, ΔV was increased by B_{EXT} in the range of 0 ~ 0.23 mT, as shown in Fig. 5. This phenomenon can be explained by considering the macrostructure model as shown in Fig. 9 a). Since the cut-off region which has magnetic substance, was broadened by B_{EXT}, ΔV increases, that is, current path changes from the upper high resistance path to the lower low resistance path. When the external magnetic flux B_{EXT} exceeds 0.23 mT, ΔV was decreased. Since B_{EXT} also destroys partially the lower superconduction part as shown in Fig. 9 a), the difference of electrical resistance between the upper path and the lower path became small. Then, ΔV decreases. For sample I_C = 1.05 A, when B_{EXT} = 0.2 mT, the highest ΔV is obtained. Consequently, the cut-off region, containing magnetic substance, is broadened until magnetic substance is uncovered completely.

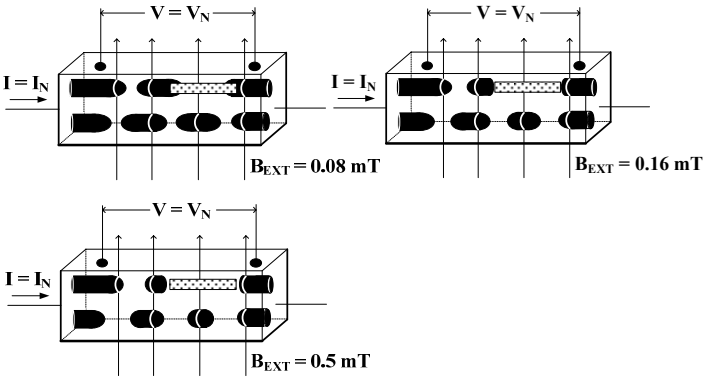
In the case of sample showing I_C = 0.52 A, when B_{EXT} = 0.16 mT, ΔV_{MAX} is obtained. Due to the cut-off region, which has magnetic substance, is broadened until magnetic substance is uncovered completely. Nevertheless, B_{EXT} will also destroy partially the lower part similarly as shown in Fig. 9c). Then, ΔV_{MAX} in this case less than the sample with I_C = 1.05 A as shown in Fig. 6.



a) Sample with I_C = 1.55 A



b) Sample with I_C = 1.05 A



c) Sample with I_C = 0.52 A

Figure 9. Illustration of a macrostructure model at various applied magnetic field

V. CONCLUSIONS

From the investigation of Current and Voltage characteristics in $GdBa_2Cu_3O_{7-x}$ superconducting ceramic material, it's found that the negative resistance phenomenon is apparently found in range of low critical current. Moreover, the magnitude of differential voltage (ΔV) depends on external magnetic field and critical current. The largest differential voltage ΔV_{MAX} is obtained by the employment of suitable B_{EXT}. Moreover, the occurrence of ΔV_{MAX} in the high-I_C sample must be applied B_{EXT} higher than the low-I_C sample.

Some experimental results can be quite explained by the macrostructure model of $GdBa_2Cu_3O_{7-x}$ superconducting ceramic materials.

***Abstract*- This paper presents an analytical method to compute a sensitivity map for the electrical capacitance tomography (ECT). These analytical equations are obtained by assuming that the gaps between each electrode around a circular cylindrical sensor are infinitely small. With this assumption, the potential on the boundary of the cylindrical sensor is known. Laplace's equation can be analytically solved and the analytical equations for the sensitivity maps are obtained. The sensitivity maps for the consecutive electrodes are excluded from the image reconstruction equation because its singularities. The reconstructed images using proposed sensitivity maps are presented. It shows acceptable results but it does not have enough resolutions to separate two close objects.**

I. INTRODUCTION

Nondestructive imaging of moisture inside objects particularly in fruits is an important issue. This paper uses the electrical capacitance tomography to monitor moisture in sample objects. The most important part of image reconstruction algorithm is to compute the sensitivity map. The sensitivity map was computed using a finite-element-method (FEM) in [1]. The sensitivity map for a pair of electrodes at a specific location inside the sensor is defined as the change of capacitance between the pair as a result of the change of permittivity in that particular location. It is a time-consuming to compute the sensitivity map for each pair of electrodes at every location. The new definition of the sensitivity map for a pair of electrodes at a specific location proposed by [2] is the dot-product of the electric field produced by applying high potential at one of the pair electrodes and the electric field produced by applying high potential at the other one of the pair electrodes at a particular location. The sensitivity map in [2] was computed using a finite difference-method (FDM). The results in [1]–[2] were done using numerical methods in both the sensitivity map calculation and the capacitance measurement. This paper presents an analytical method to compute the sensitivity maps instead of a numerical method. The ECT system is implemented. The sensor is built using a polyvinyl chloride (PVC) pipe and the capacitances are physically measured. Good reconstructed images of sample objects are obtained.

II. SENSOR STRUCTURE

Fig. 1 shows the top view of the constructed ECT sensor. The sensor consists of 6 electrodes which are fabricated from a flexible thin substrate. The dimensions of each electrode are shown in Fig. 2. Only the middle plate is used as an electrode. The top and bottom plates are a system ground and used to confine electric field in the middle region.

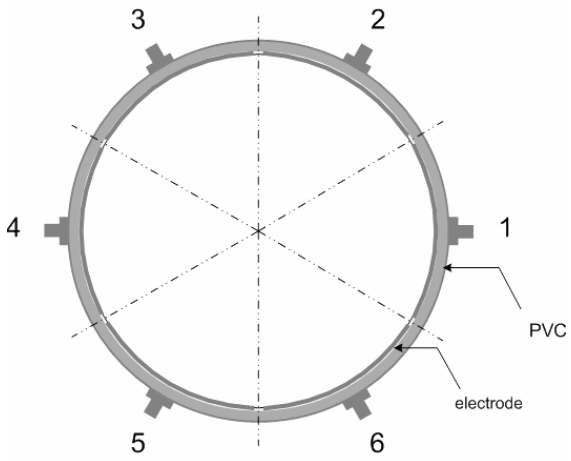

Figure 1. Top view of the circular cylindrical ECT sensor.

III. SENSITIVITY MAP CALCULATION

This paper computes the sensitivity map using the definition in [2]. The expression of the sensitivity map for a pair of electrodes at a specific location inside the sensor is given by

$$S_{ij} = -\int_{P(x,y)} \frac{\mathbf{E}_i}{V_{oi}} \cdot \frac{\mathbf{E}_j}{V_{oj}} dx'dy' \qquad (1)$$

where $\mathbf{E}_i$ is the electric field inside the sensor when the i^{th} electrode is applied with potential V_{oi}. $\mathbf{E}_j$ is the electric field inside the sensor when the j^{th} electrode is applied with potential V_{oj} and $P(x,y)$ is the region where (x,y) is its center. Using the assumption that the gap between each electrode is infinitely small, the potential inside the sensor is given by

$$V_i(r,\phi) = \sum_{m=1}^{\infty} \frac{2V_{oi}}{m\pi b^m} \sin\left(\frac{m\pi}{6}\right) r^m \cos\left(m\left(\phi - \frac{\pi(i-1)}{3}\right)\right) + \frac{V_{oi}}{6} \qquad (2)$$

where V_i is the potential inside the sensor when the i^{th} electrode is applied with potential V_{oi}. The variables r and ϕ

are the cylindrical coordinate of the potential point. They can be transformed to the Cartesian coordinate systems using simple equations. After the expression for the potential is obtained, the expression of the electric field, $\mathbf{E}$, is derived by using $\mathbf{E} = -\nabla V$. The expression is given by

$$E_{ri} = -\sum_{m=1}^{\infty} \frac{2V_{oi}}{\pi b^m} \sin\left(\frac{m\pi}{6}\right) \cos\left(m\left(\phi - \frac{(i-1)\pi}{3}\right)\right) r^{(m-1)} \quad (3)$$

$$E_{\phi i} = -\sum_{m=1}^{\infty} \frac{2V_{oi}}{\pi b^m} \sin\left(\frac{m\pi}{6}\right) \sin\left(m\left(\phi - \frac{(i-1)\pi}{3}\right)\right) r^{(m-1)} \quad (4)$$

where E_{ri} and $E_{\phi i}$ are the radial and the phi–components of the electric field respectively.

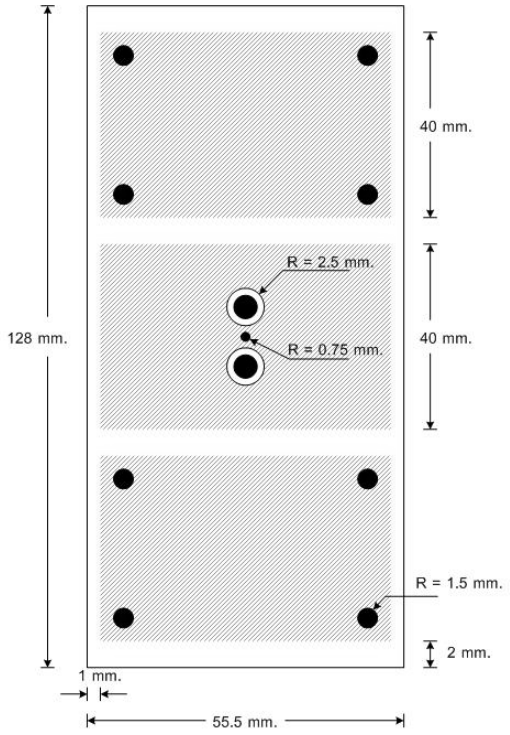

Figure 2. Dimensions of each electrode.

Using the approximation that $P(x, y)$ is so small such that the electric field in the area is almost constant and the applied potential for each electrode is one, (1) can be rewritten as

$$S_{ij} = -\left(E_{ri}E_{rj} + E_{\phi i}E_{\phi j}\right)\Delta s_{(x,y)} \quad (5)$$

where $\Delta s_{(x,y)}$ is the area of $P(x, y)$ and (3) and (4) are used for the radial and the phi–components of the electric field respectively. Fig. 3 shows the surface plot of the sensitivity map between the 1st electrode and the 2nd electrode, S_{12}. Fig. 4 shows the surface plot of the sensitivity map between the 1st electrode and the 3rd electrode, S_{13}. Fig. 5 shows the surface plot of the sensitivity map between the 1st electrode and the 4th electrode, S_{14}. The surface plot of S_{ij} where $i = j \pm 1$ is similar to the one for S_{12}. The surface plot of S_{ij} where $i = j \pm 2$ is similar to the one for S_{13}. The surface plot of S_{ij} where $i = j \pm 3$ is similar to the one for S_{14}. The radius of the sensor is 5.5 cm. Because of the singularity of the electric field in the area close to the electrodes, large errors of the sensitivity maps computation is observed. The sensitivity maps for the middle area with the radius of 4cm are used and shown in Figs. 3–5. The images outside this area are not computed.

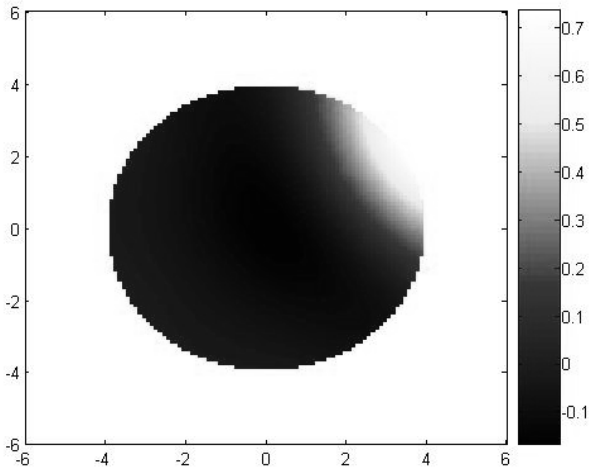

Figure 3. Sensitivity map between the 1st electrode and the 2nd electrode.

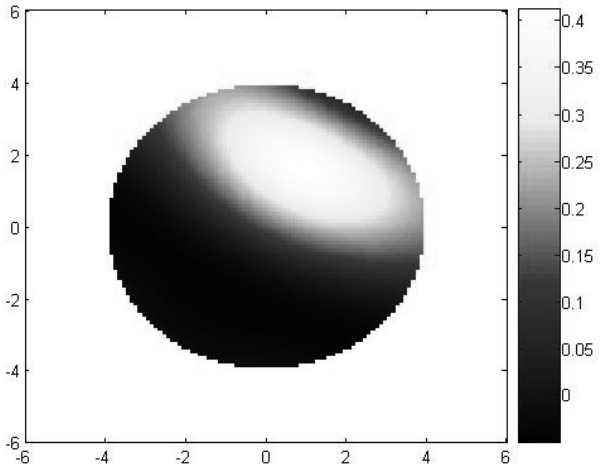

Figure 4. Sensitivity map between the 1st electrode and the 3rd electrode.

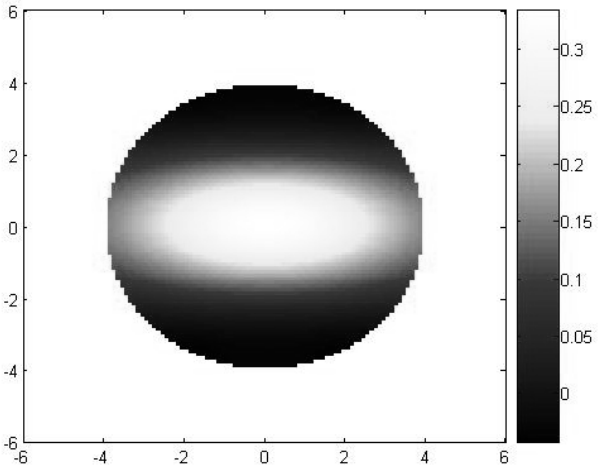

Figure 5. Sensitivity map between the 1st electrode and the 4th electrode.

IV. Image Reconstruction Technique

The image reconstruction technique used in this paper is the linear-back-projection (LBP) which is the simplest reconstruction technique. The gray level of the pixel having (x, y) as its center is given by [1]–[2]

$$G(x,y) = \frac{\sum_i \sum_j C_{ij}^* S_{ij}(x,y)}{\sum_i \sum_j S_{ij}(x,y)} \tag{6}$$

where C_{ij}^* is the normalized capacitance between the i^{th} electrode and the j^{th} electrode given by

$$C_{ij}^* = \frac{C_{ij}^{mea} - C_{ij}^{air}}{C_{ij}^{air}} \tag{7}$$

where the superscript *mea* indicates that the capacitor is measured when the sensor is filled with a sample object. The superscript *air* indicates that the capacitor is measured when the sensor is filled with air. Only the cases for *i* greater *j* are included in (6) since $C_{ij}^* = C_{ji}^*$. Due to the limitation of electrode fabrication process, the gap between each electrode is not identical. This gives a large contribution to the capacitance measurement error. In sensitivity map calculation, infinitely small gap is assumed. This causes singularities in the sensitivity maps for the consecutive electrodes. Because of these reasons, the error of the sensitivity maps for the consecutive electrodes or $i = j + 1$ is large. Because of this problem, the cases for $i = j + 1$ are not included in (6). There are only 9 terms included in each summation in (6).

V. Experimental Results

Three different sample object arrangements are used for the experiments. Each object is a water filled PVC container. The capacitance is measured using the UTI evaluation board from Smartec BV [3] shown in Fig. 6. Figs. 7–9 show the arrangements of sample objects and its reconstructed images.

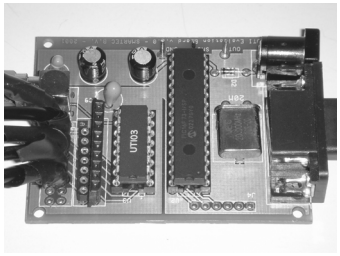

Figure 6. UTI evaluation board from Smartec BV.

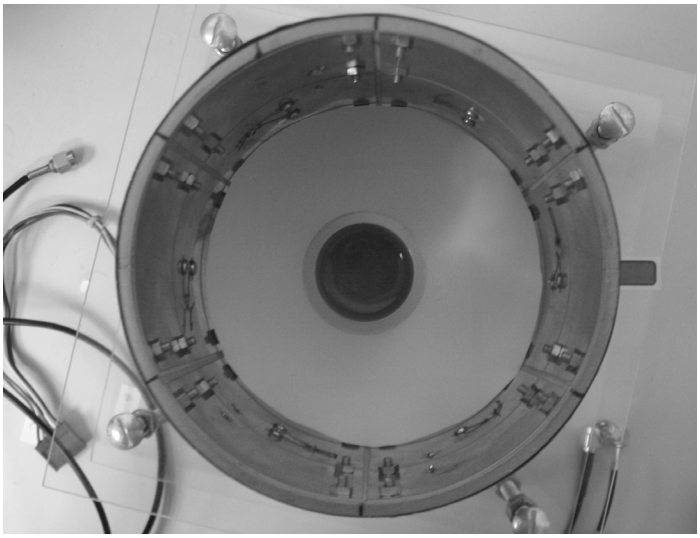
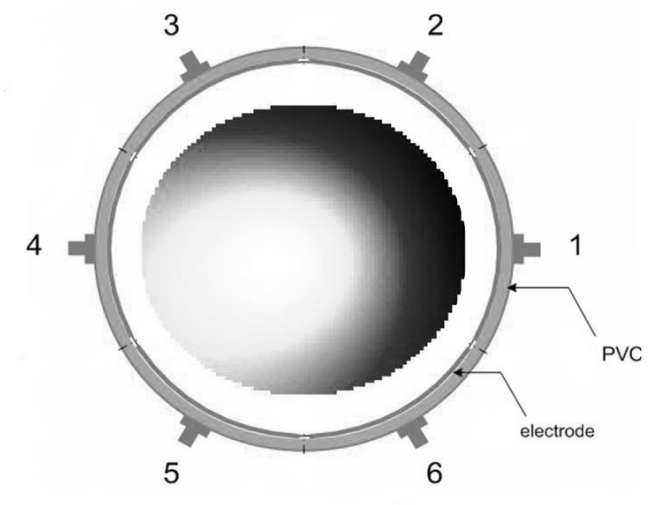


(a)



(b)

Figure 7. Case I: (a) arrangement of sample object, (b) reconstructed image.

VI. Conclusions

The results show that the reconstructed images give sizes and locations information of the sample objects. Fig. 9 shows that the reconstructed image does not have enough resolutions to separate two close objects. Increasing the number of the electrodes could improve the resolutions but it could raise the measurement error since the capacitance values would be smaller. The results serve the objective of this paper which is to implement the ECT system and show the idea of using analytical equations for the sensitivity maps instead of using the time-consuming numerical method such as FEM or FDM.

***Abstract*- A design technique for the practical implementation of a variable four-terminal floating nullor (FTFN) is presented, which contains three operational mirrored amplifiers (OMAs) and four grounded resistors. The proposed FTFN provides tunable both voltage-gain and current-gain with constant bandwidth property by varying the value of a single grounded resistor. PSPICE simulation results that agree with the theoretical analysis are obtained by modeling a variable-gain FTFN using commercial AD844 ICs.**

I. INTRODUCTION

At present, current-mode circuits have been receiving significant attention owing to its advantage over the voltage-mode, particularly for higher frequency of operation and simpler filtering structure [1]. Recently, the applications and advantages in the realization of transfer functions using four-terminal floating nullors (FTFNs) have received considerably attention. The designs of current-mode circuits employing FTFN as active devices such as amplifiers [2], current-mode filters [3-4], sinusoidal oscillators [5-6] and floating immittances [7], have been developed in the literature. Some previous-mentioned topologies have been demonstrated that an FTFN is a more flexible and all-round building block than an operational amplifier and a current conveyor [2],[4]. This is due to the fact that the nullor model of FTFN, the nullator and the norator, are isolated from each other, which is more flexible in active network synthesis. Moreover, the FTFN-based structures also provide a number of potential advantages, such as, complete absence of passive component-matching requirement, minimum number of employed passive elements. In addition, the FTFN whose the gain can be independently tuned seems to be more attractive, flexible and suitable for design and implementation of the frequency selective systems, such as, biquads, oscillator and so forth. Although some tunable FTFNs have been recently reported [8-9], they can variable only current-gain between i_w and i_z. There are no circuit realization based on tunable FTFN that can variable both voltage-gain and current-gain.

The aim of this paper is to propose a circuit technique for the practical implementation of the FTFN with variable voltage and current gains. The circuit realization uses only three operational mirrored amplifiers (OMAs) and four grounded resistors. The proposed tunable FTFN offers independently variable dc voltage and current gains while remaining a constant bandwidth. Moreover, it is interesting to show that the dc gains of the circuit can be tuned by adjusting grounded resistors without effecting the useful bandwidth. The performances of the proposed variable-gain FTFN using a commercial AD844 ICs are given with the simulation results, which will show that the characteristics of the resulting circuit become tunable.

II. CIRCUIT DESCRIPTION

An FTFN has the potential of being an extremely versatile analog active building block. It is a four-terminal active device with two input terminals (y, x) and two output terminals (w, z), whose circuit representation is shown in Fig.1. The terminal characteristics of the FTFN can be defined by means of the following relationship.

$$i_y = i_x = 0 \quad , \quad v_x = \beta . v_y \quad \text{and} \quad i_z = \pm \alpha . i_w \qquad (1)$$

where β = 1-ε, ($|\varepsilon| << 1$), and ε denotes the voltage tracking error, and α = 1-δ, ($|\delta| << 1$), and δ represents the current tracking error of an FTFN. The sign "+" is applied for the positive FTFN (FTFN+), whereas the sign "–" uses for the opposite polarity case, represented the negative FTFN (FTFN-). For an ideal FTFN, the voltage and current tracking error are equal to zero, i.e., $\varepsilon = \delta = 0$, or $\beta = \alpha = 1$. The usefulness of the FTFN can be extended if equation (1) is implemented in such a way that the voltage and current transfer ratios can be varied, in which case a more generalized tunable FTFN should be investigated.

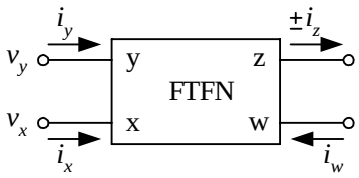

Figure 1 : Symbol of an FTFN

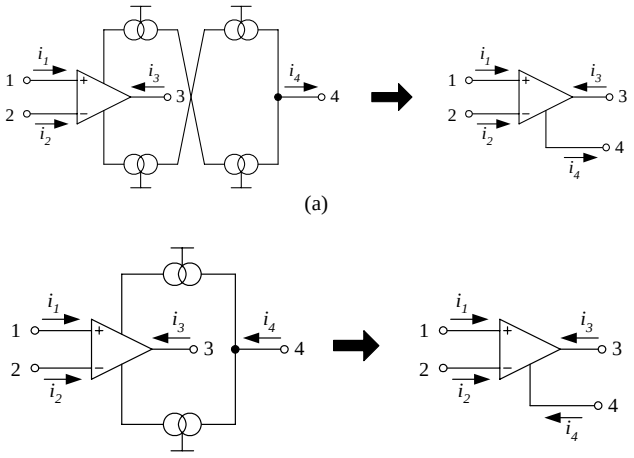
Fig.2 shows the circuit implementation and representation of the OMAs. The negative OMA (OMA-) comprising an op-amp and two pairs of current mirrors as shown in Fig.2(a) is a more general and flexible device owing to it can be equivalent to an ideal nullor or FTFN+ [1-2], whereas the other type of OMA which requires only one pairs of current mirrors is named the positive OMA (OMA+) and is shown in Fig.2(b). Therefore, it can be concluded from Fig.2 that the port characteristics of the OMA can be characterized as :

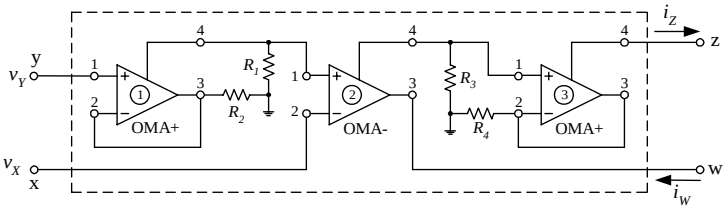
$$v_2 = v_1 \quad , \quad i_1 = i_2 = 0 \quad \text{and} \quad i_4 = i_3 \qquad (2)$$



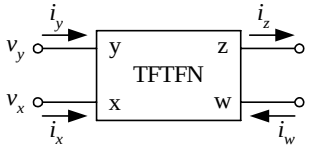
(a)

(b)

Figure 2 : Possible implementation of OMAs
(a) negative OMA (OMA-) (b) positive OMA (OMA+)



(a)



(b)

Figure 3 : Proposed tunable FTFN (TFTFN)
(a) circuit implementation (b) its symbol

The proposed tunable FTFN with arbitrary voltage-gain and current-gain, named TFTFN, is shown in Fig.3. It mainly consists of three OMAs and four grounded resistors. A detail analysis results that the voltage-current characteristics of this device can be defined by :

$$i_y = i_x = 0 \quad , \quad v_x = \left(\frac{R_1}{R_2}\right) v_y \quad \text{and} \quad i_z = \left(\frac{R_3}{R_4}\right) i_w \qquad (3)$$

Also note that the proposed TFTFN of Fig.3 is more flexible, which can be varied the voltage-gain and the current-gain through the ratio of two grounded resistors. Furthermore, if the 3rd positive OMA (OMA+) of Fig.3(a) is used instead with the negative OMA (OMA-), then the variable-gain FTFN- will also be obtained.

III. Performance Analysis

One important issue that must to be taken into account is the non-idealities of each OMA on the frequency dependent performance. Fig.4 shows the macro-model of the OMA, where β and α denote the non-ideal voltage- and current gains of the OMA. By applying the model from Fig.4 into the sub-circuit between OMA1 and OMA2 of Fig.3(a), routine analysis obtains that

$$\frac{v_X}{v_Y} = \left(\frac{\beta_1\beta_2\alpha_3 R_A}{R_2}\right)\left(\frac{1}{1+sR_AC_A}\right) \qquad (4)$$

where $R_A = R_1 // R_y // R_z$, $C_A = C_y + C_z$ and β_i and α_i are the voltage gain and current gain of the OMAi (i = 1, 2, 3). Typically, the values of R_y and R_z are too large and can also approximate to R_y , $R_z >> R_1$, then equation (4) can be rewritten as :

$$\frac{v_X}{v_Y} \cong \left(\frac{\beta_1\beta_2\alpha_3 R_1}{R_2}\right)\left(\frac{1}{1+sR_1C_A}\right) \qquad (5)$$

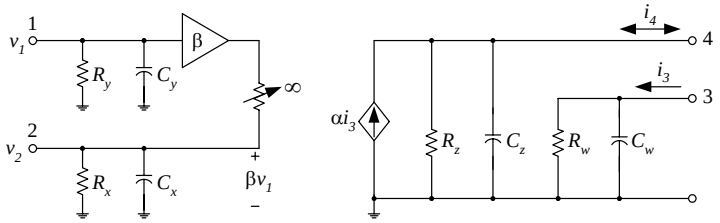


Figure 4 : Macro model for non-ideal OMA

According to equation (5), the dc voltage gain, β_{dc}, and the high-frequency dominant pole between the port y and the port x, ω_{pv}, can respectively be given by

$$\beta_{dc} = \frac{\beta_1\beta_2\alpha_3 R_1}{R_2} \tag{6}$$

and $$\omega_{pv} = 2\pi f_{pv} = \frac{1}{R_1 C_A} = \frac{1}{R_1(C_y + C_z)} \tag{7}$$

It can easily be noted from equations (6) and (7) that the dominant pole frequency can be adjusted by tuning the value of the resistor R_1, while the dc voltage-gain of this circuit can be adjusted through the resistor R_2 without affecting the bandwidth property. For example, if R_1 = 5 kΩ, C_y = 2 pF and C_z = 4.5 pF, then this pole frequency will locate at 4.89 MHz. This means that the dc voltage-gain of the proposed TFTFN can be independently varied without changing the useful bandwidth.

In the same way as above, the transfer characteristic between the currents i_Z and i_W can be considered by applying the model from Fig.4 into the sub-circuits formed of OMA2 and OMA3 of Fig.3(a). Reanalysis gives the relations :

$$\frac{i_z}{i_w} = \left[\frac{\beta_3\alpha_2\alpha_3 R_m R_z}{R_n(R_z + R_L)}\right]\left[\frac{1}{(1+sR_mC_A)(1+sR_LC_z)}\right] \tag{8}$$

where $R_m = R_3 // R_y // R_z$, $R_n = R_4 // R_x$ and R_L is the load resistance connected to the port z. Since R_3 and R_4 are very small, comparable to those resistances, i.e., R_y , $R_z >> R_3$, $R_x >> R_4$. Thus equation (8) can be reduced to :

$$\frac{i_z}{i_w} = \left[\frac{\beta_3\alpha_2\alpha_3 R_3}{R_4}\right]\left[\frac{1}{(1+sR_3C_A)(1+sR_LC_z)}\right] \tag{9}$$

if we choose $R_3 >> R_L$, then the above equation becomes :

$$\frac{i_z}{i_w} = \left[\frac{\beta_3\alpha_2\alpha_3 R_3}{R_4}\right]\left[\frac{1}{(1+sR_3C_i)}\right] \tag{10}$$

Hence, the dc current-gain, α_{dc}, and the high-frequency dominant pole between the port w and the port z, ω_{pi}, are

$$\alpha_{dc} = \frac{\beta_3\alpha_2\alpha_3 R_3}{R_4} \tag{11}$$

and $$\omega_{pi} = 2\pi f_{pi} = \frac{1}{R_3 C_A} = \frac{1}{R_3(C_y + C_z)} \tag{12}$$

From equations (11) and (12), R_3 should be selected so as to meet the desired bandwidth, whereas R_4 can be modified to change the gain without disturbing the bandwidth. Similarly, if R_3 = 5 kΩ, C_y = 2 pF and C_z = 4.5 pF, then this pole frequency is also located at 4.89 MHz. It also concludes that the dc current-gain of the proposed TFTFN can be independently controlled without changing the useful bandwidth.

IV. Simulation Results

The performances of the proposed variable-gain FTFN of Fig.3 have been simulated with PSPICE using an OMA, which consists of AD844 transimpedance op-amps as shown in Fig.5 [6]. The simulation was performed using macro-model of the AD844 IC shown in Fig.6 [12].

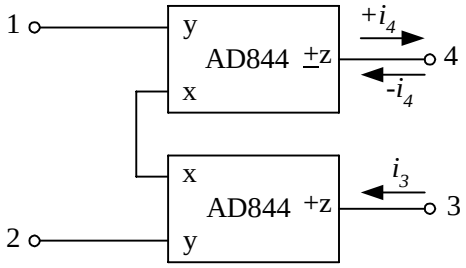

Figure 5 : Realization of OMA± with commercial available AD844 ICs

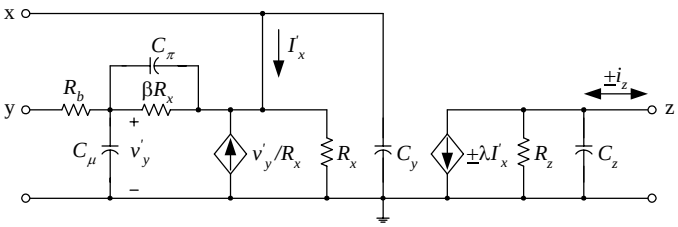

Figure 6 : Small signal equivalent circuit for the AD844 transimpedance amplifier [12] : R_b = 300 Ω, R_x = 50 Ω, βR_x = 20 kΩ, R_z = 2 MΩ, C_μ = 2 pF, C_π = 26 pF, C_x = 2 pF and C_z = 4.5 pF

Fig.7 shows the voltage frequency responses, v_x / v_y , when R_1 = 5 kΩ and R_2 is changed to 5 kΩ, 2.5 kΩ, 1 kΩ and 0.5 kΩ, which corresponds to the dc voltage gain β = 1, 2, 5 and 10, respectively.

The ac current responses of the proposed TFTFN for R_3 = 5 kΩ are shown in Fig.8. From the simulated frequency responses in Figs.7 and 8, it is evidenced in both cases that the useful bandwidth is nearly constant with respect to the variation of the voltage-gain or the current-gain of the proposed TFTFN, which are well confirmed the theoretical analysis.

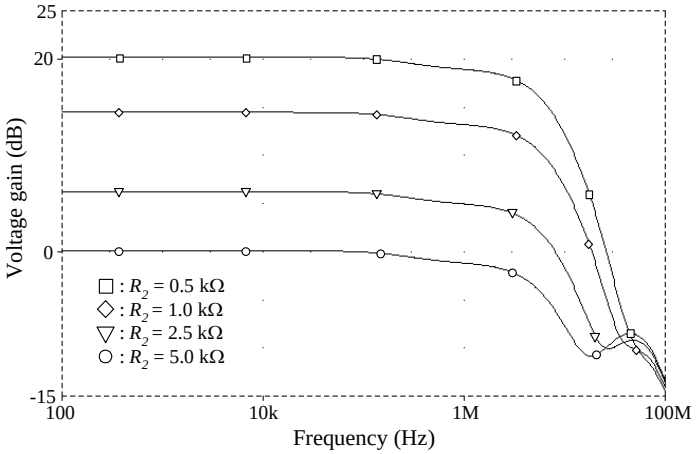

Figure 7 : Voltage transfer characteristics of the proposed tunable FTFN for R_1 = 5 kΩ

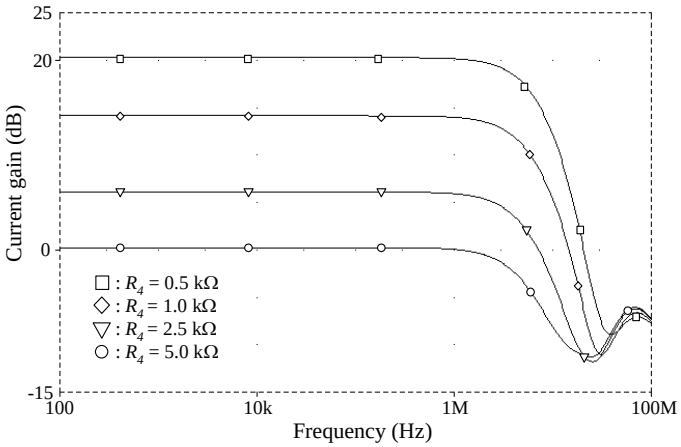

Figure 8 : Current transfer characteristics of the proposed tunable FTFN for R_3 = 5 kΩ

V. Further Applications

Finally, the proposed FTFN with variable-gain can be applied for implementing active filters with electronic control of the important circuit parameters, such as, the natural angular frequency ω_o, the quality factor (Q-factor) and the absolute bandwidth. Moreover, oscillator with electronic control of the frequency and the condition of oscillators can also be realized. But it is not demonstrated in this paper, because of some applications employing this device have been recently reported in references [7-11].

VI. Conclusions

In this paper, a circuit configuration for an FTFN with variable voltage- and current-gains is proposed in order to simplify the representation of different building block in the ideal case. The proposed tunable FTFN employs only three OMAs and four grounded resistors, and offers constant bandwidth, whereas both the dc voltage- and current-gains can be independently controlled through a single grounded resistor. PSPICE simulation results obtained from an implementation with the AD844 transimpedance op-amp have been demonstrated that its performance is quite satisfactory for discrete high-frequency circuit designs, such as, biquads, oscillators and so forth.

transfer function of the proposed filter in Fig.3 can be given by :

$$I_{o1} = -\left[\frac{g_{m1}g_{m2}}{D(s)}\right] I_1 \qquad (3)$$

and

$$I_{o2} = \left[\frac{D(s)I_2 - (sC_2 g_{m1})I_1}{D(s)}\right] \qquad (4)$$

where $D(s) = (s^2C_1C_2 + sC_2g_{m1} + g_{m1}g_{m2})$ (5)

and g_{mi} denotes g_m of the i-th MO-OTA (i = 1, 2).

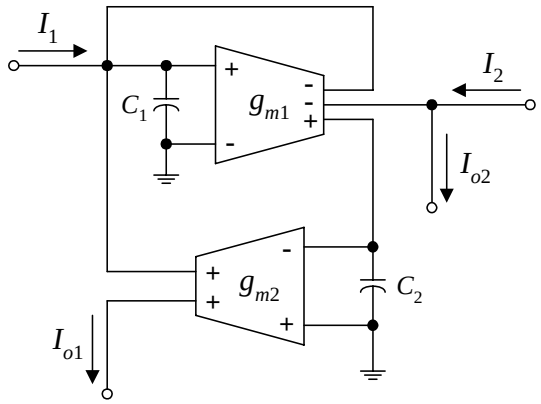

Fig.3 : Proposed TITO current-mode universal filter employing only MO-OTAs and grounded capacitors

From equations (3)-(5), it can be seen that :

1) a LP function is realized with $I_1 = I_{in}$, $I_2 = 0$ and $I_{o1} = I_{out}$.
2) a BP function is realized with $I_1 = I_{in}$, $I_2 = 0$ and $I_{o2} = I_{out}$.
3) a BS function is realized with $I_1 = I_2 = I_{in}$ and $I_{o2} = I_{out}$.
4) a AP function is realized with $I_1/2 = I_2 = I_{in}$ and $I_{o2} = I_{out}$.
5) a HP function is realized with $I_1 = I_2 = I_{in}$ and $I_{o1} + I_{o2} = I_{out}$.

Thus, the proposed TITO filter can realize all the five standard types of the biquadratic filtering functions from the same circuit configuration. Note also that the circuit needs no inverting-type current input signal for realizing any biquadratic functions. As seen from the proposed circuit configuration, it employs only grounded passive elements especially grounded capacitors and there are no critical component-matching conditions or cancellation constraints in the design, thus the circuit is very suitable for fully IC technology.

Also from equations (3)-(5), the filter parameters ω_o and ω_o/Q are given by :

$$\omega_o = \sqrt{\frac{g_{m1}g_{m2}}{C_1C_2}} \qquad (6)$$

and

$$\frac{\omega_o}{Q} = \frac{g_{m1}}{C_1} \qquad (7)$$

It can be seen from above expressions that the ω_o for all the filter responses can electronically be tuned by varying g_{m2} and/or C_2 without affecting the parameter ω_o/Q.

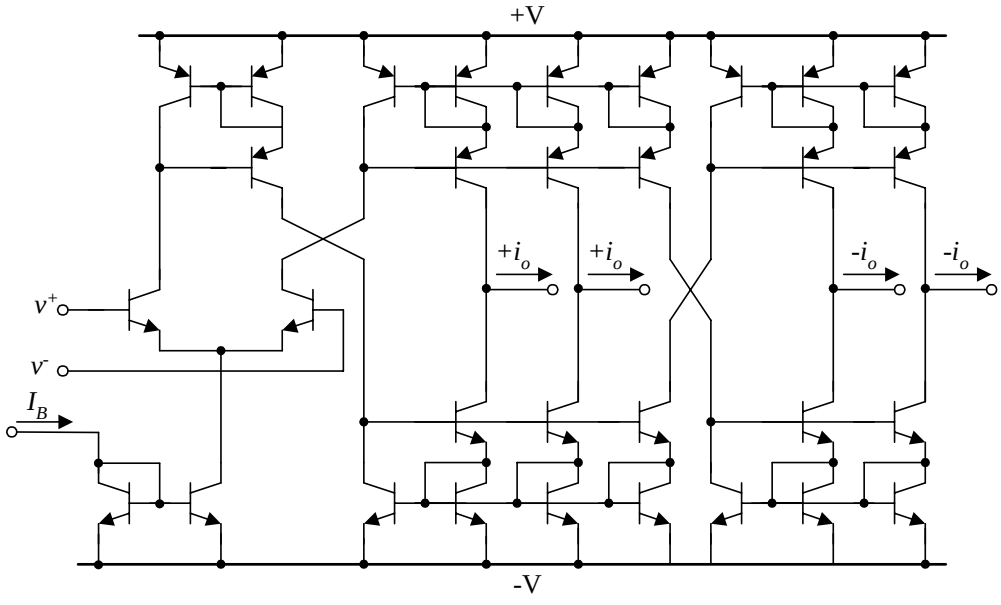

Fig.2 : Circuit diagram of an ordinary MO-OTA

Moreover, the ω_o and ω_o/Q sensitivities can be given by

$$S_{g_{m1}}^{\omega_o} = S_{g_{m2}}^{\omega_o} = \frac{1}{2} \tag{8}$$

$$S_{C_1}^{\omega_o} = S_{C_2}^{\omega_o} = -\frac{1}{2} \tag{9}$$

and

$$S_{g_{m1}}^{\omega_o/Q} = S_{C_1}^{\omega_o/Q} = 1 \tag{10}$$

All the active and passive sensitivities are not more than unity in magnitude.

III. Non-ideal Study

The circuit model of the non-ideal MO-OTA can be shown in Fig.4, where G_i and G_o are the parasitic input and output conductances, and C_i and C_o are the parasitic input and output capacitances, respectively. Therefore, re-analysis the proposed filter of Fig.3 by taking into account the non-idealities of the MO-OTA, the denominator polynomial of the non-ideal transfer function can be rewritten as :

$$D(s)=s^2C_1C_2+s[C_2(g_{m1}+G_{i1})+(C_1G_{i2})]+[g_{m1}g_{m2}+(g_{m1}+G_{i1})G_{i2}] \tag{11}$$

where G_{ik} represents the parasitic input conductance of the k-th MO-OTA.

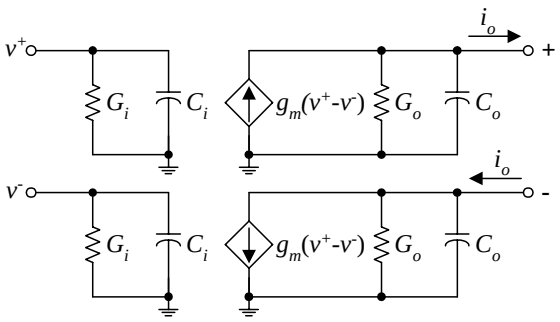

Fig.4 : Circuit model of the non-ideal MO-OTA operating in linear region

In this case, the modified parameters ω_o and ω_o/Q are calculated as

$$\omega_o = \sqrt{\frac{g_{m1}g_{m2}+(g_{m1}+G_{i1})G_{i2}}{C_1C_2}} \tag{12}$$

and

$$\frac{\omega_o}{Q} = \left(\frac{g_{m1}+G_{i1}}{C_1}\right)+\left(\frac{G_{i2}}{C_2}\right) \tag{13}$$

From these relations, the active sensitivities can be found as

$$S_{G_{i1}}^{\omega_o} = \frac{1}{2}\sqrt{\frac{G_{i1}G_{i2}}{g_{m1}g_{m2}+(g_{m1}+G_{i1})G_{i2}}} < \frac{1}{2} \tag{14}$$

$$S_{G_{i2}}^{\omega_o} = \frac{1}{2}\sqrt{\frac{(g_{m1}+G_{i1})G_{i2}}{g_{m1}g_{m2}+(g_{m1}+G_{i1})G_{i2}}} < \frac{1}{2} \tag{15}$$

$$S_{G_{i1}}^{\omega_o/Q} = \frac{1}{2}\left[\frac{G_{i1}C_2}{C_2(g_{m1}+G_{i1})+C_1G_{i2}}\right] < \frac{1}{2} \tag{16}$$

and

$$S_{G_{i2}}^{\omega_o/Q} = \frac{1}{2}\left[\frac{G_{i2}C_1}{C_2(g_{m1}+G_{i1})+C_1G_{i2}}\right] < \frac{1}{2} \tag{17}$$

It can easily be observed from equations (14)-(17) that the entire active sensitivities are still less than 0.5 in magnitude. Thus, the proposed filter structure displays a low sensitivity performance.

IV. Simulation Results

To verify the theoretical prediction, the characteristics of the proposed current-mode universal filter of Fig.3 have been simulated with PSPICE program. The MO-OTA is simulated using the bipolar structure given in Fig.2 with DC supply voltages of ±3V. The transistors model parameters are taken from the PR100N (PNP) and NP100N (NPN) of the bipolar arrays ALA400 from AT&T [8].

Fig.5 shows the simulated frequency responses of the LP, BP and HP filter functions of the proposed circuit in Fig.3. In simulations, equal bias current values of I_{B1} = I_{B2} = 100 μA, and capacitance values of C_1 = C_2 = 1 nF were chosen to obtain $f_o = \omega_o/2\pi \cong 318$ kHz and Q = 1. With the same setting, the gain and phase responses of the BS and AP filters are also given in Figs.6 and 7, respectively. All the simulation results agree quite well with the theory.

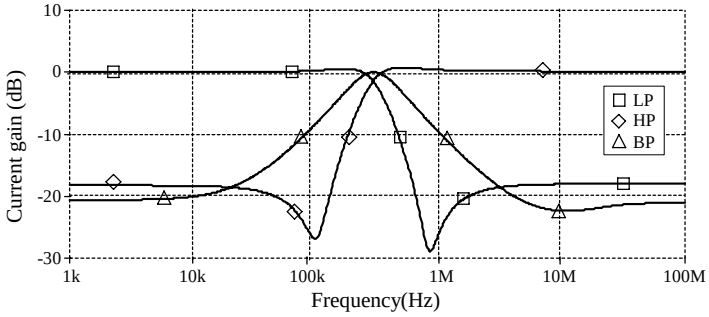

Fig.5 : LP, BP and HP current responses of the proposed current-mode universal filter in Fig.3.

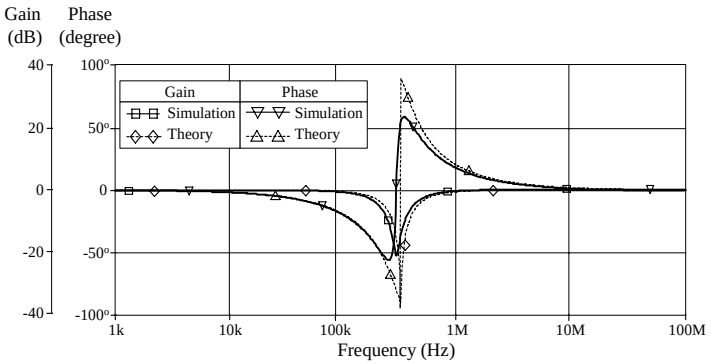

Fig.6 : BS current response of the proposed current-mode filter.

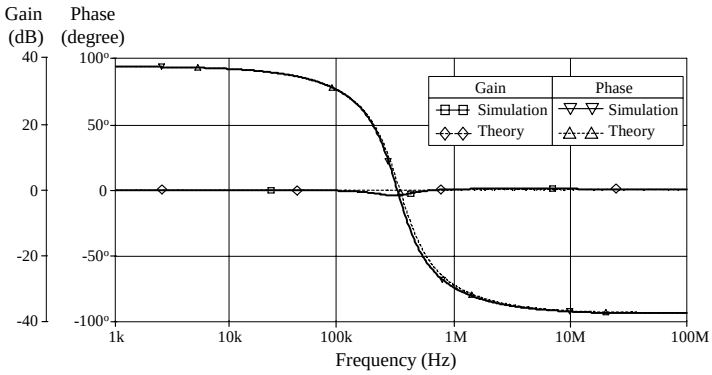

Fig.7 : AP current response of the proposed current-mode filter.

V. CONCLUSIONS

In this paper, a two-input two-output current-mode universal biquadratic filter that employs a minimum number of active and passive components has been described. The configuration consists of only two MO-OTAs and two grounded capacitors, which is advantageous from IC fabrication. The proposed filter can realize all the five standard biquadratic filter functions without any matching conditions. The filter parameters ω_o and ω_o/Q are tuned electronically and independently, and all the passive and active sensitivities are low.

***Abstract*-This paper studies the adaptive FEC control algorithms to improve control the amount of redundancy. The recently adaptive FEC "CNR algorithm" considers the history of packet loss in the network before changing the amount of redundancy and does not waste time. The performance of the CNR algorithm is used for simulation model. The smoothing parameter is varied in order to adapt and changed the characteristics of time series from the packet loss. Result shows the adaptive error control algorithm can decrease the loss rate by using a variability smoothing factor to appropriate network condition.**

I. INTRODUCTION

The motivation for transporting audio stream over IP networks potential is cost savings to achievable by eliminating or bypass the circuit-switched telephony infrastructure. The conversation quality between the sender and the receiver in the Internet telephony system is depends on specific impairments such as packet loss, delay, jitter, etc., which related to the characteristic of packet network. A number of techniques dealing with packet loss problems exist for application that exchange real-time voice [2].

Packet loss causes degradation in the quality of audio transmission applications. Forward Error Correction (FEC) methods which add redundant information to audio packets can be used to minimize the effects of packet loss. While these methods can reduce the effects of packet loss, they increase the amount of bandwidth used by an audio stream [9].

Most of audio transmission applications use UDP as the transport layer protocol. The Real-time Transport Protocol (RTP) [4] is used to provide additional functionality including sequence numbers and time stamps. The Real Time Control Protocol (RTCP) is used to return receiver statistics (e.g., the number of packets detected as lost) to the sender. RTCP packets are sent every 5 seconds by a receiver to a sender and consume very little bandwidth. IP networks are inherently best effort networks with variable packet delays and loss. While audio traffic can tolerate some amount of packet loss, a packet loss rate greater than 5% is considered harmful to the audio quality [8]. The amount of packet loss rate that can be tolerated depends on the nature of the encoding algorithm and on the sampling rate of the audio stream. Changing the IP infrastructure to support guaranteed bandwidth sessions would allow for effective transport of audio streams. Changing the Internet infrastructure is a difficult proposition, hence the interest in application level techniques for compensating for packet delay jitter and loss. Algorithms using Forward Error Correction (FEC) methods have been developed to compensate for packet loss.

However, existing methods which used media specific FEC technique can not forecast a network performance in advance. The drawback of this algorithm is in part of increasing combination number (number which specific the pattern of a redundant copy of packet) [7].

Using a currently loss report to make a decision for a transmission rate that suited for the next loss situation has not always accurate. Because of the loss rate in the next interval may not be rated to the previous intervals.

The single exponential smoothing (SES) technique is a simple and pragmatic approach to forecasting, whereby the forecast is constructed from the exponentially weighted average of pass observation [5]. If the packet loss prediction use bounded adaptive smoothing constant from the forecast loss rate in the next interval. The loss rate will be a predictable variation sequence of the number as time series (time series of packet loss), more correctly and less error in case of significant time series average changing [1].

In this paper, to study the media specific FEC-based algorithm based on increasing the combination number. The adaptive FEC control algorithm developed in [11] (the "CNR algorithm") is studied and significant improvements are evaluated. Also, Redundant Codec Combination Selection (RCCS) algorithm uses smoothing factor to calculate the reward and penalty at selecting combination [8]. Both RCCS and CNR are FEC-based error control mechanisms that the amount of redundancy is controlled by the network loss rate. This paper is to develop mechanism that attempts to eliminate or at least minimize the impact of packet loss and end-to-end delay on the quality of the audio delivered to the destinations. Analyze the effect of the variability parameters that use in process of each algorithm for improve audio transmission in the future.

This paper is organized as follows. Section II reviews the adaptive error recovery algorithms which use media specific FEC-based technique and smoothed loss scheme. Section III and IV are the experiment setup and experimental result respectively. Finally, section V presents the conclusions.

II. RECOVERY ALGORITHM WITH SMOOTHED LOSS

A. RCCS Algorithm

Myoung-Kyoung Ji[8] proposed new adaptive FEC-based algorithm, called RCCS algorithm using loss and delay in order to improve the internet telephony. They used smoothing factor for update the reward and the penalty of current combination, as in equation (1) and equation (2).

$$R_i = \alpha(L_b / L_a) + (1-\alpha)R_{i-1} \quad (1)$$

$$P_i = \alpha(D_a / D_b) + (1-\alpha)P_{i-1} \quad (2)$$

This algorithm has 3 steps: the first step updates the reward and the penalty of current combination. The second step is the procedure that selects the combination whose estimate of loss rate within the maximum and minimum threshold. The last is selects the combination that exceeds the maximum of end-to-end delay.

B. CNR Algorithm

Centre for Network Research (CNR) algorithm [11] is the media specific FEC-based algorithm. Improves the Bolot (1996) [6] algorithm by increasing the combination number of audio redundancy by one (1) in each period. This will reduce waste time from CNR algorithm chooses G.723.1 codec, because it is the most widely-used audio codec in the IP Telephony system and it has low bit rate enough (6.3 kbps) [11]. Besides, it is better than encoding each audio unit two times with high and low bit rate codec. The CNR algorithm requires the Real-time Transport Control Protocol (RTCP) packet including packet loss rate before and after the reconstruction at the receiver. Whenever the RTCP packet is received, the reward value (the L_a and L_b ratio) of current combination R_c using the loss information in the packet is calculated such as equation (3) in Figure 1.

```
For each receiver report packet received do
1.Update reward of the current combination
  //Let Rc stands for reward of the current combination
                    Rc = Lb/La                          (3)
2. Calculate the percentage of packets lost
   before reconstruction, Lb
   Lb = Number of packets lost before
        reconstruction / Number of
        packets expected
3. Calculate the percentage of packets lost
   after reconstruction, La
   La = Lb / Reward associated with current
        combination number
4. If (La > HIGH) then
     new_combination = MAX_COMBINATION
     For i =1 to MAX_COMBINATION
       Lai = Lb / reward of combination #i
       If (Lai <= HIGH) then
         new_combination = i
         exit for loop
     combination = new_combination
5. If (La < LOW)for N times then
     Decrement combination
```

Figure 1. The pseudo code of the CNR algorithm

C. Proposed Method

Base on our research, the CNR algorithm can uses the exponential smoothing method to calculate the reward value in the next interval. The reward value in a previous interval will be used to decide which combination number should be adjusted.

We added the adjustment smoothing constant which was developed by Trigg and Leach [3] in the CNR algorithm to calculate reward value for unpredictable variation sequences of the number via time series method, as in Figure 2.

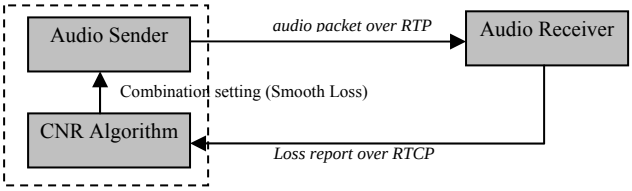

Figure 2. Mechanism to smoothing loss report

The smoothing value can obtain by the following equation. [10]

$$S_t = \alpha X_t + (1-\alpha)S_{t-1}(X) \quad (4)$$

Where S_t represents for smoothed value at time t with $0<\alpha<1$ is a smoothing factor.

Change the reward calculation (R_c) by including smoothing factor in reward formula following equation (4) by equation (5), like reward calculation in RCCS algorithm.

$$R_c = \alpha(L_b / L_a) + (1-\alpha)R_{i-1} \quad (5)$$

III. EXPERIMENT SETUP

This experiment simulated the CNR algorithm which included the adaptation logic of smoothing factor using NS-2 program [13] used a network simulator.

The topology of the simulation model is shown in Figure 3. All links are drop tail links. Most of them have 10 Mbps capacity and 1ms delay except the bottleneck link between N2 and N3 which has 2 Mbps capacity and 50 ms delay.

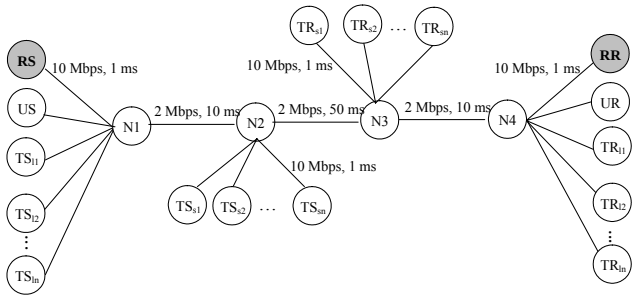

Figure 3. The topology of simulation model

The audio packets was sent from the sender (node RS) to the receiver (node RR) via the Real-time Transport Protocol (RTP) in every 30 milliseconds. RR sends the receiver report every five (5) seconds to RS. There were other nodes that sent the Transmission Control Protocol (TCP) and User Datagram Protocol (UDP) traffics. Each session was repeated by adding the smoothing factor by 0.1 until it is 0.98. The whole experiment would be repeated in each level of the loss model.

IV. Experimental Result

The performance of the recovery algorithm can be evaluated from many important parameters. Table I shows some statistics from NS-2 trace files in network. All average parameters were calculated from N1 source and N2 destination node. The packet size was 24 bytes. The audio traffic started to send a packet at 0.1 second and stopped at 1200 seconds.

The results shows that is used 0.2 as smoothing constant in the unloaded traffic situation, the receiver (RR) would receives amount of packets greater than smoothing constant at 0.98.

TABLE I
SIMULATION RESULTS FROM NS-2 TRACE FILE

Parameters	α = 0.2	α = 0.98
No. period that L_a>high threshold	19	16
Received Packets	528,500	516,505
Average Throughput (kbps)	1,882.86	1,871.72
Average Delay (ms)	7.82829	7.68629
Average Jitter1(ms)	71.018	78.1758

Figure 4 shows the comparison of different traffic congestion. It also shows that smoothing constant of 0.2 can be used in the unloaded traffic to have better amount of the received packets. And for the better result in the loaded and congested traffics, recommended adjusting the smoothing constant is 0.98.

Using the CNR to compare with RCCS mechanism for simulated the topology in the loaded traffic network, the results shown in Figure the effect of higher smoothing factor is better for adaptive error control mechanism than the lower value, as Figure 5.

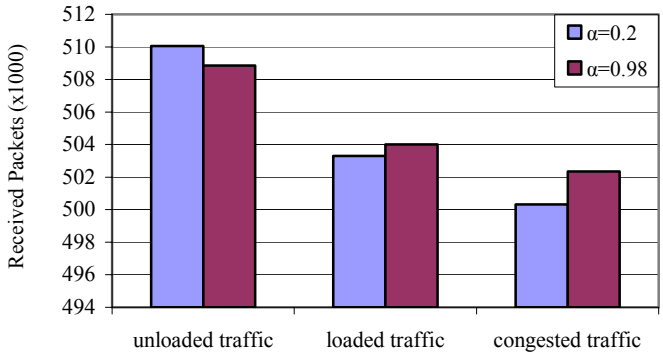

Figure 4. The received packets in different traffic congestion

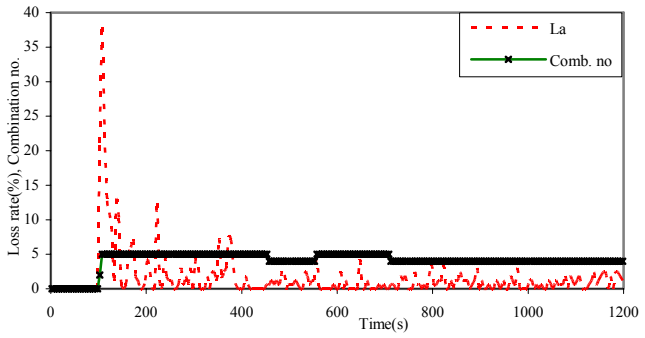

Figure 5. Behavior of loss rate when reward value follows equation (3)

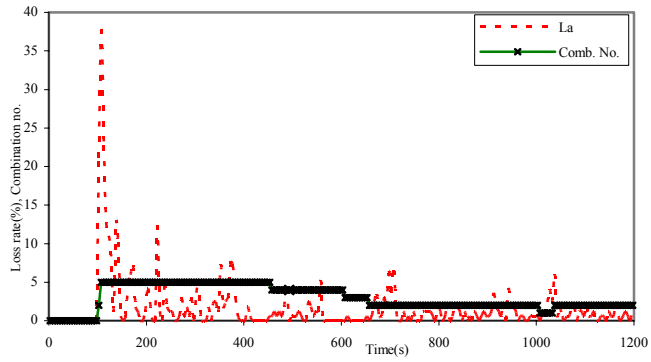

Figure 6. Behavior of loss rate when reward value follows equation (5)

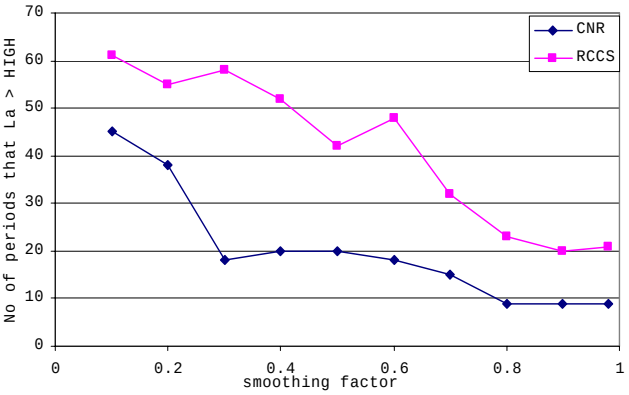

Figure 7. L_a when smoothing factor is 0.1 until 0.98 in unload traffic

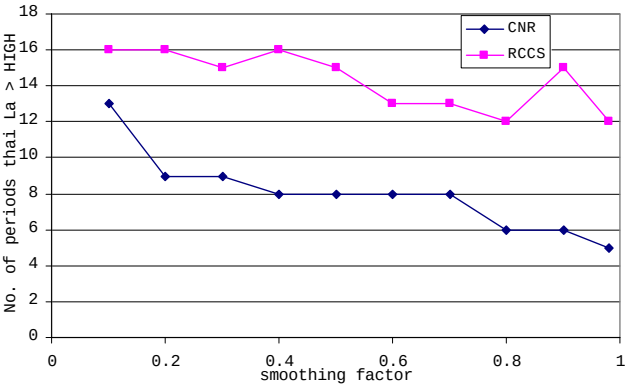

Figure 8. L_a when smoothing factor is 0.1 until 0.98 in loaded traffic

We observed from running the CNR algorithm the behavior perform follow Figure 5-8 that after changing the combination number of loaded and unloaded traffic, these two behaviors use the same value of smoothing factor, which was 0.98. However, when we adjusted a situation of network by using a smoothing factor of 0.2 in the unloaded traffic behavior and calculated the reward value (R), the results showed that the loss rate was not greater than the high threshold (5%) and not lower than the low threshold (1%). Moreover, the combination number of communication transmission was decreased. Consequently, the redundant packets were decrease. The receiver and the sender would have a better quality of communication in exchanging the real time voice.

V. CONCLUSION

In this paper, introduce an adaptive parameter exponential smoothing method to solve the drawback of the media specific FEC algorithm in part of increasing combination number. The CNR algorithm performs well when varying smooth parameter at low value (0.2) in unloaded traffic and better performance when set this parameter at high value (0.98) in loaded or congested traffic. The suited redundant information of audio packets can be adjusted to appropriate network in advance. Therefore, the adaptive recovery algorithm can apply the smooth method to recovery mechanism in order to obtain more available utilized bandwidth.

***Abstract*-This paper describes design of rectangular wave delta modulation (RWDM) buck regulator for voltage regulator modules (VRM). This regulator does not require clock generator as PWM regulators do. It has simple and compact circuit; it consumes less chip area. Hence, it is suitable for VRM application. The proposed regulator was simulated by HSpice simulation program using AMIS 0.5 µm CMOS parameters to verify the concept. It shows very fast transient response and 70.55% maximum efficiency. Moreover, the proposed buck regulator can easily be integrated onto a monolithic chip.**

I. INTRODUCTION

Buck regulators have seen increasing popularity in their utilization in the voltage regulator modules (VRM) for modern microprocessor system. To decrease power consumption and increase the speed, the microprocessors will operate at significantly low voltage and high current. A VRM is used to deliver highly accurate supply voltage regulation and high output current to the microprocessors.

Conventional buck regulators in VRM use pulse width modulation (PWM) signal to control on and off duration of switches in order to supply the input voltage to load. The switching is done at constant frequency and on time of the switch is adjusted to control the average output voltage. There are many control techniques both in analog and digital can be used to make PWM signal to control buck regulators [1-2]. However, to obtain high performance and efficiency of the regulators, a larger chip area and complexity are required to facilitate the required high performance control circuitries such as amplifier, saw-tooth generator, oscillator, A/D converter and an embedded controller in fully digital control. Function of the wave generator circuit is always critical under modern low voltage environment and having power supply variations from battery operation. Then a robust wave generator, which always comes with a high cost, will be needed. As a result, a high performance PWM-based regulator becomes expensive for a practical implementation.

RWDM principle is also another attractive technique that can be used in high performance DC-DC converters because the RWDM output signal is pulse like PWM but fewer devices are required in the control circuitries. RWDM principle is firstly applied to switching power converter system in an inverter [3]. It shows an excellent low order harmonic attenuation. Recently, the RWDM control approach has been applied and successfully implemented onto a class-D audio amplifier [4-5] of which 92% maximum power efficiency has been achieved. In scenario of efficiency, ease of control, simple and compact structure, the RWDM is seen as another promising technique to be implemented in the control loop of a buck converter. This paper presents a new RWDM-based buck regulator scheme having four advantages. First, the triangular wave generator or oscillator is not required. Second, the integrator of the RWDM loop is reduced since the actual output voltage, which is essentially proportional to the switching rectangular wave, can be used instead. Third, the switching frequency is variable. Then, the power loss is low at low load current [6]. Finally, it provides faster transient response than V^2 control method [7]. The proposed architecture is verified through HSpice simulation program.

This work has been supported by a grant from Shell Centennial Education Fund.

II. RWDM PRINCIPLE

The RWDM principle is shown in Fig. 1 [8]. Conceptually, RWDM is similar to PWM except that the input signal $V_R(t)$ is compared with the feedback signal $V_e(t)$, which is essentially the integrated signal of RWDM by integrator. Then, $V_e(t)$ can track the amplitudes of $V_R(t)$ within the ΔV hysteresis boundary. From Fig. 1, the frequency of RWDM signal can be given by

$$f = \frac{1}{T^+ + T^-} = 1 \Big/ \left(\frac{\Delta V}{m^+ - x'(t)} + \frac{\Delta V}{m^- + x'(t)} \right) \qquad (1)$$

where m^+ and m^- denote the slopes of the rising and falling

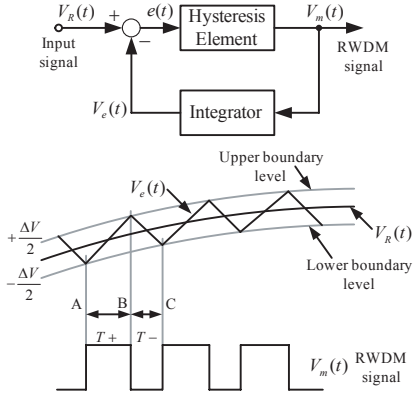

Figure 1. RWDM principle

curve of the feedback signal $V_e(t)$, respectively. $x'(t)$ is the average slope of the input signal $V_R(t)$ and ΔV is the tracking boundary corresponding to the magnitude of the hysteresis loop which is controlled directly by the trip voltage of the comparator. m^+ and m^- are also controlled by the time constant of the integrator in the feedback path. Derived in Eq. (1), the frequency of RWDM output signal is variable frequency. The frequency is a function of hysteresis boundary and slopes of both input and feedback signal.

Based on the principle, RWDM controller is simple for implementation. RWDM-based converters can then be integrated with less area consumption than conventional PWM converters. Considering Eq. (1), it can notice that the slope of the input signal $x'(t)$ of the RWDM loop is normally small in the application of switching regulator as compared to m^+ and m^-. Then, the variation of the switching frequency is not too broad and can be a predictable parameter.

The RWDM-based buck regulator is illustrated in Fig. 2. It is noted that the preliminary integrator in the RWDM loop is cancelled out of the circuit, while the integration of RWDM signal is taken from the output voltage of error amplifier node. However, this is double integral signal because a buck regulator is always second order system.

III. Buck Regulator Analysis and Design

The steady state analysis and design of RWDM-based buck regulator is discussed in this section. Fig. 3 demonstrates the ideal waveforms of output voltage and inductor current used for calculation. The proposed buck regulator is designed to meet a following specification for VRM: V_{in} = 12 V, V_{out} = 1.5 V ±1%, and I_{out} = 20 A. The inductor L is 0.9 µH, output capacitor C is 3300 µF and load resistor is 75 mΩ.

A. On-Time Interval

During MP is closed and MN is opened (t_{on}). It is obviously seen that, this is a second order system with DC forced response. The differential equation of the output voltage is

$$\frac{d^2}{dt^2}v_{out} + \frac{d}{dt}\frac{v_{out}}{R_L C} + \frac{v_{out}}{LC} = \frac{V_{in}}{LC}. \quad (2)$$

The t_{on} can be straightforward analyzed by solving second order differential equation of the output voltage under the initial condition of $v_{out}(0) = V_{out}$ and $i_L(0) = I_{L\min}$. The t_{on} is the time that $v_{out}(t) = V_{out}$. Calculating Eq. (2) yields t_{on} = 0.343 µs.

B. Off-Time Interval

The off-time interval (t_{off}) is taken during MP is opened and MN is closed. This is a second-order system with zero forced response. Thus, the differential equation of the output voltage is

$$\frac{d^2}{dt^2}v_{out} + \frac{d}{dt}\frac{v_{out}}{R_L C} + \frac{v_{out}}{LC} = 0. \quad (3)$$

Similar to the t_{on}, the t_{off} can be determined by solving Eq. (3) under the initial condition of $v_{out}(0) = V_{out}$ and $i_L(0) = I_{L\max}$. The t_{off} is the time that $v_{out}(t) = V_{out}$. Calculating Eq. (3) yields t_{off} = 2.4 µs.

C. Switching Frequency

From the above analysis, it can be observed that the time intervals are a function of L, C, load resistance, input voltage and output voltage level. Then, the switching frequency is varied as a function of these values and directly obtained from

$$f = \frac{1}{t_{on} + t_{off}} = 364.564\,\text{kHz}. \quad (4)$$

D. RWDM Signal Slopes

Referring to Eq. (1), the frequency of the RWDM signal depends on signals' slope. The input signal of the RWDM is the regulated output voltage and the feedback signal is the PI-controller output voltage. The rising and falling slope of the regulated output voltage can be approximated as follow:

$$S_R = \frac{\Delta V_{out}}{t_{on}} = 87463.56\,\text{V/s} \quad (5)$$

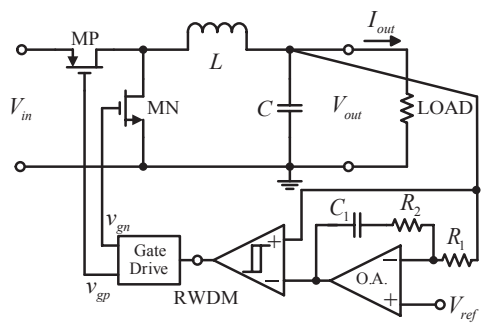

Figure 2. RWDM buck regulator

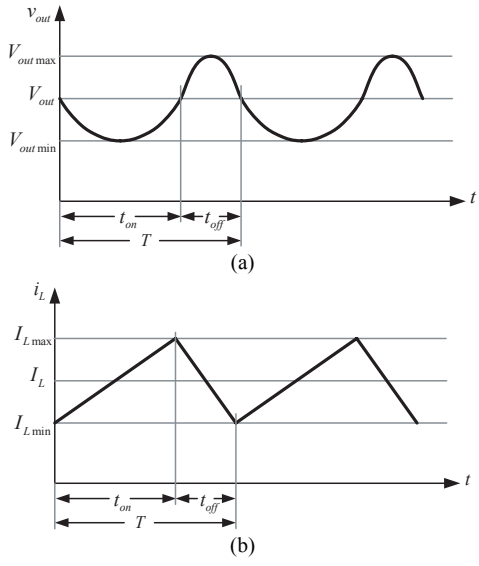

Figure 3. Ideal waveforms, (a) output voltage and (b) inductor current

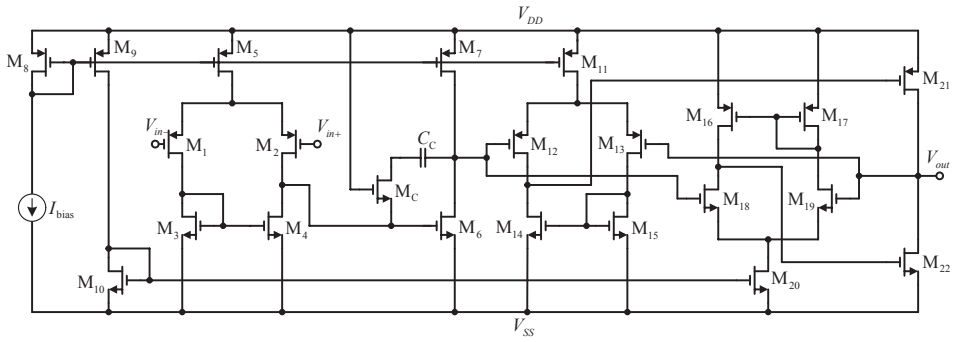

Figure 4. CMOS operational amplifier

$$S_F = \frac{\Delta V_{out}}{t_{off}} = 12500\ \text{V/s} \tag{6}$$

where S_R and S_F are the slopes of rising and falling curve, respectively. ΔV_{out} is a desired output ripple. The feedback signal slopes (m^+ for rising and m^- for falling curve) are obtained by multiplying slopes of the regulated output voltage with error amplifier gain. Error amplifier is designed using PI-controller with the gain of 50 and the integrating time of 1 ns. Thus, m^+ = 4373177.843 V/s and m^- = 625000 V/s.

E. Hysteresis Boundary

The average slope of the regulated output voltage is much smaller than feedback signal slopes. Then, the $x'(t)$ in Eq. (1) can be neglected as

$$f = \frac{m^+ m^-}{\Delta V\left(m^+ + m^-\right)}. \tag{7}$$

Substituting known value (f, m^+, and m^-) into the Eq. (7), the hysteresis boundary of the RWDM loop can then be obtained as ΔV = 1.5 V.

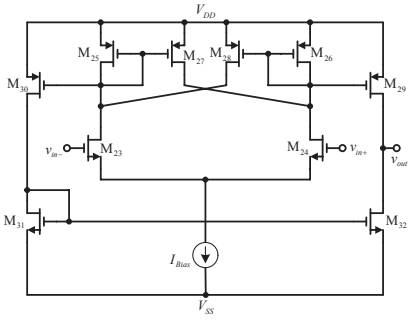

Figure 5. CMOS hysteresis comparator

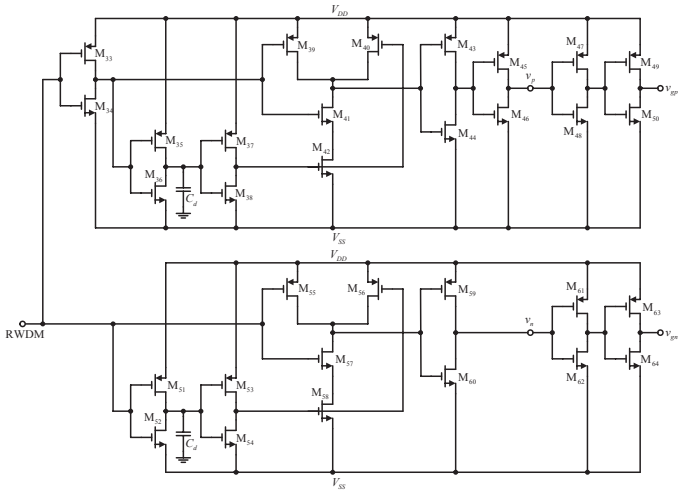

Figure 6. CMOS gate driver with dead time

IV. Simulation Results

The proposed buck regulator has been verified through HSpice using AMIS 0.5 μm CMOS parameters. The PMOS switch (MP) with W/L = 600 mm/1 μm and the NMOS switch (MN) with W/L = 200 mm/1 μm were employed. They showed 0.01 Ω on resistance. The parameter of a 0.9 μH MVR series Coilcraft inductor was used. It had 1.72 mΩ of dc resistance. The output capacitor was 3300 μF with 3 mΩ ESR. The CMOS opamp with class-AB output buffer was used as illustrated in Fig. 4. The simple CMOS hysteresis comparator in Fig. 5 was also utilized. The gate driver was design using CMOS inverter chains [9] with 100 ns dead time, demonstrated in Fig. 6. The control circuitries were biased with regulator input voltage and I_{bias} = 50 μA. The transistors aspect ratios and component values are listed in Table 1. The simulation results of the output voltage are shown in Fig. 7 and 8. The output voltage has maximum ripple of 11.8 mV and switching frequency of 407.554 kHz at 20-A output current.

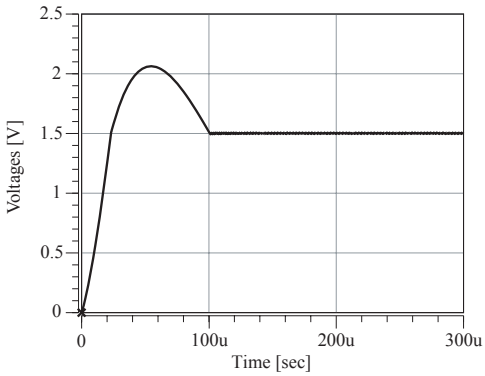

Figure 7. Simulated output voltage

Fig. 9 exhibits the regulated output voltage and current when output current is stepped from 10-A to 20-A. It can be seen that the RWDM buck regulator provides very fast transient response (approximately 1.5 μs). In addition, the switching frequency only depends on output current, but the output voltage level and ripple are not affected.

Finally, the power efficiency as a function of output current at V_{in} = 12 V and V_{out} = 1.5 V is illustrated in Fig. 10. It shows maximum power efficiency of 70.55% at 10-A output current. The power efficiency of the designed RWDM buck regulator is not too high, because the employed CMOS process is improper for high power operation. To improve power efficiency, the external discrete power MOSFET should be used as switches.

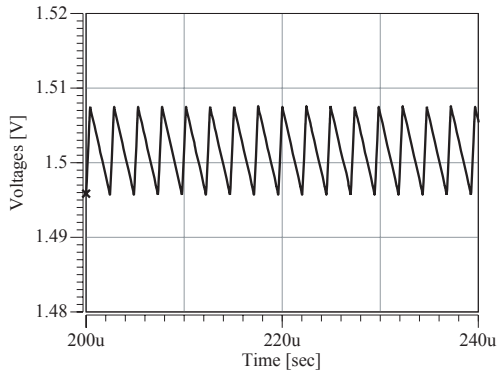

Figure 8. Simulated output ripple

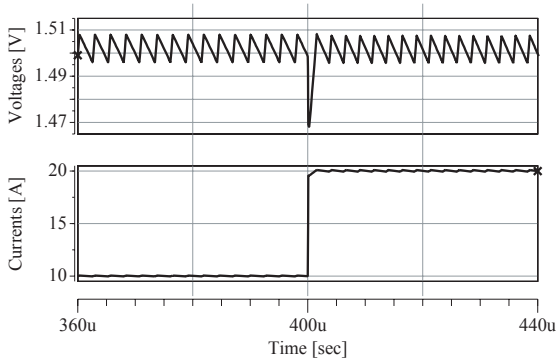

Figure 9. Regulated output voltage when output current is stepped

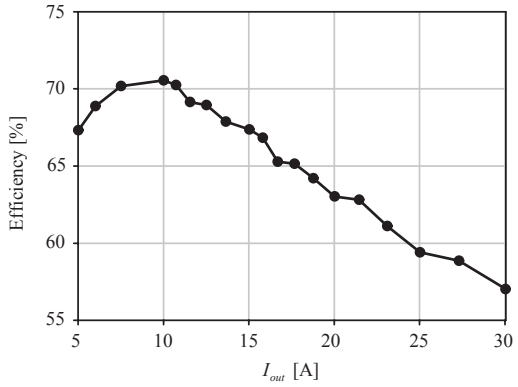

Figure 10. Power efficiency versus output current

V. Conclusion

The analysis and design of RWDM-based buck regulator for VRM is presented in this paper. It has simple circuit and can be easily integrated onto monolithic chip. Furthermore, the proposed regulator provides very fast transient response, which suitable for VRM applications. The HSpice simulation results are included to confirm the theory. They agree well with the theoretical calculations. They show 1.5 μs transient response and 70.55% maximum power efficiency.

***Abstract*— This paper presents a realization of grounded passive elements first order all-pass networks using a multiple-output operational transconductance amplifier (MO-OTA) and three grounded passive elements. The proposed circuit is operated in current-mode for the good benefit as well as high output impedance and cascadability. Therefore, it can be directly employed as a subsystem of monolithic circuit without additional matching circuits. Furthermore, a new quadrature oscillator is presented as an application for confirmed the theory and realistic practically. The PSpice simulation results verifying of theoretical are also included.**

I. INTRODUCTION

Current mode signal processing circuits have recently demonstrated many advantages over their voltage mode counterparts including increased bandwidth, higher dynamic range and better suitability for operation in reduced supply environment [1]. In many papers, current mode circuits are presented by using CCII based [2]-[4]. Unfortunately, CCII does not have a differential input. The OTA is a familiar device for voltage-mode and current-mode applications. The OTA provides a highly linear electronic tunability and a wide frequency range. Moreover, OTA-based circuits require no resistors and therefore, are suitable for monolithic implementation and small die area [5]-[6]. The MO-OTA has been proposed in previous paper [7]. From the strong points, due to many output of OTA, the MO-OTA has more flexible to use in term of a modern analog signal processing as well.

The previously presented all-pass filter topologies employing conventional OPAMP [8-9] that ensure the low bandwidth and voltage-mode are achieved. The FTFN [10], Current Differencing Buffer Amplifier (CDBA) [11] and CCII [2]-[4] are also introduced but some of these reports suffer from floating passive components. The floating components are trade-off in the practical realizations, parasitic capacitances, bandwidth restrictions, complicated adjustment. The floating node passive devices have to avoid in the design for minimized the error reasons.

This paper presents the design of all grounded passive elements all-pass network using one MO-OTA and three grounded passive elements. The presented topologies can be designed by using both in CMOS or bipolar technology. The circuits comprise phase lead and phase lag Moreover, current gain can be adjust by a transconductance (gm) through I_{abc}. The simple construction and low voltage are proposed that suitable for further IC fabrication.

II. THEORY AND PRINCIPLE

The OTA is a simple device that has been found in many recently reports. The benefit of OTA is a voltage and current mode realization can be done with a simple structure. The tunable characteristic is a strong excellent point for the future applications. The single output OTA is a conventional device that might be has some restrictions on the design. The modification of OTA can be eliminated that restrictions by extended the output port namely a multiple-output OTA (MO-OTA).

A. Multiple-output operational transconductance amplifier

The OTA has input as voltage and current output. The simple structure of the well-known OTA, having used only four transistors and current source. Figure 1 shows the symbol of MO-OTA. The output current of MO-OTA yields

$$I_o = \pm g_m (V_+ - V_-) \qquad (1)$$

The transconductance g_m is variable by bias current I_{abc}. Note that the transconductance base on CMOS and bipolar technology are equal to $(\beta I_{abc}/4)^{1/2}$ and $I_{abc}/2V_T$ respectively. A possible implementation of OTA using multiple output operation transconductance amplifiers was proposed [12].

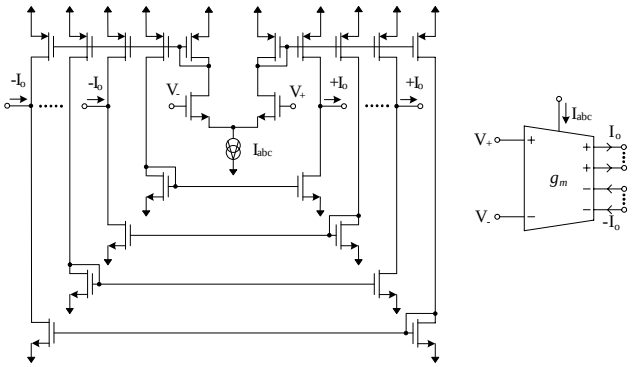

Fig.1. (a) CMOS MO-OTA structure and (b) symbol

The transconductance of above CMOS OTA can be expressed as:

$$g_m = \sqrt{\frac{\beta I_{abc}}{4}} = \sqrt{\frac{\mu C_{OX} W I_{abc}}{4L}} \qquad (2)$$

The realization of the proposed all-pass network filter using OTA is show in Fig.2. The circuit comprises one MO-OTA, 2 grounded resistors and a grounded capacitor. From this point of view, the proposed structure is simpler than the other existing all-pass realizations [2]-[4]. In Fig.2(a) and Fig.2(b), the all-pass transfer functions are realized as eq.3 and eq.4 respectively.

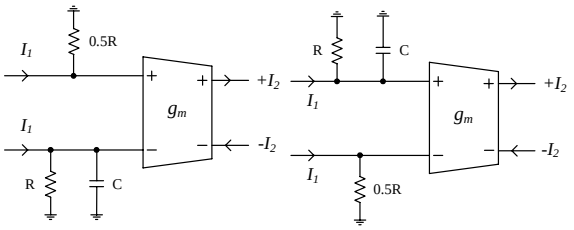

Fig.2. Proposed Allpass Filter Networks

$$\frac{I_2}{I_1} = \pm K\left(\frac{sCR-1}{sCR+1}\right) \qquad (3)$$

$$\frac{I_2}{I_1} = \pm K\left(\frac{1-sCR}{1+sCR}\right) \qquad (4)$$

Gain (K) is a constant and defined as

$$K = \frac{g_m R}{2} \qquad (5)$$

From Eq.(3), the phase shift are varying between 180° to 0° while (4), the phase shift are varying between 0° to -180°. The pole frequency (ω_o) can be expressed as

$$\omega_o = \frac{1}{RC} \qquad (6)$$

The passive sensitivities can be obtained as

$$S_R^{\omega_O} = S_C^{\omega_O} = -1 \qquad (7)$$

In Fig. 2, it can see that the output impedance of the circuit is very high due to the OTA current output; hence it can be directly interconnection with load or any current mode circuits without the buffer circuit. The output current gain can be adjusted by gm through the bias current I_{abc}.

The circuit model of a non-ideal OTA operating in saturation region is shown in figure 3, where C_i is the input capacitance, C_O is the output capacitance and G_O is the output conductance. Generally G_O is less than g_m. The proposed circuits in figure 2(a) and 2(b) can be express in term of high frequency as eq(8) and eq(9), respectively.

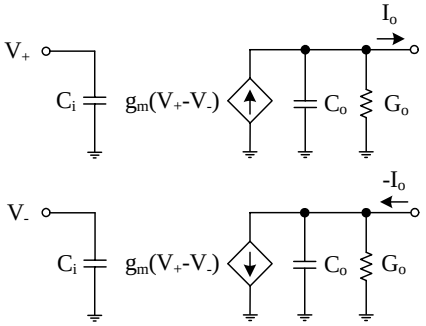

Fig.3. Circuit model for non-ideal case of the MO-OTA

$$\frac{I_2}{I_1} = \pm K\left(\frac{sR(C+2C_i)-1}{(sRC+1)(0.5sRC_i+1)}\right) \qquad (8)$$

$$\frac{I_2}{I_1} = \pm K\left(\frac{1+sR(C+2C_i)}{(1+sRC)(1+0.5sRC_i)}\right) \qquad (9)$$

From (8)-(9) imply that the parasitic capacitances affect to the poles and zeros of the transfer function at the high frequency.

III. Quadrature Oscillator Application

The quadrature oscillator based on all-pass network is shown in Fig. 4. The circuit consists of phase-lead and phase-lag all-pass network configurations in Figs. 2(a) and (b). In Fig. 4, the circuit can be oscillated due to the loop-gain is unity, the transfer function can be expressed as

$$T_1(s)T_2(s) = K_1K_2\left(\frac{1-sC_2R_2}{1+sC_2R_2}\right)\left(\frac{sC_1R_1-1}{sC_1R_1+1}\right) = 1 \qquad (10)$$

Where the constants are $K_1=g_{m1}R_1/2$ and $K_2=g_{m2}R_2/2$, loop-gain is unity independent with the any transconductances , g_{mi}. The phase of first all-pass network is written as

$$\phi(\omega) = -2\tan^{-1}(\omega\tau_1),\ \tau_1 = C_1R_1 \qquad (11)$$

Likewise, the phase of second all-pass network is

$$\phi(\omega) = 180 - 2\tan^{-1}(\omega\tau_2),\ \tau_2 = C_2R_2 \qquad (12)$$

The frequency of oscillation can be given as

$$\omega = \frac{1}{\sqrt{\tau_1 \tau_2}} \qquad (13a)$$

or

$$\omega = \frac{1}{\sqrt{C_1 C_2 R_1 R_2}} \qquad (13b)$$

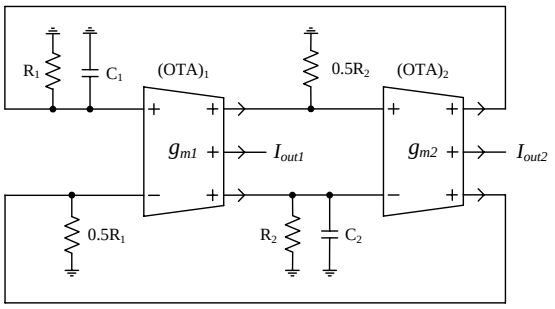

Fig. 4. The quadrature oscillator using proposed all-pass networks

From (13), the oscillation frequency is depended on passive elements, R_1, R_2, C_1 and C_2. The components are defined identically as $R_1=R_2=R$ and $C_1=C_2=C$. The oscillation frequency is actually becomes

$$\omega = \frac{1}{\sqrt{CR}} \qquad (14)$$

IV. Simulation Results

In order to confirm the validity of the proposed circuits, PSpice simulation was carried out. The parameters used in simulation are 0.5µm CMOS model obtained through MIETEC as listed in table 1. The W/L parameters of MOS transistors are assumed of 20µm/1µm for NMOS and 60µm/1µm for PMOS. The supplied voltages are V_{DD} = -V_{SS} = 1.5 V. The corner frequency of 15.9 kHz are obtained with such passive elements setting as R=10kΩ and C=10nF. The simulation results are illustrated for the current transfer function characteristic in Fig.6 (a) and Fig.6 (b). The characteristics represent for the phase response of phase-lead and phase-lag all-pass filter, respectively. It can be observed that the circuits provide a bandwidth for a several MHz. From Fig.6, the effective of parasitic capacitances at output of OTA are taken in order to the high frequency according to eq. (8) and (9).

The application of proposed all-pass networks is a quadrature oscillator as shown in Fig.4. The simulation result of proposed oscillator application has shown in Fig. 7. The 2 outputs can be obtained for a quadrature behavior. The phase different is about 90° according with the theoretical. The waveform of the quadrature oscillator are in the assuming conditions, $g_{m1}=g_{m2}$=200µs, $R_1=R_2$=10kΩ and $C_1=C_2$=0.01µF. The oscillation frequency can be obtained ensure that are in agreement with the above theoretical about 16 kHz.

V. CONCLUSION

The dual input multiple-output OTA all-pass filter topologies with all grounded passive elements are presented. The phase-lead and phase-lag can be simply modification with a few passive components changed. The proposed topologies does not limit for the implementation in bipolar or CMOS technology. The proposed circuits tried to use the MOS transistors for OTA realization. The output current can be applied to next circuit without the any matching devices. The cascadable topology is a benefit of proposed current mode schemes. The cascade of proposed both types can be obtained a quadrature oscillator as an application. Due to the minimized component, decreasing components can be done by the electronic resistors [13] that implemented from only 2 MOS transistors. The oscillator will used only 2 capacitors for the passive elements. The filter and oscillator simulation results are obtained a good agreement with the theories suitable for further IC fabrication.

***Abstract*- A physics-based, large-signal SPICE model for an abrupt-junction uniform-base InP/InGaAs SHBT is reported. This work was developed from the physics-based model for AlGaAs/GaAs SHBT. The SPICE parameters for this model are directly and automatically calculated from the transistor profile. A specific InP/InGaAs SHBT was studied. The simulations of the IV characteristics were compared with the measurements. The results show a good agreement between this work and the measurements. The comparison between the DC characteristics of InP-based HBT and of GaAs-based HBT demonstrates better suitability of this model to InP-based HBT due to the reduction of a deviation of the V_{CE} offset voltage (ΔV_{CE} offset). That of InP-based and GaAs-based SHBTS are ~0.16V and ~0.30 V, respectively.**

I. Introduction

Full-custom IC design is usually carried out by first choosing an IC manufacturing technology and then circuit development is conducted until it reaches satisfactory. This conventional IC design has the restriction upon the choices of transistor technologies and its profile. This restriction became an inspiration for a newly proposed way to design ICs. This new approached is called "Physical ICs Design" [1]. "Physical IC Design" offers a door of opportunity for circuit designers to modify and to investigate the impacts of changes of a transistor profile upon circuit performance. The new idea requires a physics-based transistor model which can provide a monitoring tool for electrical effects resulted from changes in transistor profile. This physics-based transistor model was initially begun with AlGaAs/GaAs Single Heterojunction Bipolar Transistors (SHBTs). Lately, due to an immerging of new III-V semiconductors such as InP-based HBTs casts a light into this research by reapplying the physics-based model for AlGaAs/GaAs SHBTs into InP-based HBTs. For high-speed ICs designs, InP-based HBTs are generally favorable comparing with GaAs-based HBTs because InP-based HBTs show the superior in microwave characteristics. Hence InP-based HBTs become an excellent candidate for high-speed and high-frequency applications [2].

Consequencely, the purpose of this work is to investigate the possibility for reapplying the Physical ICs design principle designed for AlGaAs/GaAs SHBTs to InP-based SHBTs. The set of SPICE parameters is directly calculated from the given profile. An accuracy of this model was verified by comparing the simulations with the measurements.

List of Symbols

D_{pE}	Hole diffusivity at emitter ($cm^{-3}\ s^{-1}$)
$\Delta Ec, \Delta Ev$	Conduction and valence band discontinuities (eV)
$\Delta En, \Delta Ep$	Electron and hole back barrier heighs (eV)
Eg_B, Eg_E	Band-gap energy at the base and the emitter (eV)
$\hbar$	Planck's constant divided by 2π (J-s)
J_C, J_E	Collector and emitter current density (A/cm^2)
L_E	Diffusion length of hole at emitter (cm)
k	Boltzmann's constant $(=1.38\times10^{-23}\ J/K)$
m_n^*	Electron effective mass at emitter (in unit of m_0)
$\overline{n}_{B0}$	Electron density at thermal equilibrium (cm^{-3})
n_{in}, n_{ip}	Intrinsic carrier density at the emitter and the base (cm^{-3})
N_B, N_E	Doping density at the base and the emitter layers (cm^{-3})
$\overline{p}_E$	Equilibrium hole concentration in emitter (cm^{-3})
q	Electron charge $(=1.6\times10^{-19}C)$
T	Absolute temperature (K)
V_{bi}	Built-in voltage (V)
V_{bc}	Applied voltage across the B-C junction (V)
V_{be}	Voltage across the B-E junction (V)
V_T	Thermal voltage $(=kT/q)$ (V)
V_{TnE}, V_{TpE}	Electron and hole thermal velocity at the emitter (cm/s)
W_E	Emitter layer thickness (cm)
Xne, Xpe	Depletion region at the emitter and the base (cm)
γ_n	Tunneling factor
$\varepsilon_B, \varepsilon_E$	Dielectric constant of the base and the emitter layers
χ_B, χ_E	Electron affinity of the base and the emitter (eV)

II. Device Structure

Table 1 shows a doping profile of an InP/InGaAs SHBT grown by MOVPE (Metal Organic Vapor Phase Epitaxy). This profiled is obtained from Topaloglu S. [3] and the electrical properties for this device are referred to [4] and [5].

Table 1
Transistor profile of InP/InGaAs SHBT
for the emitter area (A_E) of 1x15 μm^2 [3]

Emitter-cap	n++ InGaAs	1E19cm-3	100nm
Emitter contact	n++ InP	1E19cm-3	50nm

III. HBT MODEL

A. *Abrupt-Junction Uniform-Base HBTs model*

This work focuses on a large-signal InP/InGaAs HBT model [6] for the case of an abrupt-junction uniform-base structure only. The specific AlGaAs/GaAs SHBTs model development for "physical IC design" was proposed by Sa-ngiamsak C. [1]. The report of Sa-ngiamsak C. shows a good agreement between the I-V characteristic of the simulations and the measurements; Her work becomes an initiation for this work to investigating on reapplying this model to an InP/InGaAs SHBT due to its superior properties over GaAs/AlGaAs HBTs.

Reapplying the existing model of GaAs/AlGaAs HBTs to InP-based HBTs is not a straight forward task. The following investigations have to be carried out:

1. Linearity of electron back barrier high(ΔE_n)
2. Linearity of hole back barrier high(ΔE_p)
3. Effects of tunneling factor (γ_n)

The details and reasons for this condition checkout are thoroughly explained in [1] and [6]

B. *Voltage dependency parameters of an InP/InGaAs HBTs model*

According to [1], [6] and [7], the SPICE-based HBT model can be represented by using the Ebers-Moll (E-M) BJT model when Aij parameters are constant only.

The emitter and the collector currents for the E-M BJT model are written as:

$$J_E = -A_{11}\left(e^{qV_{be}/kT}-1\right)+A_{12}\left(e^{qV_{bc}/kT}-1\right)$$
$$J_C = A_{21}\left(e^{qV_{be}/kT}-1\right)-A_{22}\left(e^{qV_{bc}/kT}-1\right) \quad (1)$$

Reapplying the E-M model to represent a SHBT cannot be directly accomplished due to the Aij parameter for SHBTs are not constant.

For example, the A_{11} parameter of a SHBT is shown below:

$$A_{11} = \frac{u_n y_n \bar{n}_{B0}}{1+\frac{u_n y_n}{z_n}} + \frac{J_{PE}}{R_E}\cosh\left(\frac{W_E}{L_E}\right) \quad (2)$$

where $J_{PE} = qD_{pE}\bar{p}_E / L_E \sinh(W_E / L_E)$ and

$R_E = 1+\left(J_{pE} / qV_{TpE}\bar{p}_E\right)\exp\left(-\Delta Ep / kT\right)\cosh(W_E / L_E)$ [7]

The first and the second terms reflect the electron and the hole currents, respectively. The first term of A_{11} can be simplified as: $\bar{n}_{B0} Z_n$ where $u_n y_n / z_n >> 1$ in case of an abrupt junction [6] and $z_n = qv_{TnE}\gamma_n e^{-\Delta E_n / kT}$. Moreover, the electron back barrier height (ΔE_n), the hole back barrier height (ΔE_p) and tunneling factor (γ_n) are all a voltage dependency parameter Overcoming this matter, if the $\gamma_n e^{-\Delta E_n / kT}$ term of an InP/InGaAs SHBT can be proven as an exponential, then there is a possibility to define this term in a single diode equation.

The investigation of the linearity of the electron and hole back barrier height are shown in Fig.1 & Fig.2.

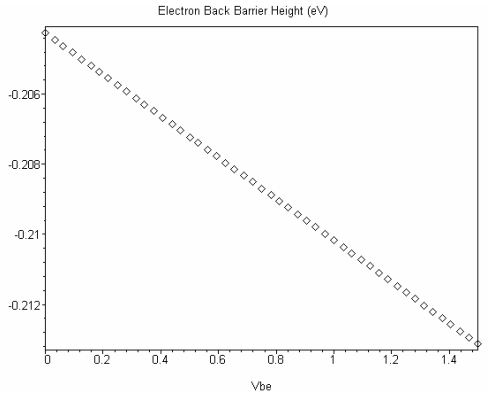

Fig. 1 Electron back barrier height in the emitter-base junction of InP/InGaAs HBTs.

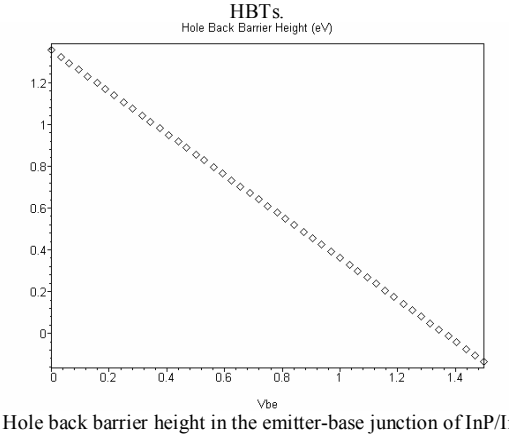

Fig. 2 Hole back barrier height in the emitter-base junction of InP/InGaAs HBTs

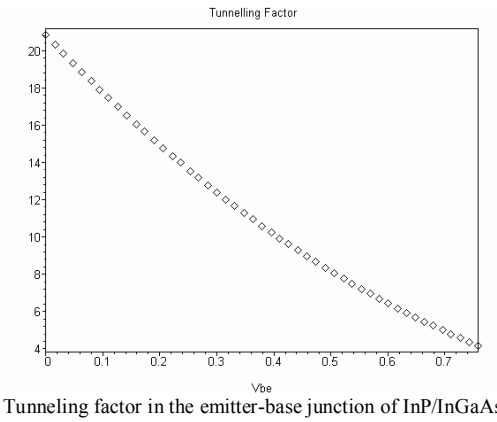

Fig. 3 Tunneling factor in the emitter-base junction of InP/InGaAs HBTs

PDF-XCHANGE Click to buy NOW! www.docu-track.com

Fig.1 demonstrates that the simulation result of the relation between ΔE_n and a bias voltage (V_{be}) is linear and so that of ΔE_p and V_{be} as shown in Fig.2. Hence, the $e^{-\Delta E_n / kT}$ term located in z_n parameter can be expressed in a diode-like format and merging the effects of ΔE_n into the E-M model in Eq.(1).

Regarding the characteristic of the tunneling factor (γ_n) shown in Fig.3, it depicts that the tunneling factor for the case of an InP/InGaAs HBT possessed an exponential relation with the bias voltage (V_{be}). So that, the $\gamma_n e^{-\Delta E_n / kT}$ terms in z_n can be exponentially expressed. In conclusion, $A_{ij}\left(e^{qV_{be}/kT}-1\right)$ and $A_{ij}\left(e^{qV_{bc}/kT}-1\right)$ of Eq.(1) can be defined in a single diode equation.

C. *Verification of Assumptions in the Model*

The assumption of $(u_n y_n / z_n)+1 \approx (u_n y_n / z_n)$ which was applied to Eq.(1) is proven in Fig.4

Fig.4 is a plot of $(u_n y_n / z_n)$ of the InP/InGaAs SHBT profile shown in Table 1. This figure clearly demonstrates that $(u_n y_n / z_n) >> 1$ for the normal mode operation range of V_{be} (0.4-1.0 Volt).

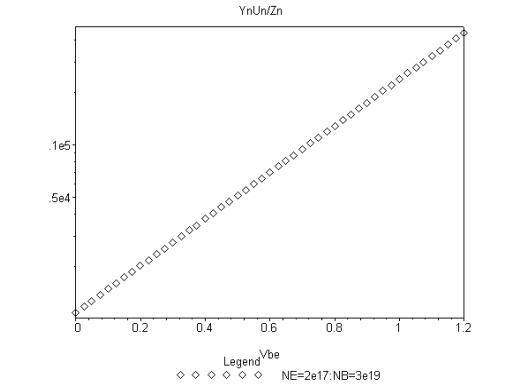

Fig. 4 The estimation result of $u_n y_n / z_n$ term in case of InP/InGaAs SHBT, for the doping profile listed in Table 1

An exponential expression of the voltage-dependent term $\left(\gamma_n e^{-\Delta E_n / kT}\right)$ describes the carrier transport across a heterojunction. The $\gamma_n e^{-\Delta E_n / kT}$ term which consists of physics-based equations of the device is fitted to $A^* e^{-V_{be}/SVt}$ where A^* and S are constant. The results of the best fit for the InP-based SHBT profile given in Table 1 are show in Fig.5. The best-fit parameters (A^* and S) for a range of doping concentration were calculated and listed in Table 2.

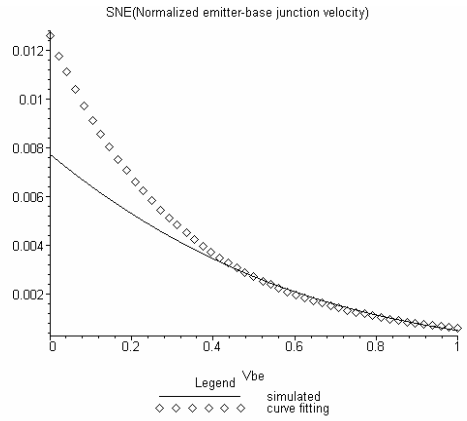

Fig. 5 The product $\gamma_n e^{-\Delta E_n / kT}$: comparison of the result from computation and the best-fit, over the bias range 0.4-1.0 V. for the uniform-base InP/InGaAs SHBT

IV. Results and Discussions

This section presents the comparisons of the DC characteristic obtained from the simulation and the measurements [3] of the InP/InGaAs SHBT profile given in Table 1. The simulation results were generated by using PSpice where the list of the calculated SPICE parameters is in Table 3. The simulation results (dashed-lines) and the measurements (solid-lines) are depicted in Fig.6.

Table 3
SPICE parameters of InP/InGaAs SHBT [6]

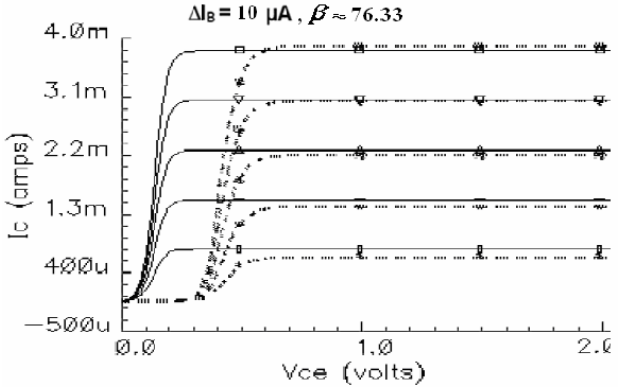

Fig. 7 Comparison of the DC characteristics between measurements(dashed-lines) and simulations (solid-lines) of the AlGaAs/GaAs HBTs where [1]

Fig.6 demonstrates a nice agreement of extending this model into InP/InGaAs SHBT devices. However, the deviation increases with smaller I_b due to the influence of the surface recombination effect being ignored at the low-level injection of carrier into emitter-base heterojunction [8].

Moreover, this model is proven to be more suitable to InP/InGaAs SHBT devices than AlGaAs/GaAs SHBT due to a smaller deviation of the V_{CE} offset voltage between the simulations and the measurements. The comparison of this figure between InP/InGaAs SHBTs (Fig.6) AlGaAs/GaAs SHBTs (Fig.7) listed in Table 4.

V. Conclusion

The extension of the physics-based HBT model for AlGaAs/GaAs HBTs has been successfully applied to InP-based HBTs. The set of SPICE parameters for a given transistor profile was calculated; and the accuracy of this approach was verified by comparing the simulations with the measurements of the specified transistor for the case of an abrupt-junction uniform-base InP/InGaAs SHBTs. The results show a good agreement in DC characteristics and an improvement in the reduction of an error regarding to knee voltage. This work can benefit to further study on the finding of a suitable InP-based SHBT profile for a specific-purpose integrated circuits which is the core of "physical ICs design" approach.

Appendix: Electron and hole back barrier heights ($\Delta E_n, \Delta Ep$) [1]

From the energy band diagram of a heterojunction is shown

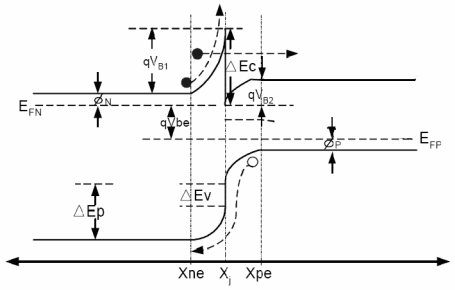

Fig.A1 Energy band diagram of an abrupt-junction and graded base HBT

The electron barrier height (ΔE_n) of an abrupt heterojunction is given by

$$\Delta E_n = qV_{B2} - \Delta Ec \qquad \text{(A1)}$$

where $qV_{B2} = \frac{qN_B}{2\varepsilon_B} Xpe'$, $Xpe = \sqrt{\frac{2N_E\varepsilon_E\varepsilon_B(Vbi - Vbe)}{qN_B(N_E\varepsilon_E + N_B\varepsilon_B)}}$,

$$\Delta Ec = \chi_B - \chi_E,\ Vbi = \Delta Ec - \frac{Eg_E}{2} + \frac{Eg_B}{2} + \frac{kT}{q}\left(\frac{N_E N_B}{n_{in} n_{ip}}\right).$$

The hole barrier height (ΔE_p) is defined as a level of energy which holes need to travel from the heterojunction to the emitter area. The function of the hole barrier height is given by

$$\Delta E_p = qV_{B1} - \Delta Ev \qquad \text{(A2)}$$

where $qV_{B1} = \frac{qN_E}{2\varepsilon_E} Xne'$, $Xne = \sqrt{\frac{2N_B\varepsilon_E\varepsilon_B(Vbi - Vbe)}{qN_E(N_E\varepsilon_E + N_B\varepsilon_B)}}$,

$$\Delta Ev = \Delta Eg - \Delta Ec$$

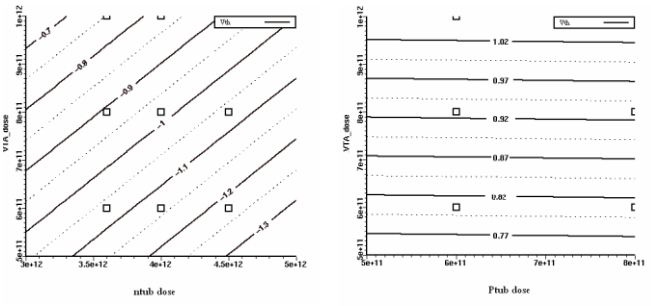
***Abstract*-This paper describes the concept, design and characterizations of 0.8 CMOS for technology development at Thai Microelectronics Center (TMEC). Both NMOS and PMOS have been designed form concept and using the process simulation software TSUPREM-4 and device simulation software MEDICI. Device design emphasis for example threshold voltage, off state leakage current, punchthrough voltage and Drain Induced Barrier Lowering (DIBL) effect have been seriously investigation to improve the device performance. Furthermore, the sensitivity of following parameters such as N-well dose and energy, voltage threshold adjust(VTA) dose and energy, gate oxide thickness and gate length variation have been determined. Extraction of devices model have been done on test chip. Based on measurements results, the I-V characteristics of MOSFET and Voltage Transfer Characteristics (VTC) of a testing inverter were present.**

I. INTRODUCTION

TMEC have been developed the 0.8 μm CMOS technology fabrication. Some parameters such as threshold voltage, off state leakage current, punchthrough voltage, and subthreshold behaviors should be carried out and determined. TSUPREM-4 and MEDICI are used to simulate that act as a guide line. In this paper, the design, fabrication and device characterization of 0.8 CMOS technology were proposed

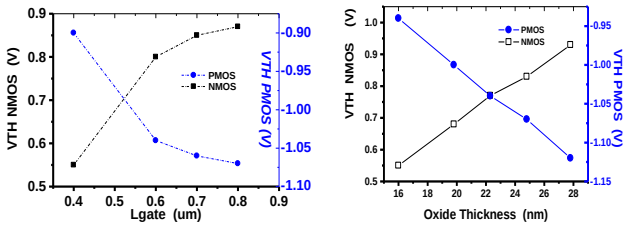
II. DEVICE DESIGN

Twin well process is used for NMOS and PMOS independently. The N-well and the P-well were fabricated by phosphorus with dose of 3.6×10^{12} cm^{-2} and boron implantation with dose of 6×10^{11} cm^{-2}. For its dose, N-well and P-well doping concentration were approximately 3.0×10^{16} cm^{-3} and 1.0×10^{16} respectively. Both well are done on p type substrate 5 ohm-cm. of resistance .In order to minimize the complexity of fabrication process, n^+ polysilicon is fabricated for gate electrode. A boron ion implantation for threshold voltages adjust in a channel was implemented in order to match the threshold voltage of the NMOS and PMOS device, as require in the modern CMOS technology process. As a result, a surface channel and a buried channel are formed in NMOS and PMOS respectively. The magnitudes of threshold voltage depend on various parameters in channel doping implants simulated by MEDICI shown in Fig.1. In order to get the threshold voltage $|V_{TH}|\cong$ 1.0 V for NMOS and PMOS, the N-well implantation dose must be 4.5×10^{12} cm^{-2} and the boron implantation dose must be more than 9.0×10^{11} cm^{-2}. Fig.2 shown the threshold voltage of both MOSFET versus gate length and oxide thickness also. The threshold voltage is change rapidly as the gate length is less than 0.6 μm. The low threshold voltage is designed to improve the output current. The Anti-punchthrough implantation of NMOS is used for punchthrough suppression. The energy is 50 KeV. So that the channel peak concentration is approximately the S/D junction depth to reduce the lateral widening of depletion region at the drain end and prevents the Drain Induced Barrier Lowering (DIBL) effect also.



(a) (b)

Fig.1. Simulated threshold voltage of NMOS and PMOS versus (a) N-well implantation dose and VTA implantation dose and (b) P-well implantation dose and VTA implantation dose



(a) (b)

Fig.2. Simulated threshold voltage of NMOS and PMOS versus (a) gate length and (b) oxide thickness

For isolation, the field oxide thickness is 650 nm .The field threshold voltage which is more than 15 V for supply operation under the thick field oxide is designed. The N-field implantation beneath the field oxide is implanted for increasing the field threshold voltage. However, the bird's break encroachment must be controlled in order to affect the source/drain formation. Besides this effect, the bird's beak encroachment into the active area must be determined in order to know the minimum design gate width which has an

enough active area will be form. To reduce the hot carrier, phosphorus with 6×10^{13} cm^{-2} and boron with 1×10^{13} cm^{-2} is implemented to form the lightly doped drain (LDD) of NMOS and PMOS structure. As and BF_2 are implemented to produce source/drain to achieve 54 Ω/sq for n^+ and 65 Ω/sq for p^+ source/drain. From simulation results, the S/D junction depth was 0.3 and 0.5 μm for NMOS and PMOS and the effective channel length was approximately 0.6 μm of both MOSFET also. The shallow junction will be improved the subthreshold swing to 80 mV/dec and minimized the Drain Induced Barrier Lowering(DIBL) effect.

III. Process Fabrication

Twin well process are fabricated for NMOS and PMOS independently. The N-well and the P-well were implemented by phosphorus with dose of 3.6×10^{12} cm^{-2} and boron implantation with dose of 6×10^{11} cm^{-2}. For its dose, N-well and P-well doping concentration were approximately 3.0×10^{16} and 1.0×10^{16} cm^{-3} respectively. Both tubs are done on p type substrate 5 ohm-cm. In order to minimize the complexity of fabrication process, n^+ polysilicon is fabricated for gate electrode. A self align n^+ polysilicon gate was 350 nm in thickness and gate oxide was 25 nm in thickness. A boron ion implantation for threshold voltage adjusts in a channel was implemented in order to match the threshold voltage of the NMOS and PMOS device, as require in the modern CMOS technology process. As and BF_2 are implemented to produce source/drain to achieve 54 Ω/sq for n^+ and 65 Ω/sq for p^+ source/drain. The 350 nm polysilicon is grown on gate oxide and used phosphorus implanattion to form n^+ polysilicon gate. After NMOS and PMOS LDD implantation, the sidewall is formed and the following S/D implantations are done. The annealing process 900°C, 30 min is done to activate impurity and maintain the impurity doping profile. After front end process, the oxide, SOG and oxide dielectric layer is deposited and reflow at 750 °C. The contact windows are opened and 30/80 of Ti/TiN are deposited and follow by metal1,TiN deposition and patterning. After an IMD layer is deposited follow by the via, windows are opened. The metal 2 and TiN are deposited and patterned. The next deposition layer is nitride to act as a passivation layer. After passivation layer, the pad window is opened to measure.

IV. Device Characterization

Measurement and extraction of a testing device are tested on a test chip. Some performance such as threshold voltage, saturation drain current, leakage current and punchthrough voltage have been determined. All I-V characteristics measurements have been done at the room temperature. The measurement system is consisted of probe station cascade ALESSI REL6100 model, semiconductor parameter analyzer HP4156B, Precision LCR meter HP 4184A, low leakage switch E5250A and ICS software for measurement through PC computer as a controller. The device parameters with N-well dose of 3.6×10^{12} cm^{-2} and VTA with dose of 9×10^{11} cm^{-2} are illustrated in table I

TABLE I
DEVICE PARAMETERS

Parameter	NMOS	PMOS	Units
Threshold Voltage	0.77	-0.68	V
Body Factor	0.6	0.64	$V^{1/2}$
Process Transconductance	74.6	26.3	$\mu A/V^2$
Effective Channel Length	0.57	0.78	μm
Width Encroachment	0.18	0.2	μm
Punch Through Voltage	12	-13	V
Leakage Current	1	1.5	pA/μm
Maximum Drain Current	328	148	μA/μm
Poly Field Threshold	10	-12	V

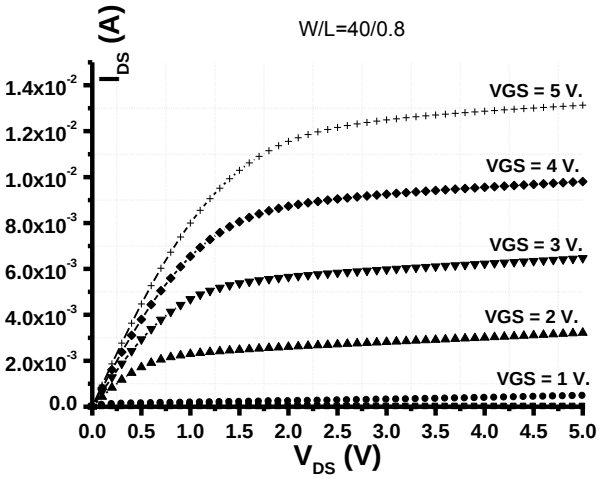


Fig.3. Measured I_{DS} &V_{DS} of NMOS with different V_{GS} (0→5 V, 1V./step)

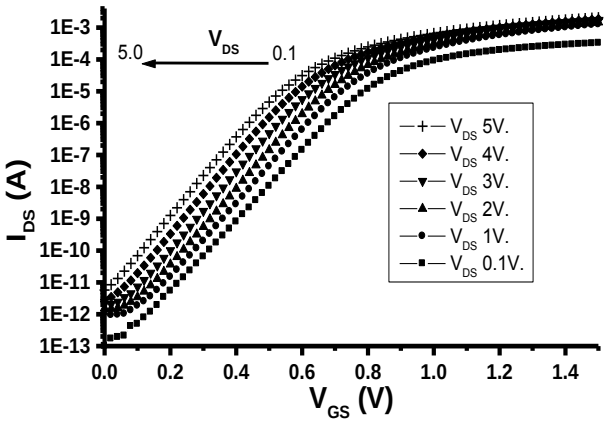

Fig.4. Measured Log I_{DS} &V_{GS} of NMOS with different V_{DS} (1./step)

Fig.3 shows the I_{DS}&V_{DS} characteristics of NMOS. The saturation current per width of NMOS and PMOS is 328 and 148 μA/μm respectively. Fig.4 shows the I_{DS}&V_{GS} characteristics of NMOS as the gate voltage V_{GS} is sweep from 0V to 1.5 V at different drain voltage V_{DS} and grounded

source and substrate together. The off stage current is in order of pA/μm for both.

The subthreshold swing is measured and compared with simulation results. The measured subthreshold swing is approximately 100mV/dec for both. The measured curve indicated that there was no punchthrough effected on a testing device same as the simulation results. The punchthrough effect is measured on I_{DS}&V_{DS} curve by sweep the drain voltage from 0 V to 20 V and ground gate and source terminal. The punchthrough voltage detected at drain current of 1nA/μm [1] is 12 V for NMOS and -13 V for PMOS.

The DIBL effect is observed by a shift of threshold voltage as a function of drain voltage The threshold voltage measurement for testing device is performed by measuring a set of I_{DS}&V_{DS} with increasing V_{DS} value as a parameter. The gate voltage at which the drain current of 0.1μA/μm is claim the threshold voltage. The measured DIBL is 40mV/V and 50 mV/V of NMOS and PMOS respectively. Since the buried channel PMOS, then more leakage current flow.

Based on the spice model level 3, the extraction model parameter was done on the testing device with the W/L ratio 40/40, 40/0.8 and 0.8/40 of value. Fig.5 show the measurement and simulation I-V curve for 40/0.8 NMOS device. It can be seen that the prediction model does not fit well with experiment. This may be because of limitations in spice model level 3.

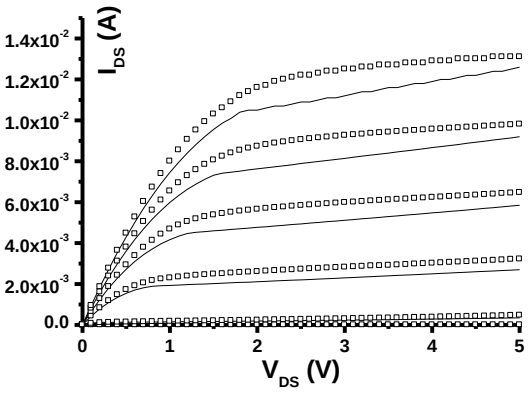

Fig.5. comparison between measurement (square symbol) and simulation (straight line)I-V characteristics of NMOS with dimension 40/0.8 .the drain bias is sweep from 0 to 5 V.(0.1V/step) and the gate voltage is step from 0 to 5V, (1V/step)

For a basic circuit testing, we test the basic CMOS inverter with a difference size of PMOS to compare with NMOS. The minimum dimension W/L of NMOS is designed at 1.6/0.8. The Voltage Transfer Characteristics (VTC) of a testing CMOS inverter show in Fig.6. The supply drain current I_{DD} versus input voltage Vin for CMOS inverter show in Fig.7. The maximum supply drain current is 130 μA at the midway of input voltage and the maximum power dissipation is a function of supply voltage.

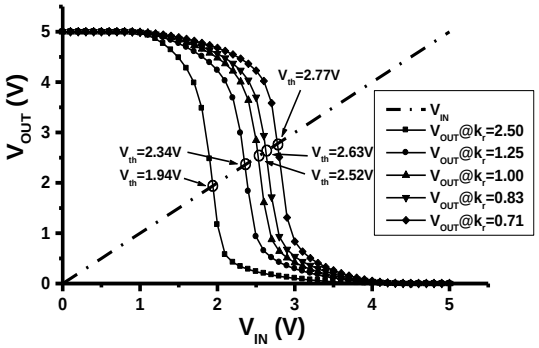

Fig.6. Measured Voltage Transfer Characteristics of a CMOS inverter with K_r as a parameter (K_r=2.5[$(W/L)_n/(W/L)_p$])

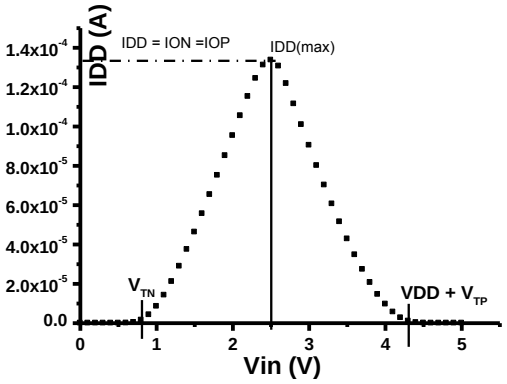

Fig.7. Measured CMOS supply drain current at K_r = 1.0

V. CONCLUSION

The 0.8 CMOS technology fabrication have been designed and developed at Thai Micro Electronics Center. A single Voltage Threshold Adjust (VTA), Anti Punthrough (APT) process and n^+ polysilicon gate electrode are fabricated to minimize the complexity of fabrication process can be achieved. The I-V curve show that the MOSFET is a good turn off rate in subthreshold region and no punchthrough problems. Surface DIBL investigation shows no surface leakage current. Using an inverter for a basic circuit testing, The VTC shows a good curve at Kr = 1.0.

ACKNOWLEDGEMENT

Characteristics of GaAs-based Phototransistors After High-Power Operation

N. Thudsalingkarnsakul, S. Thainoi and S. Kanjanachuchai
Semiconductor Device Research Laboratory, Department of Electrical Engineering
Faculty of Engineering, Chulalongkorn University, Phayathai Road
Bangkok 10330, Thailand

***Abstract*-A commercial phototransistor (SG-105F) with a rated power of 50 mW has been subject to high-power operation (at 300 mW). Its electrical and optical characteristics before and after 24, 48 and 72 hours of high-power operation are analyzed. The output electrical characteristics (I_C-V_{CE}) and the sensitivity (I_C/I_{LED} ratio) show degradation behaviors which correlate well with the optical measurements. The photocurrent-wavelength plot indicates that the intrinsic properties of the material do not change while the reduction in the peak photocurrent values, together with the electrical results, positively identifies increased contact resistance as the source of the device's degradation.**

I. INTRODUCTION

Phototransistors are widely used in many applications; for examples, in floppy disk drives and in toll booths. After several years of operation, the phototransistors may lose their sensitivities and may malfunction as a result. The purpose of this paper is to subject a sample phototransistor to high-power operation and study the degradations in electrical and optical characteristics.

The high-power operation or high-current injection is an attempt to simulate long-term operation of the device under normal biasing conditions and thus can be thought of as an accelerated DC aging process [1, 2].

The main function of phototransistors is to detect light, or photons. The structure of phototransistors is the same as a typical bipolar junction transistor (BJT) which consists of an emitter (E), a base (B) and a collector (C). Only the E and C terminals are available; the base is exposed to the environment via a transparent capping material. Photon can travel through the capping material and be absorbed by the base, generating free carriers which can move under an externally applied electric field (V_{CE}, for example). The output from the phototransistor is the collector current (I_C) whose magnitude depends on the biasing circuit and the wavelength and the intensity of the input light.

The phototransistor under test will be characterized electrically and optically before and after being subject to high-power operation. The electrical measurements will examine how much output (I_C) can be obtained for a fixed input light, while the optical measurements will determine the range of wavelengths to which the device is sensitive.

The organization of the paper is as follows: the experimental procedures will be given in Section II, followed by results and discussions in Section III and the conclusion in Section IV

II. EXPERIMENT

The device under test is a commercially available phototransistor (SG-105F) manufactured by Kodenshi. The SG-105F is a reflection-based device that consists of an infrared light-emitting diode (LED) placed next to an npn GaAs-based phototransistor.

The LED emits light at a peak wavelength of 940 nm. The sensitivity of phototransistor can be measured from the I_C/I_{LED} ratio. Given a constant I_{LED}, the higher the output current I_C the more sensitive the device to the input light. The I_C/I_{LED} ratio will be used extensively in the analysis in the next section.

The electrical measurements set-up is shown in Fig. 1. The LED is fed with a constant current of I_{LED} = 40mA by a power supply, Advantest TR6143. The light is reflected off a mirror towards the phototransistor which is biased at a constant voltage of V_{CE} = 5V, while the collector current I_C is simultaneously measured (by a Pico-ammeter, HP4140B). This set-up is considered a normal operating condition.

In the high-power operating mode (to simulate long-term operation), the power dissipation at the phototransistor is set well above the rated output power of 50mW. The phototransistor is thus operated at 300mW (I_C = 20mA, V_{CE} = 15V) when subject to high-power operation. Due to the small package of the SG-105F, the LED which comes with it does not provide sufficient light to drive the phototransistor to 300mW. Consequently, the high-power operation is carried out using a separate LED (TOIR – 50b94bCEa manufactured by OASIS) which can output high intensity light at the wavelength of interest.

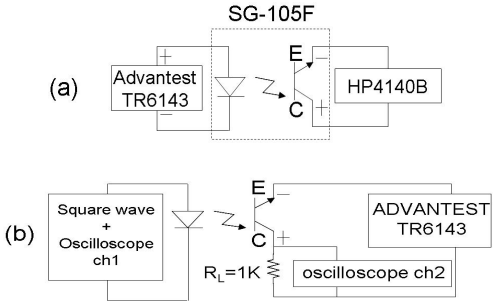

Fig. 1. Electrical set-up for (a) normal and high-power operation (b) response time measurement.

Another important electrical measurement which can be used to study the phototransistor is the response time measurement whose set-up is shown in Fig. 1(b). The purpose of this measurement is to determine the dynamical characteristics of the phototransistor, mainly to measure the rise time (t_r) and the fall time (t_f). In order to do so, the input (LED) is fed with a 500Hz, $4V_{p-p}$ square wave. The LED thus generates light at the same frequency; the phototransistor correspondingly detects the LED light. The phototransistor is connected in series to a 1-kΩ resistor is order to study the rising and falling edges of the output current I_C using an oscilloscope. The time response of the output (I_C), however, lacks those of the input (I_{LED}), giving rise to non-abrupt changes in the rising and falling edges.

The rise and fall times depend mainly on the *RC* time constant and thus are a good indicator of physical changes of the device, whether intrinsic or extrinsic. All electrical measurements are carried out in the dark, with only intended light from a relevant LED.

The optical measurement serves to illustrate the range of wavelengths of light to which the phototransistors can respond. The set-up shown in Fig. 2 makes use of a wavelength filter (the spex 1000M monochromator) which at one end receives a broad spectrum light from a tungsten lamp and at the other end outputs a monochromatic light of wavelength set by internal gratings. The monochromatic output light is then shone onto the phototransistor which is biased at V_{CE} = 5V. The resulting current is simultaneously measured by a digital multimeter (Keithley 485). The monochromator can be programmed to scan from one wavelength to another at a specified wavelength step. The resolution of the scanning mechanism is better than 1 Å and when coupled with the current readout (from Keithley 485) can provide a high-resolution photocurrent response of any photo device, including phototransistors.

III. RESULTS AND DISCUSSIONS

The phototransistor's characteristics, both electrical and optical, are measured before and after high-power operations; the latter is measured in intervals: at 24, 48 and 72 hours of operation. The following results thus comprise a set of four curves corresponding to 0, 24, 48 and 72 hours of high-power operations.

The output electrical characteristic (I_C-V_{CE}) of the phototransistor is shown in Fig. 3. All curves are measured at a constant input light, I_{LED} = 40mA. It is clear from the figure that after each high-power operation, the resultant output degrades. For example, the output current I_C at V_{CE} = 10V reduces from 0.275 mA to 0.267, 0.250 and 0.241 mA after 24, 48 and 72 hours of high-power operations, or over 12% after 3 days .

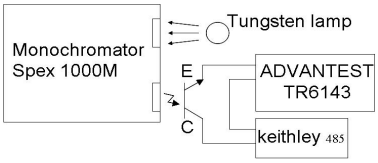

Fig. 2. Set-up for photocurrent measurement

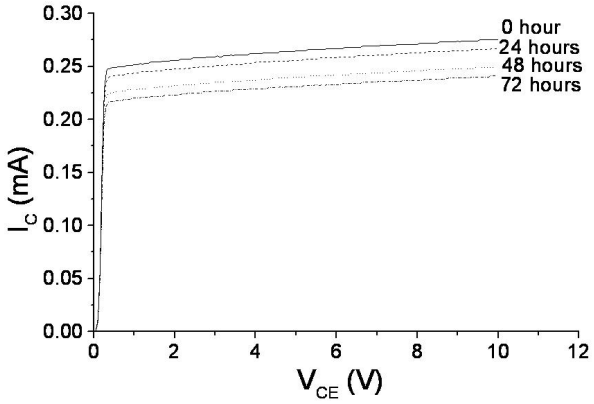

Fig. 3. Output electrical characteristic (I_C-V_{CE}) of the phototransistor before and after being subject to high-power operation for 24, 48 and 72 hours. I_{LED} = 40mA for all curves.

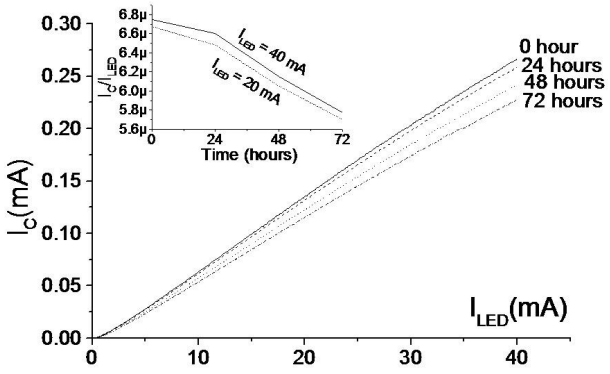

Fig. 4. The I_C-I_{LED} plot and (inset) the I_C/I_{LED} ratio vs time plot of phototransistor before and after being subject to high-power operation for 24, 48 and 72 hours. V_{CE} = 10V for all curves.

The I_C-I_{LED} plot shown in Fig. 4 further supports the above results. It can be seen in Fig. 4 that for all I_{LED}'s, the longer the high-power operation, the further reduction in the output current I_C. This fact is made more obvious in the I_C/I_{LED} plot shown in the inset of Fig. 4 which shows the reduction in the I_C/I_{LED} ratio as a function of the number of hours of high-power operation.

In order to understand the underlying mechanism(s) that cause the degradation in sensitivity of the phototransistor it is important to examine the factors that influence the I_C/I_{LED} ratio. Since the LED light is kept constant for all tests, the carriers thus get generated in the base by the same amount. The I_C/I_{LED} ratio can thus be interpreted as the I_C/I_B ratio whose value is given by [3]:

$$\beta = \frac{I_C}{I_B} \cong \frac{\tau_n}{\tau_t} \qquad (1)$$

where τ_n is the electron recombination lifetime in the base and τ_t is the transit time across the neutral base width W_b. The reduction in β can thus be explained by the reduction in τ_n, or the increase in τ_t, or the combination both. The reduction in

τ_n, however, can be discarded due to the fact that τ_n is a material parameter which depends on impurity concentration, and is unlikely to change during tests. The increase in τ_t is thus a more likely cause for the reduction in β.

The value of τ_t can be shown to be related to the neutral base width W_b according to [3]:

$$\tau_t = \frac{W_b^2}{2D} \tag{2}$$

where D is the diffusion coefficient which, in turn, depends on the carrier mobility μ in the base according to the Einstein's relationship:

$$\frac{D}{\mu} = \frac{kT}{q} \tag{3}$$

where k is the Boltzmann's constant, T is the temperature, and q is the electronic charge. Therefore, the value of D is also unlikely to change during tests due to the fact that the mobility, which depends on the doping concentration, is not affected by high-power operation. The increase in τ_t can thus only be explained by the increase in W_b.

The neutral base width W_b depends on the depletion regions at the emitter junction (a) and the collector junction (b) according to the relationship:

$$W_b = W - a - b \tag{4}$$

where W is the metallurgical base width, see Fig. 5 for visual representation of W, W_b, a and b. The variations in either a or b, or both, can thus have an impact on W_b, and, in turn, on τ_t and β.

It has been found that high-power operation of semiconductor devices can increase contact resistances to the outside world due to electromigration or degraded metal/semiconductor interface [4]. The operation at 300mW in our case in much higher than the rated 50mW which the device can adequately dissipate. The heat can thus build up throughout the device, affecting all contacts and can degrade (increase) contact resistance. The small-signal equivalent circuit of the BJT shown in Fig. 5(b) shows that at a constant V_{CE}, the increase in emitter contact resistance (r_e) and the collector contact resistance (r_c) will affect the voltages dropped across the emitter and collector junctions, respectively. The voltage drops result in the reduction in a and b because the depletion width x of a p-n junction depends on the voltage drop V across it according to:

$$x = \left\{ \frac{2\varepsilon_s \varepsilon_0 V}{q} \left(\frac{1}{N_a} + \frac{1}{N_d} \right) \right\}^{\frac{1}{2}} \tag{5}$$

where ε_s is the relative permittivity of the semiconductor, ε_0 is the permittivity of vacuum, and N_a and N_d are the acceptor and donor concentrations of the p- and n-side of the junction, respectively.

The increase in contact resistances r_e and r_c thus results in the reduction in voltage drops across the emitter and collector junctions which, according to (5), decrease a and b. Consequently, W_b increases, due to (4), which increases τ_t, due to (2), and ultimately decreases β, due to (1).

The increase in contact resistance as the cause of reduced sensitivity is further supported by the response time measurements. Table 1 summarizes the rise and fall times of the phototransistor before and after 24, 48 and 72 hours of high-power operation. While the rise time increases by approximately 4%, the fall time increases by a greater percentage of 8%. The combined 12% increase in rise and fall times very well reflects the similar reductions in the output current in Fig. 3 and the I_C/I_{LED} ratio in Fig. 4.

The electrical characterizations above suggest that after long-term operation at high-power condition (300mW), only contact resistances increase while basic material parameters do not change. If this is the case, the absorption/emission characteristics of the phototransistor should reflect this.

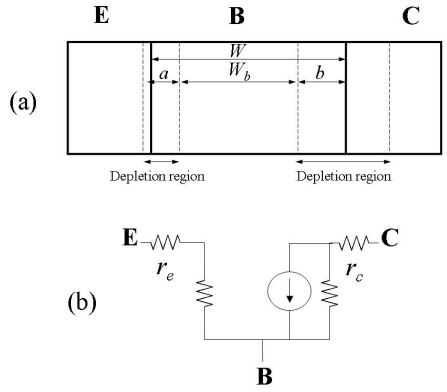

Fig. 5. (a) Cross section and (b) small-signal equivalent circuit of a BJT

TABLE I
Measured rise and fall times of the phototransistor before and after 24, 48 and 72 hours of high-power operation.

duration of high-power operation (hrs)	t_r (μsec)	t_f (μsec)
0	50	48
24	50	48
48	52	52
72	52	52

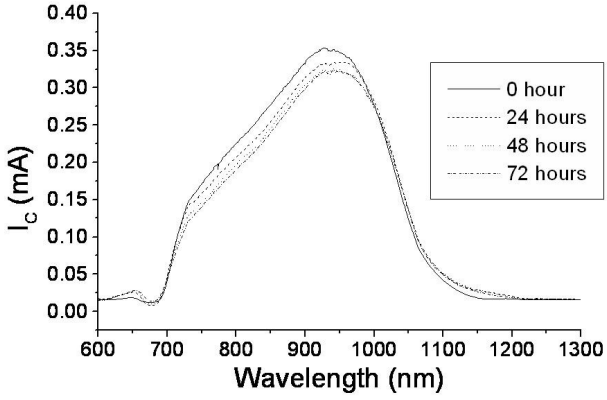

Fig. 6. The photocurrent plot of the phototransistor before and after being subject to high-power operation for 24, 48 and 72 hours. V_{CE} = 5V for all curves.

The photocurrent as a function of wavelength is shown in Fig. 6 for the phototransistor before and after high-power operations.

It can be seen that for all conditions, the device's optical characteristics remain virtually the same: the two peaks (at 730- and 940nm) and the full-width-at-half-maxima (FWHM = 274nm) of the normalized curves (not shown) are the same. Further examination of the peak absorption at 730- and 940-nm wavelengths shows that the reduction in I_C is approximately 12%.

The fact that the peak positions and the FWHM do not change implies that the intrinsic properties of the device (thus the material) are not affected. The reduced peak, however, can be explained by the increase in contact resistances, r_c and r_e, which results in reduced in voltages dropped across the emitter and collector junctions, in good agreement with the electrical results.

IV. CONCLUSION

In summary, a commercially available phototransistor has been subject to high-power operations (300mW as opposed to the nominal, rated power of 50mW) and its electrical and optical characteristics studied. It is found that the device's electrical and optical behaviors are degraded in the same way: the electrical sensitivity reduced by approximately 12%, and the optical responses around the sensitivity peaks are reduced by approximately 12%. The dynamic behaviors also indicate an increase of rise and fall times by the same amount. The resulting electrical and optical degradations have been explained in terms of increased contact resistances, while the intrinsic properties of the device remain unchanged.

***Abstract*— This paper presents a CMOS Digital-to-Analog Converter (D/A) Circuit. The voltage clipping circuit building blocks based on minimum circuit and electronic resistor are deployed. The proposed circuit uses a worth of current-mode signal processing for minimized circuitry. The clipping circuit can be obtained the current output according to its voltage output and the electronic resistor. The clipping voltage output is achieved by input clipping voltage and input voltage relations. The D/A currents output can be simply obtained by summing of their currents. The direct connection method and n-bits expandable without any restrictions can be obtained that is an advantage of current-mode approach. The integrity analog output can be obtained either current or voltage. The simulation results are performed by PSpice based on MOSIS CMOS process 0.25µm. The analog integrity output can be obtained.**

I. INTRODUCTION

In analogue signal processing [1], [3], digital-to-analog converter (D/A) is an important part for interpret a digital word to an analog signal. The familiar OPAMP D/As [2] have been found in very long time ago such as linear combination and 2-2R ladder [4], [5]. The complicated resistors design has been found and slow response behavior cause of the OPAMP bandwidth.

The clipping circuit based on OPAMP and zener diode has been introduced [4-6] that operates in voltage-mode. The clipping voltages are set by each zener diode across voltage. The mention clipping circuit is not practical because zener diodes are complicated to find out. The OPAMP-based is used a large die area in fabrication and the frequency response is also limited by its gain-bandwidth (GBW).

This paper is focused on the components reduction and without the resistor. This paper describes a CMOS D/A based on voltage-clipping circuit. The voltage clipping circuit is modified by a minimum circuit [8]. The current mirrors and electronic resistors have been added for obtained a current output. The D/A circuit is constructed by n-clipping circuits for n-bits digital signal. The reference voltage can be simply adjusted by a particular voltage weighting assignment. The number of digital bit inputs can be flexible increased and decreased without changing of the topology that is a benefit of proposed D/A. The output current is quite accurate according to the input signal and clipping reference voltage. The expected analog signal output can be obtained either in current or voltage.

II. THEORY AND PRINCIPLE

The proposed circuit is constructed by n-parts of clipping circuit. The CMOS transistors are realized for a clipping circuit. The minimum circuit and electronic resistor are deployed for obtained the current output.

A. Shunt-Feedback Buffer Circuit

Fig. 1 shows shunt-feedback buffer circuit [7]. It contains the 2 current sources and 3 transistors. The transistor M_1 is using for supply its source voltage, M_2 using for supply current at node V_O and M_3 is done for output current. All transistors are operated in saturation region. So, the voltage output can be written as follows :

$$V_O = V_C - \sqrt{\frac{I_1}{k_N}} - V_{TN} \qquad (1)$$

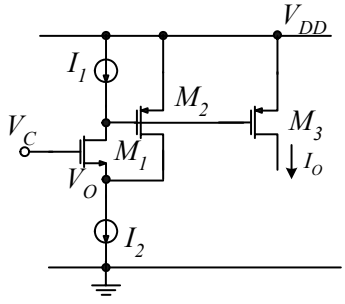

Fig. 1 The Shunt-Feedback Buffer Circuit

The output current I_O equals I_2-I_1 obtaining from current mirror M_3. However, the bias I_1 can be cancelled by symmetry scheme because I_1 is constant, while the transistors of both sides must be identical. The current source I_1 is a drain current of M_1 and I_2 is a total current source of circuit. While input voltage (V_C) is applied in gate of M_1, source voltage is appeared. The enough current should be supplied in case of load connected at node V_O. Thus, M_2 and I_2 are deployed to supply such current.

B. Minimum Circuit

The minimum circuit [8] as shown in fig.2 can be realized by the 2 shunt-feedback buffer circuits with a swapping of bias transistor M_2 and I_2. Suppose that, the input section 1 and 2 are perfectly matched. The transistor M_{51} and M_{52} will operate according to which the gate voltage input is lower. The source voltages (V_{OUT}) are connected together that take care the current output by the negative current sources M_{81}, M_{82}.and positive current source I_2. The output voltage is appeared according to the V_{IN1} and V_{IN2} that can be written as:

$$V_{OUT} = V_{\min}\Big|_{V_{IN1},V_{IN2}} \tag{2}$$

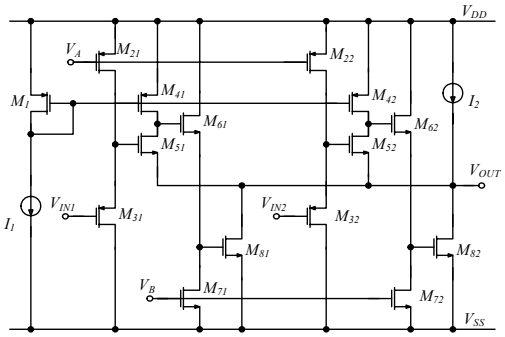

Fig.2 CMOS Minimum Circuit

C. MOS Electronic Resistor

The MOS electronic resistor circuit [9] as shown in Fig.3 has been introduced in 1990. This electronic resistor circuit is performed as a grounded resistor. The resistance can be adjusted by its supply voltage and its aspect ratio (*W/L*). The transresistance of the electronic resistor circuit can be expressed in Eq.(3).

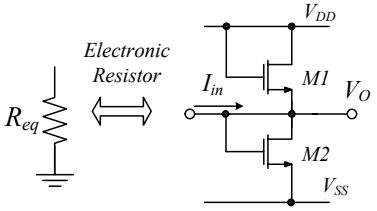

Fig.3 MOS Electronic Resistor Circuit

$$R_{eq} = \frac{V_O}{I_{in}} = \frac{L}{2\mu C_{OX} W\left(V_{DD} - V_T\right)} \tag{3}$$

D. Clipping Circuit

For clipping building block, the above minimum circuit and electronic resistor are deployed. The clipping voltage input is applied in a particular port and V_{in} is applied in the rest port as shown in Fig.4. The transistors M_9 and M_{10} are connected as an electronic resistor. The resistor current based on the clipping and input voltage conveyed to the output by the current mirrors M_{81} - M_{84}. The simplify building block can be described in fig. 5. The current output of clipping circuit according to the input, clipping voltage and electronic resistor can be expressed as:

$$I_{OUT} = \frac{V_{\min}}{R_{eq}}\Big|_{V_{IN1},V_{CLIP}} \tag{4}$$

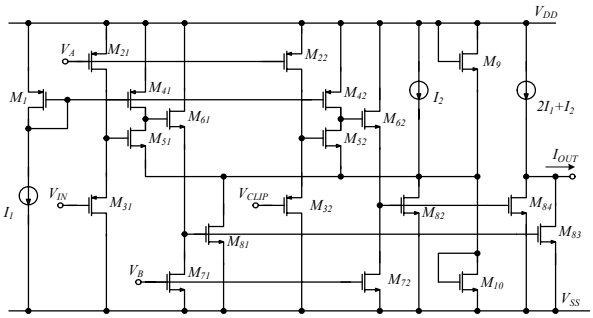

Fig.4 Complete Clipping Circuit

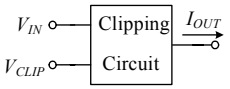

Fig. 5 Simplify Clipping Circuit Building Block

III. DIGITAL-TO-ANALOG CONVERTER

The D/A is a useful building block and found in analog signal processing area. The variety mix-signal processing integrated circuits can be processed in digital or analog approaches. Although, the analog can be process perhaps a digital process can be also well done. The natural signal input always analog that should be convert to digital for taking some process and finalized output in analog again. So the A/D and D/A are very important parts to carry out this point.

The CMOS D/A has been reported [10] that used CMOS based diode connection for clipped a signal. That circuit was worked seem to be a rectifier function. The low-output impedance is a problem of current mode that giving the errors when the summation current outputs are connected.

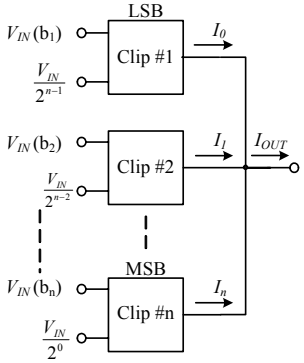

Fig.6 The D/A Block Diagram

The proposed D/A scheme has been shown in fig.6 using connection of n-stages clipping circuits. The current output can be obtained by the summing of several clipping circuit outputs. Each signal output is controlled by particular data digital bit input (0 or 1) that applied by V_{in}. The current output

is weighted by the clipping voltage according to the bit significant.

The summation of their current can be simply direct connection cause of worth in current-mode processing. From the current-mode approach, the data bit inputs enjoy more expandable without any restriction. The voltage output can be also easily obtained using R_L connected. The b_1 and b_n are least significant bit (LSB) and most significant bit (MSB), respectively. The current output of D/A can be obtained as:

$$I_O = \frac{V_{IN}}{R_{eq}}\left(\frac{b_1}{2^{n-1}} + \frac{b_2}{2^{n-2}} + ... + \frac{b_n}{2^0}\right) \qquad (5)$$

or

$$I_O = \frac{V_{IN}}{R_{eq}}\sum_{i=1}^{n}\frac{b_i}{2^{n-i}} \qquad (6)$$

From Eq. (6), the linear combination algorithm can be seen without the complicate resistor design. The full-scale current output is given by all bits set to '1'. Supposed that n is approach to infinite. The current output will become:

$$I_O\big|_{fs} \to \frac{2V_{IN}}{R_{eq}}; \quad (n \to \infty) \qquad (7)$$

The only LSB is '1' that the output can be obtained to

$$I_O\big|_{1LSB} \to \frac{V_{IN}}{2^{n-1}R_{eq}} \qquad (8)$$

IV. Simulation Results

The proposed D/A in fig.6 can be assumed for 4 bits by identical 4-stages of clipping circuit. The performances have been confirmed by PSpice. The level 3 model T14Y MOSIS 0.25µm with the following parameters, V_{TN} = 0.42V, V_{TP} = -0.55V, $\mu_N C_{OX}$ = 250.1048$\mu A/V^2$ and $\mu_P C_{OX}$ = 51.94153. $\mu A/V^2$ is assumed. The aspect ratio of transistors is shown in table 1 and CMOS model is listed in table 2

TABLE 1. THE ASPECT RATIO OF TRANSISTORS

Transistors	W/L($\mu m/\mu m$)
M_{2i}, M_{3i}, M_{5i}-M_{7i}	2/0.5
M_{8i}	30/0.5
M_1, M_{4i}	10/0.5
M_9, M_{10}	0.5/0.5

The bias currents, I_1 and I_2 equal to 21.4µA and 100µA, respectively. The bias voltages, V_A and V_B are 0.9 Volts. The supply voltage, ±1.5 volts is used. The voltage reference of various clipping circuit are given in the rule of Eq. (5). The minimum circuit carries out the input range of 0.5 volts for V_{IN}. The clipping reference voltages of LSB to MSB are achieved as 0.0625, 0.125, 0.25 and 0.5, respectively.

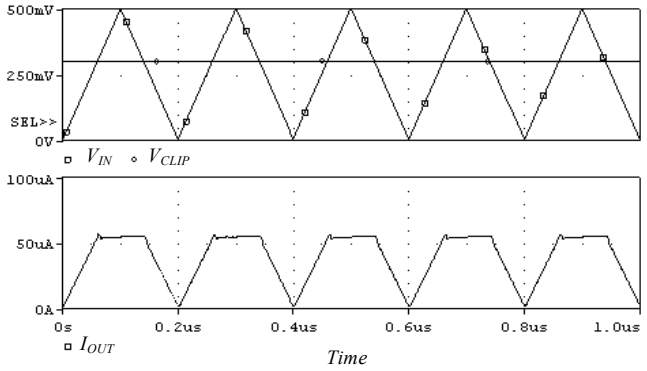

Fig.7 The current output of clipping circuit in fig. 4

The electronic resistors that used in this paper are performed by M_9 and M_{10} with aspect ratio in table.1. The resistance can be obtained about 5kΩ. The clipping performance can be confirmed by applying saw-tooth signal of 0.5 $V_{p\text{-}p}$ with 0.25 volts offset for V_{IN} and clipping voltage is set at 0.3 volts. The current output can be obtained the accurate clipping as shown in fig. 7.

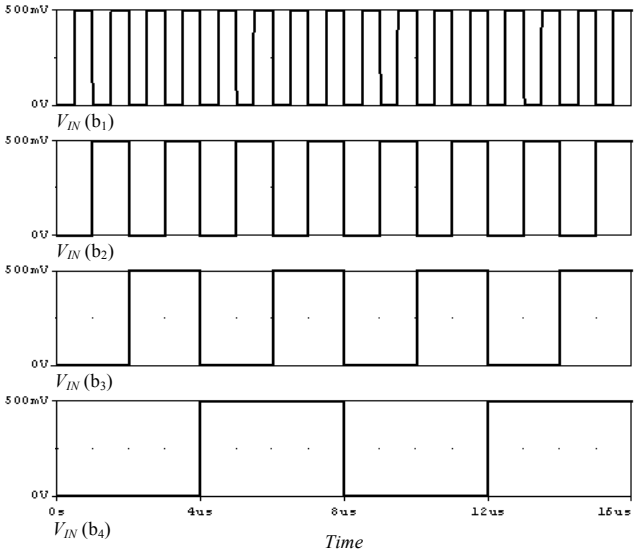

Fig.8 Digital input signal for proposed 4 bits D/A

The 4 bits D/A performance can be simulated by giving the data input as different consecutive pulses trains as shown

in fig. 8. The sampling frequency of digital input is supposed at 1 MHz.

The full scale current output due to 4 bits inputs can be roughly calculated using Eq. (7) about 187.5μA. The 1LSB current output using Eq. (8) can be also found about 12.5μA. The simulation results are confirmed the current outputs are in agreement with the calculation about 172.64μA and 12.22μA for full scale and 1LSB current output, respectively. The output signal that seems to be a ramp signal can be obtained in fig. 9.

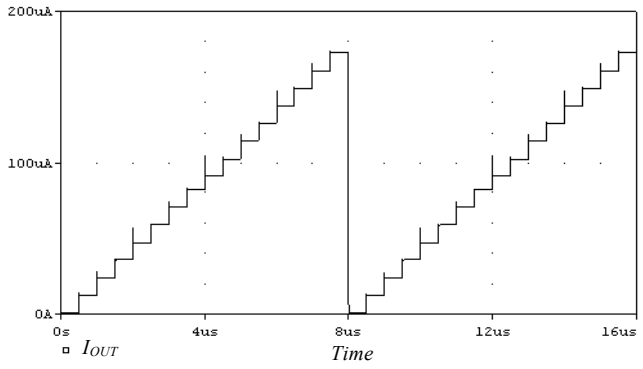

Fig.9 Analog output current of proposed D/A

For voltage output, the 5kΩ resistor is connected to the output port of proposed D/A circuit. The full scale voltage output due to 4 bits inputs can be roughly calculated using Eq. (7) about 937.5mV The 1LSB current output using Eq. (8) can be also found about 62.5mV. The simulation results are confirmed the current outputs are in agreement with the calculation about 784.52mV and 53.54mV for full scale and 1LSB voltage output, respectively. The output signal that seems to be a ramp signal can be obtained in fig. 10. The achieved output voltage has some error due to the load resistance connection.

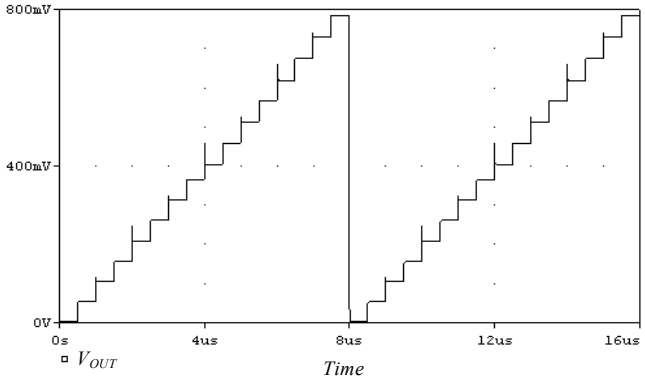

Fig.10 Analog output voltage of proposed D/A while R_L= 5kΩ connected

V. CONCLUSION

The CMOS Digital-to-Analog Converter (D/A) Circuit based on clipping circuits is proposed. The signal of proposed circuit is processed in current-mode for minimized a circuitry. The minimum circuit and electronic resistor are implemented for a clipping circuit. The current output of D/A can be simply obtained by summing of their clipping current outputs. This algorithm can be flexibly increased and decreased the number of digital bits input. The reference voltage can be simply calculated by basic mathematical. The analog output can be obtained either current or voltage.

***Abstract*-Blue light-emitting diodes (LEDs) have been subject to high-current DC aging process at room temperature in order to study its degradation characteristics by electrical and optical characterizations. Electrical measurements show that after each cycle of aging, the diode's ideality factor increases at all forward bias levels. The reverse saturation current also increases after each aging process. Optical measurements show that although the peak wavelength of the diode remains almost constant at 468nm, its full-width-at-half-maximum (FWHM) value broadens from 27nm to 34nm after 24-hr of aging, and nearly saturate at 39nm after 48 hours. The peak wavelength intensity also decreases steadily with time. We attribute the LED's degradation to the creation (or activation) of defect levels inside the band gap. These levels provide pathways for non-radiative recombination, resulting in dimmed LEDs under forward bias. They also contribute to generation current under reverse bias.**

I. INTRODUCTION

Blue light-emitting diodes (LEDs) are widely used in general electrical appliances and electronic devices such as function panels in cars and keypads light in mobile phones. In general, LEDs are finding more lighting and signaling applications as they are more efficient than other light sources. Because of growing usage, LED characteristics must be fully understood. When used in commercial applications, warranties are usually given against LED malfunction. For manufacturers or system designers to be confident of the warranty period, it is important to subject blue LEDs of interest to accelerated DC aging and study the electrical and optical properties of the LEDs before and after aging.

The blue LED under test is a commercially available, InGaN-based high-brightness blue LED. The LED is well encapsulated under blue cover and its rated nominal working parameters are 20mA of forward injection current, and 3.2-3.9V of forward voltage under the ambient temperature at 25^{o}C. For the reverse bias region, the maximum bias should not exceed -5V in order to avoid damage to the LED. At normal forward bias operation, the peak wavelength is 464nm and the full-width-at-half-maximum (FWHM) is 23nm.

It is generally known that long-term operation of diodes degrades their electrical and optical characteristics: LEDs become dimmer and consume more power with time. It usually takes a long time for such degradation to be noticeable. In order to simulate the aging process in a controlled environment, all the LEDs used in this study are subjected to accelerated DC aging where power larger than the rated value is intentionally supplied to the LEDs. Since the power supplied is larger than the amount that the packaging can dissipate, the heat builds up inside the device and accelerates the degradation mechanisms. With proper DC bias and power supplied, it is possible to subject the LEDs to one day under test which has a theoretical equivalence of one year of continuous operation at the rated conditions. Care must be taken, however, for LEDs can easily be damaged in the event of sudden change of device temperature. By studying the LED characteristics before and after accelerated DC tests, it is possible to estimate the LED's lifetime which has important implications for warranty periods.

The LED's characteristics of interest are optical and electrical performances before and after the aging process. What follows in the remaining of the paper will show how the electrical and optical characteristics are degraded, and what are the causes and consequences of the degradation. The structure of the paper is as follows: the experimental procedures including the electrical and optical measurement set-ups will be given next in Section II. This is followed by Section III where the results are shown and discussions are given, followed by the conclusion in Section IV.

II. EXPERIMENT

The structure of the blue LED under test is shown in Fig. 1. The device is grown on a sapphire substrate starting from n-type contact layer (n-GaN), InGaN active layer, p-AlGaN emitter and p-GaN as the top contact layer. The device is subjected to the accelerated DC aging process shown in Fig. 2. For each cycle of the process, the LED's electrical and optical characteristics are measured using the set-ups shown in Figs. 3 and 4, respectively.

The schematic flow diagram in Fig. 2 describes how the LED is subjected to tests and measurements. The LED is measured before (0 hour) and after each of the three 24-hour aging cycles (24, 48 and 72 hours). A computer program has been written to control a power supply (Advantest TR6143) in such a way that only dissipated power needs be input. The program will automatically adjust the current and voltage to match the power required. The program has a ramp-up and down features to prevent sudden temperature change of the device. The program is set to supply the required power (500mW) for 24 hours before being terminated. Afterwards, the LED's electrical and optical characteristics are measured

and the LED is further subjected to the same aging process until it is aged by 72 hours, which corresponds to approximately 3 years of operation at the nominally rated conditions.

The electrical measurement set-up shown in Fig. 3 consists of a control personal computer (PC) which is connected to a power supply via a general-purpose interface bus (GPIB). The power supply is either a HP 4140 or Advantest TR6143, depending on the required current/power used in measurement or for aging process. In either case, the power supply outputs a current (I) and measures the voltage (V), or vice versa. Each data point (I,V) can be subsequently read back by the PC via GPIB.

The optical measurement set-up shown in Fig. 4 consists of a monochromator, a photomultiplier and a digital multimeter (DMM). The PC is used to adjust the grating of the manochromator so that only selected wavelength can go through it. The filtered light is subsequently detected at the other end by a photomultiplier whose output is measured by the DMM and read back by the PC. The control value (λ required) and the result read back (volt, corresponding to light intensity) are then used to plot the optical characteristic.

III. RESULTS AND DISCUSSIONS

The electrical characteristic of the LED in Fig. 5 shows the current-voltage (I-V) of the diode before and after being aged at 500mW for 24, 48 and 72 hours. The semi-logarithmic plot shows that the electrical characteristics of the diode's forward and reverse biases are significantly affected, most notably after the first 24 hours of aging. The inset of Fig. 5 shows that the reverse saturation current of the LED increases with the aging time, indicating that there may be physical changes in the active area of the LED.

The reverse saturation current is associated with generation centres in the semiconductor band gap. The centres may be inactive as grown, but become active after prolonged usage.

These mid-gap centers can also become active at forward bias conditions where they are effective as recombination centers. This is evident in Fig. 6 which shows the plot of ideality factor as a function of forward bias for two conditions: new and 24-hour aged LEDs. The ideality factor η can be determined from the relationship [3]:

$$I = I_0(\exp(qV/\eta\, k_B\, T)-1) \qquad (1)$$

where I is the current, V is the voltage, I_0 is the reverse saturation current, q is the electronic charge, k_B is the Boltzmann constant, and T is the temperature.

The ideality factor depends on relative contribution of diffusion and recombination currents. The value of η approaches 1 if all current components are diffusion currents, and reaches 2 when recombination current dominates [2,3]. Fig. 6 shows that the ideality factor η increases for all bias levels [1]. Ideality factor even greater than 2 is possible if the quasi-Fermi levels splitting is less than bias voltage and the recombination spreads out over a wide region [5].

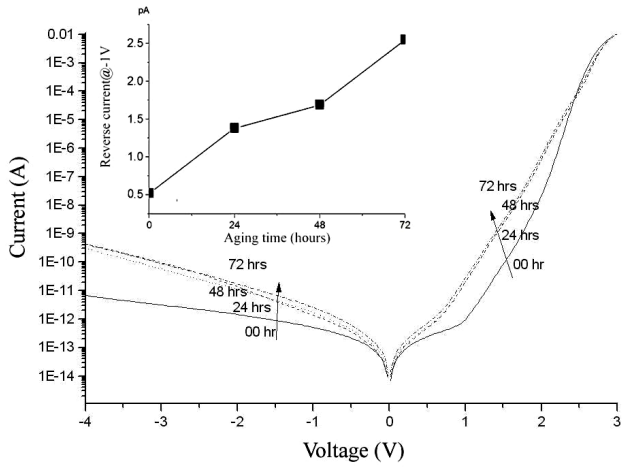

Fig. 5. The current-voltage (I-V) characteristics of the blue LED before and after being aged at 500mW for 24, 48 and 72 hours.

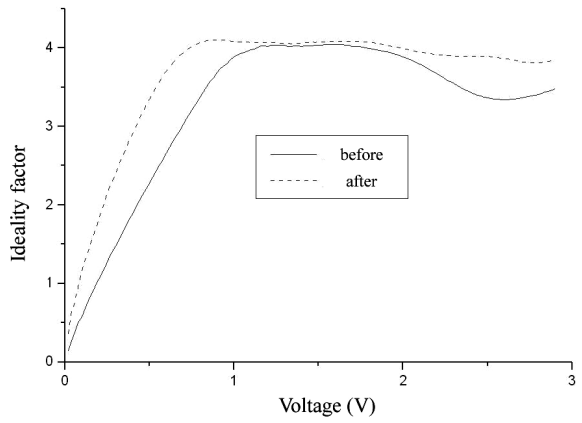

Fig. 6. Ideality factor of the LED before and after being aged at 500mW for 24 hours.

The optical characteristic of the LED is shown in Fig. 7. The intensity of light output from the LED when it is forward biased at the rated current (20mA) is shown before and after being aged at 500mW for 24, 48 and 72 hours. The inset shows the relative peak intensity and FWHM values of each aged cycle.

The optical results show that the peak wavelengths stay almost constant at the rated value of 465 nm while the intensity at the peak wavelength reduces significantly, most notably between the first and the second aged cycles (i.e between 24 and 48 hours). The FWHM values which indicate the "purity" of the color that the eyes perceive also degrade after each aging cycle. The reduced intensity results in dimmer LEDs after long-term operation while the broadened FWHM contributes to the change in color that human eyes perceive.

The fact that the electrical characteristic undergo a critical change after 24 hours of aging while the optical characteristic undergo a critical change between 24 and 48 hours of aging is indicative that different mechanisms may be responsible for electrical and optical degradations However, it has been suggested that defects in recombination region may be responsible for both types of degradations [4].

In order to explain our results, and in agreement with the mechanism suggested by Cao [4], we propose a simple model to illustrate why the reverse current increases and the emission efficiency decreases after each aged cycle.

Fig. 8 shows a plot of (upper) energy-wave vector (E-k) diagram and (lower) energy-distance diagrams across a p-n junction in the case of (left panels) new and (right) aged LEDs. A mid-gap energy level (E_r) is shown only for the aged LEDs. The existence of E_r in the E-k diagram means that carrier recombination can occur via indirect recombination, which results in heat or phonons. E_r in the energy-distance diagram shows that it can function as an effective generation center under reverse bias conditions [3], resulting in increased reverse current as shown by the comparatively larger arrow in Fig. 8.

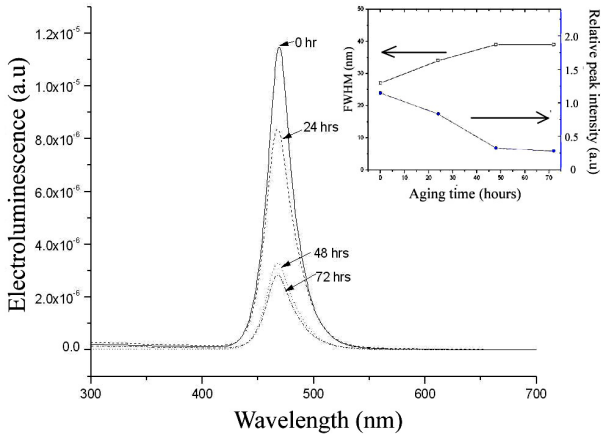

Fig. 7. Optical emission from the LED before and after being aged at 500mW for 24, 48 and 72 hours. The inset shows the peak wavelength and FWHM of each cycle.

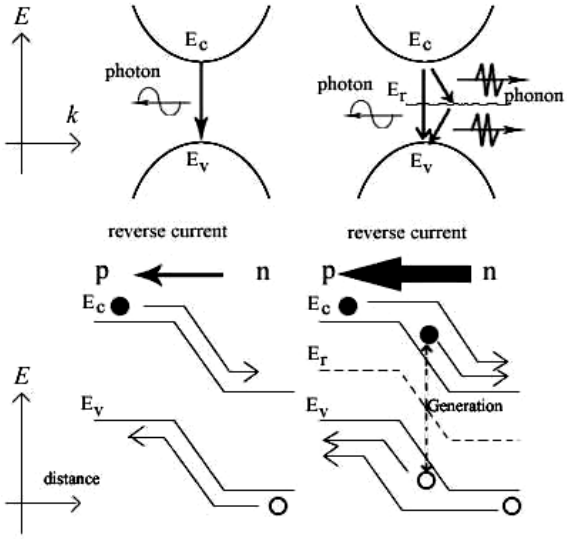

Fig 8. Energy-wave vector (upper) and energy-distance across a p-n junction (lower) of new (left) and aged (right) LEDs.

IV. CONCLUSION

In conclusion, commercially available blue LEDs have been subject to accelerated DC aging process and their electrical and optical characteristics are measured. It is found that both characteristics are degraded after each aging cycle: the ideality factor and the reverse saturation current in *I-V* characteristics increase while the peak wavelength intensity in the electroluminescence characteristic decreases. We attribute the degraded characteristics to the formation (or activation) of mid-gap energy levels which can effectively function as non-radiative recombination centres in the forward-biased mode, and generation centres in the reverse-biased mode.

***Abstract*- This paper presents FPGA implementation of an Acoustic Echo Canceller (AEC) for teleconferencing systems. For AEC adaptation, a Normalized Least Mean Square (NLMS) algorithm is employed. Two circuit techniques, namely Distributed Arithmetic (DA) and Multiply and Accumulation (MAC), are utilized to improve resource utilization in the proposed AEC. Synthesis of the AEC is achieved via VHDL language. Simulations are presented to confirm functionalities of AEC and investigate performance of FPGA implementation.**

I. INTRODUCTION

In a teleconferencing system, the coupling between loudspeakers and microphones usually results in many undesirable properties [1]. To overcome the difficulties, it is well accepted that an Acoustic Echo Canceller (AEC) is required. Operation of AEC is illustrated in Fig. 1. Essentially, the adaptive filter endeavors to model the room characteristics possibly using an FIR filter. Attempts have been made towards implementation of AEC using several techniques including FPGA, see e.g. [2], [3]. However, most existing works do not address the issue of optimal implementation.

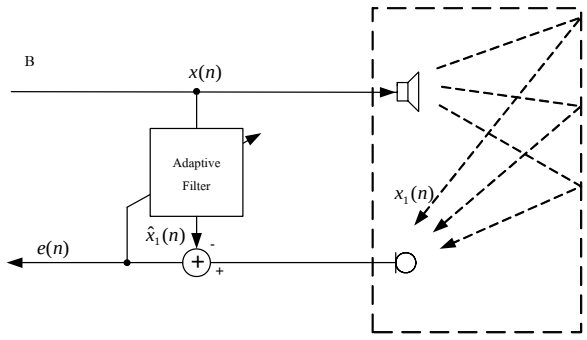

Figure 1 AEC Block Diagram

This paper presents efficient FPGA implementation of AEC using NLMS algorithm. Two circuit techniques, particularly Distributed Arithmetic (DA) and Multiply and Accumulate (MAC) are exploited leading to efficient implementation. The paper is organized as follows. Section 2 reviews NLMS algorithm that is used for AEC adaptation. Section 3 descries method of acoustic echo canceller part structure processor unit in the , Section 4 MAC, Section 5 DA , Section 6 design and implementation, Section 7 the testing , and Conclusion in section 8.

II. NLMS ALGORITHM

An adaptive filter [1] is different from a general filter in that its coefficients are not fixed but rather changed in accordance with signal and environment statistics. Basically, it consists of two parts, i.e. a filter and adaptation. The popular filter structure is FIR filter due to its simplicity. As for the adaptation algorithm, there exist many techniques presented, see e.g. [1] and reference therein. In AEC context, it is accepted that a Normalized Least Mean Square (NLMS) is one of the most appropriate algorithms in terms of tradeoff between performance and computational complexity.

The original Least Mean Square (LMS) algorithm has a limitation in terms of convergence speed. By introducing step-size normalization, NLMS can overcome the problem. In this case, convergence is guaranteed if the step-size

$$0 < \mu < \frac{2}{(p+1)E\{|x(n)|^2\}} \tag{1}$$

where $x(n)$ is the input signal at time n and E{•} denotes expectation operation. From the above equation, the expected input power is estimated by its time average, i.e.

$$\hat{E}\{|x(n)|^2\} = \frac{1}{p+1}\sum_{k=0}^{p}|x(n-k)|^2 \tag{2}$$

Thus convergence is guaranteed if

$$0 < \mu < \frac{2}{\mathbf{x}^H(n)\mathbf{x}(n)} \tag{3}$$

Using Eq. (3), the update equation for NLMS is easily obtained by replacing the LMS step-size with

$$\mu(n) = \frac{\beta}{\mathbf{x}^H(n)\mathbf{x}(n)} = \frac{\beta}{\|\mathbf{x}(n)\|^2} \tag{4}$$

resulting in the following update equation

$$\mathbf{W}(n+1) = \mathbf{W}(n) + \beta \frac{\mathbf{x}^*}{\varepsilon + \|\mathbf{x}(n)\|^2} e(n) \tag{5}$$

where $\mathbf{w}(n)$ and $\mathbf{x}(n)$ denotes the weight and input vector at time n. In addition, $e(n)$ is the error signal and β is the step-size. Note that ε in Eq. (5) is used to avoid numerical instability.

III. Distributed Arithmetic

Basically, distributed arithmetic [4]-[7] is a bit serial computational operation that forms an inner (dot) product of a pair of vectors in a single direct step [4]. The technique significantly reduces hardware complexity [7], as a fundamental MAC operation becomes a simple shift and add operation. Eq. (6) shows DA, which has a similar form to an FIR filter.

$$y(n) = \sum_{k=0}^{N-1} A_k \bullet x_k(n) \tag{6}$$

where A_k is fixed coefficient, x_k is data input, and N is the total number of taps. If each data input x_k is a 2's-complement binary number scaled such that $|x_k| < 1$, then it can be written as

$$x_k = -x_{k0} + \sum_{b=1}^{B-1} \left(x_{kb} \bullet 2^{-b} \right) \tag{7}$$

where B is number of input data, x_{kb} is bit of input value 0 or 1, and x_{k0} is a sign bit of theinput data. By substituting x_k from Eq. (7) into Eq. (6), we obtain

$$y = \sum_{k=0}^{N-1} A_k \left(-x_{k0} + \sum_{b=1}^{B-1} x_{kb} \bullet 2^{-b} \right) \tag{8}$$

Rearranging Eq. (8), we obtain

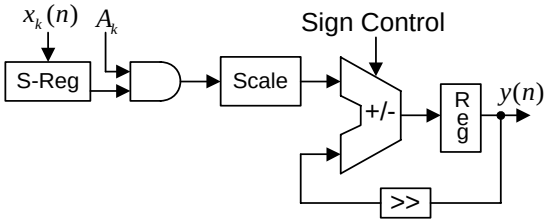

Figure 2 Block diagram of Distributed Arithmetic (1 Tap)

$$y = -\sum_{k=0}^{N-1} x_{k0} A_k + \sum_{b=1}^{B-1} 2^{-b} \left(\sum_{k=0}^{N-1} x_{kb} A_k \right) \tag{9}$$

Explicitly expressing all the product terms under the summation symbols results in the DA equation:

$$\begin{aligned} y = &-\left[\left(x_{00}A_0 + x_{10}A_1 + x_{20}A_2 + \ldots + x_{(N-1)0}A_{N-1} \right) \right] \\ &+ \left[\left(x_{01}A_0 + x_{11}A_1 + x_{21}A_2 + \ldots + x_{(N-1)1}A_{N-1} \right) \right] 2^{-1} \\ &+ \left[\left(x_{02}A_0 + x_{12}A_1 + x_{22}A_2 + \ldots + x_{(N-1)2}A_{N-1} \right) \right] 2^{-2} \\ &\ldots \\ &+ \left[\left(x_{0(B-1)}A_0 + x_{1(B-1)}A_1 + x_{2(B-1)}A_2 + \ldots + x_{(N-1)(B-1)}A_{N-1} \right) \right] 2^{-(B-1)} \end{aligned} \tag{10}$$

Each multiplication of a x_{kb} term and an A_k term is the product of a coefficient word with an input bit. This can be implemented by using an AND gate between each bit of the coefficient word and the input bit. Each scaling factor (2-i) can be implemented by shifting the data to be scaled right i bit. Eq.(10) therefore becomes the summation of the scaled summation of a series of AND gate. This operation could be performed in parallel, or bit-serially, where each clock cycle a single bit from every x_k is multiplied by the corresponding A_k, forming one bracketed term in Eq.(10). These partial products are then accumulated together with the appropriate scaling to produce a final multiplier output. An example of bit-serial multiplication for a single coefficient and input is shown in Fig.2.

IV. MAC Processor

Generally, a relationship between the input $x(n)$ and output $y(n)$ of an FIR filter with the impulse response $h(n)$ is expressed as

$$y(n) = \sum_{k=0}^{N-1} h(k)x(n-k) \tag{11}$$

Implementation of Eq. (11) can be achieved using a multiply-and-accumulate processor (MAC) [8]. Fig. 3 illustrates implementation of a four-tap FIR filter using MAC processor. Its operation is as follows. During cycle 0, the processor multiply the input at time instant n with the first weight stored in ROM. The result then accumulated with the previous regis-

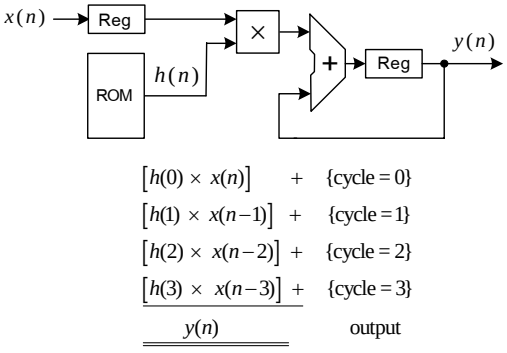

Figure 3 Structure MAC

ter value. Finally, the accumulated is stored in the register.

V. FPGA IMPLEMENTATION OF AEC

Fig. 4 depicts a structure of the proposed AEC. It relies upon DA together with reusable MAC processors. A First-in First-out (FIFO) register is used for realization of a unit-delay. After delay, a Parallel-in-Serial-out (PISO) converts the data from parallel to serial format. Here, the Least Significant Bit (LSB) is shifted first. The data is then fed to COF where it is multiplied with the error forming the coefficients for each tap. Another FIFO is employed in the COF to store the coefficients, which are updated during the next time instant.

The PISO output is also fed to MUX for step-size computation in RAM. The output from RAM is fed to power-of-two circuit that estimates $\|\mathbf{x}(n)\|^2$. The sum of product output for each serial bit is then scaled, shifted to produce the complete output. The last part of circuit aims for MAC reuse control.

TABLE I
AEC SPECIFICATION

VI. RESULTS

The proposed AEC was realized by means of VHDL language. Firstly, simulations were conducted through Xilinx ISE to evaluate performance of the proposed structure. Table I lists the proposed AEC specification, while Table II shows synthesis results on Xilinx XC2VP30FF896-7. It is seen that resource utilization is moderately low. Further reduction of resource utilization can be achieved by reusing MAC processors. A timing diagram of the proposed AEC is illustrated in Fig. 5. The AEC output obtained from simulations was compared with one obtained from MATLAB using fixed-point arithmetic. It was found that the simulation results resembled the MATLAB results confirming AEC functionalities. Next, the proposed AEC is implemented on the Xilinx development tool kits. The input under test was white Gaussian noise with unity variance. Fig. 6 shows the error output of the proposed AEC. Clearly, it is seen that AEC converged after n=2,000 iterations.

VII. CONCLUSION

In this paper, FPGA implementation of AEC using NLMS algorithm has been presented. Distributed arithmetic and MAC reusing techniques have been introduced for optimizing resource utilization in the proposed AEC. Simulation and experimental results have demonstrated that AEC can be realized with moderate resource utilization.

***Abstact*-This paper describes analog nonlinear integrated circuits operable on low voltage supplies. The paper presents three analog functional circuits as follows: the squarer, square-root, and multiplier. These circuits make use of voltage level shift buffer as fundamental circuit. All circuits have simple structure and do not use many devices. Simulation results are given to show performance of the proposed circuits. Experimental result is done to confirm operation.**

I. INTRODUCTION

Squaring circuit, square-rooting circuit, and multiplier are nonlinear signal processing functions which are very useful in instrumentation, communication, and control systems. Nonlinear circuits were published by using operational amplifier[1] and current conveyor[2]. These circuits were not suitable for implement in integrated circuit form. Then some circuits[3-5] using only CMOS have been proposed. These circuits use many devices and have complex structure. In this paper we propose nonlinear circuits using the voltage level shift buffer, and all circuits have simple structure and do not use many devices. The voltage level shift buffer was applied to transconductor[6], composite transistors[7]and current conveyor[8], so in this paper the voltage level shift buffer is applied to nonlinear circuits. Presently, the power supply voltages for monolithic integrated circuits have been continuously reduced, since the MOS transistor has turned out to be the device most amenable to microstructure downscaling. Analog circuit design intends low voltage circuits, so the circuits in this paper are designed for low voltage supplies.

II. PRINCIPLE OF OPERATION

Assume that all CMOS transistors in this paper operate in saturation region with individual well connected to their source to eliminate the body effect, and the drain current of transistor can be expressed as

$$I_D = K(V_{GS} - V_T)^2 \qquad (1)$$

where K is the transconductance parameter, V_{GS} is the gate-to-source voltage, and V_T is the threshold voltage.

A. *The voltage level shift buffer*

The voltage level shift buffer is performed by shunt-series feedback configuration shown in fig. 1.

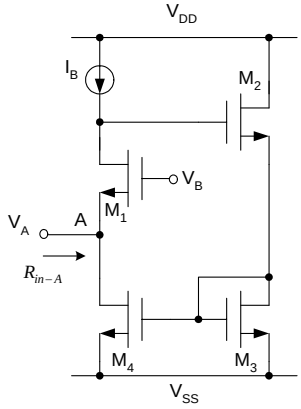

Fig. 1 The voltage level shift buffer

The voltage level shift buffer generates the adjustable voltage source. The relationship of the voltage at the terminal A, V_A, to bias current I_B and the input voltage V_B can be expressed

$$V_A = V_B - \sqrt{\frac{I_B}{K}} - V_T \qquad (2)$$

The equation (2) shows that V_A can be varied by V_B and I_B. Defining $I_B \cong 0$ and $V_B = 0$, so the above equation can be rewritten as

$$V_A = -V_T \qquad (3)$$

The input resistance at terminal A, R_{in-A}, was analyzed in [9] and can be expressed as

$$R_{in-A} = \left(1 + \frac{g_{m2} g_{m4} r_{o1}}{g_{m2} + g_{m3}}\right)^{-1} \cdot \frac{1}{g_{m1}} \qquad (4)$$

where g_{mi} is the transconductance of the transistor M_i, the r_{o1} represents the output resistance of I_B. The equation (4) shows that the circuit has very low input resistance required much for voltage source. The voltage level shift buffer can get the current from other circuit, and it can supply a little current which is less than I_B. The sinking current at terminal A will pass M_4 and effects change of gate terminal voltage of M_4, but V_A constant as long as V_B and I_B constant. The voltage level shift buffer is set to $V_A = -V_T$ for squaring circuit and square-rooting circuit and set to $V_A = V_B - \sqrt{\frac{I_B}{K}} - V_T$ for multiplier.

B. *The squaring circuit*

The squaring circuit shown in fig. 2 consists of a differential amplifier and the voltage level shift buffer.

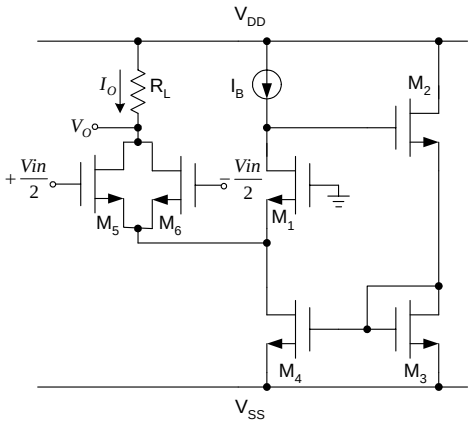

Fig. 2 The squaring circuit

In Fig. 2 the source terminal voltage of both M_5 and M_6 is equal to $-V_T$. The transistors M_5 and M_6 are biased in class B when V_{in} is signal voltage with no dc offset voltage. The relationship of output current I_o to input voltage V_{in} can be expressed as

$$I_o = K\left(\frac{V_{in}}{2}\right)^2 \qquad (5)$$

Note that if V_{in} is positive value, M_5 will turn on (whereas M_6 turn off) and if V_{in} is negative value, M_6 will turn on (whereas M_5 turn off)

C. *The square-rooting circuit*

The square-rooting circuit shown in fig. 3 consists of an MOS transistor and the voltage level shift buffer.

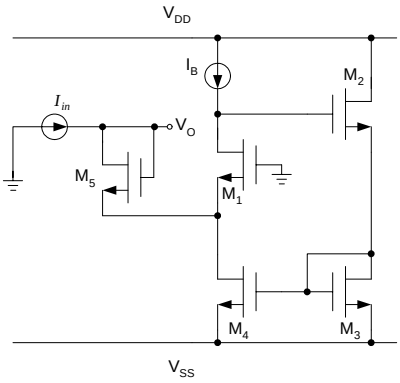

Fig. 3 The square-rooting circuit

The transistor M_5 in fig. 3 is used as a simple current-to-voltage converter. When source terminal voltage of M_5 is equal to $-V_T$. The relationship of input current I_{in} to output voltage V_o can be expressed as

$$V_o = \sqrt{\frac{I_{in}}{K}} \qquad (6)$$

D. *The four- quadrant analog multiplier.*

The core of many MOS four-quadrant analog multipliers which have been proposed thus far is based on the four cross-coupled transistor circuit of fig. 4[5].

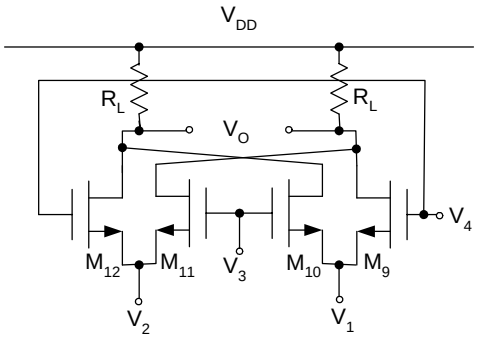

Fig. 4 The core of multiplier

Consider the circuit of Fig. 4, where four transistors are matched and in the saturated mode of operation. Using (1) to each device yields

$$V_o = KR_L(V_3 - V_4)(V_1 - V_2) \qquad (7)$$

To ensure all devices in their saturation region, it requires

$$(V_4, V_3)_{\min} > (V_1, V_2)_{\max} + V_T \qquad (8)$$

To design the multiplier under condition of (8), voltage level shift buffers are used. The proposed multiplier consists of two

voltage level shift buffers and the core of multiplier shown in Fig. 5

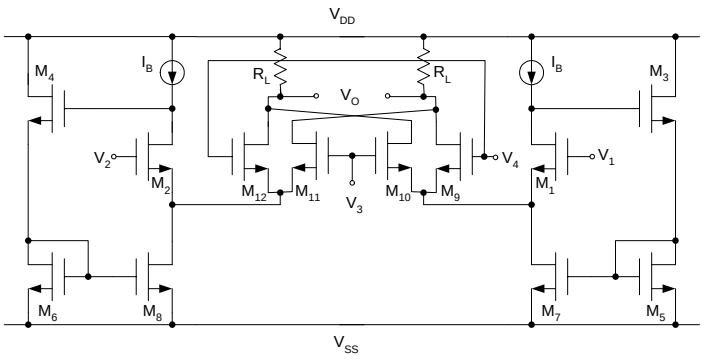

Fig. 5 The four quadrant analog multiplier

The output voltage of the proposed multiplier is the same as (7)

III. RESULTS

To verify the operations of the circuits, the designs were simulated in a 0.25µm T14Y model of MOSIS with level 3. The aspect ratio of transistors is shown in table 1 which likes the aspect ratio of ones in literature [9]. The voltage supplies are set to $V_{DD} = -V_{SS}=1$ volts and load resistors R_L are 10kΩ. Squaring circuit and square-rooting circuit use $I_B = 1\mu A$, and the multiplier circuit uses $I_B = 20\mu A$.

Table 1 W/L ratio of proposed circuits

squaring and Square-rooting circuits		The multiplier circuit	
transistor	W/L(µm/µm)	transistor	W/L(µm/µm)
M_1	10/1	M_1, M_2	200/1

The dc transfer characteristic of the squaring circuit is demonstrated in Fig. 6 when V_{in} is varied from -1_V to 1_V compared to expected curve $\left(= \frac{V_{in}^2}{16555}\right)$, and the frequency double in Fig. 7 is done by applying 1_Vp-p, 1MHz-sinusoidal signal to input of the squaring circuit and the output signal accord to the equation as $\sin^2 \omega t = \frac{1}{2}[1 - \cos 2\omega t]$. The dc transfer characteristic of the square-rooting circuit is demonstrated in Fig. 8 when I_{in} is varied from 0_A to 100_µA compared to expected curve $\left(= 65\sqrt{I_{in}}\right)$. The dc transfer characteristics of multiplier are shown in Fig. 9(a) and (b) by alternating the input signal V_{12} and V_{34}.

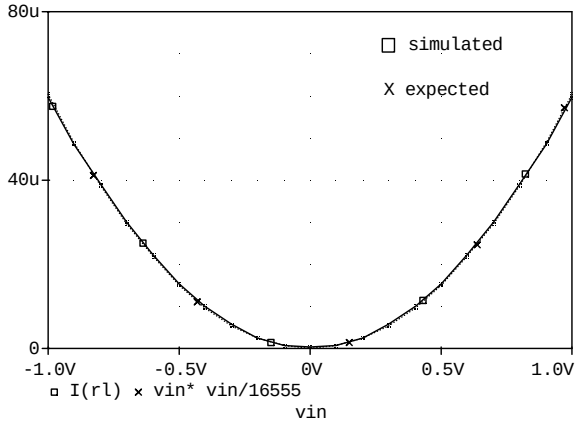

Fig. 6 The dc transfer characteristic of the squaring circuit

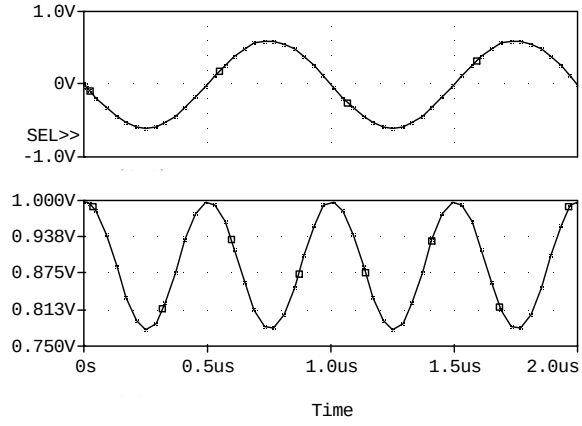

Fig. 7 frequency doublers where input is 500mVp, 1MHz-sinusoidal signal(upper trace) and the output waveform(lower trace)

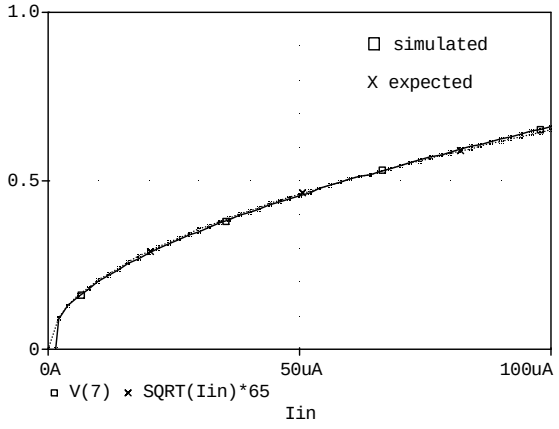

Fig. 8 The dc transfer characteristic of the square-rooting circuit

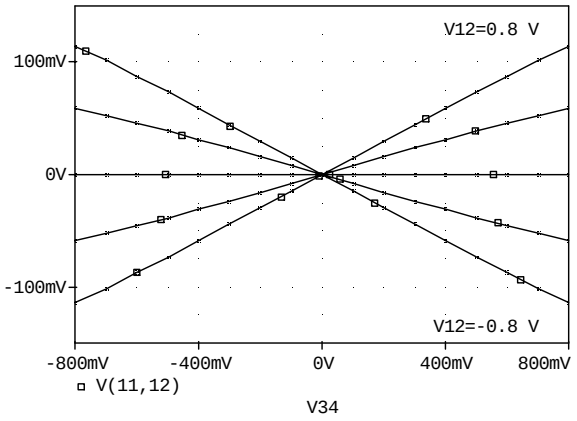
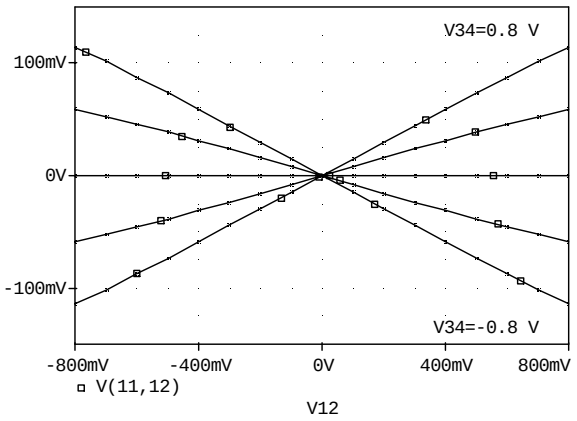


(a)



(b)

Fig. 9 The dc-characteristics of multiplier

The relative error of Fig. 6 is 1.1 % within the ±1_V input range (%error=$\left|\frac{X_e - X_s}{X_e}\right| \times 100\,\%$, X_e is expected value, X_s is simulated value). The relative error of Fig. 8 is 1.2 % within the 100μA input range. The total harmonics distortion (THD) of the proposed multiplier is 1.1% (where V_{34} is a $800mV_{P\text{-}P}$ input signal at 1MHz and V_{12} is 0.4_V dc voltage) and 0.8% (where V_{12} is a $800mV_{P\text{-}P}$ input signal at 1MHz and V_{34} is 0.4_V dc voltage). The -3dB bandwidth of multiplier circuit is 16GHz (where V_{34} is ac signal and V_{12} is dc signal) and 142MHz by alternating the input signal V_{12} and V_{34}.

The proposed squaring circuit in Fig. 2 is tested experimentally by using commercial CMOS transistor arrays (CD4007) The voltage supplies were set to V_{DD}=-V_{SS}=4 Volts, the load resistor R_L was 10kΩ . Fig. 10 shows the output voltage waveform when V_i is a $800mV_{P\text{-}P}$, 10 kHz-sinusoidal signal.

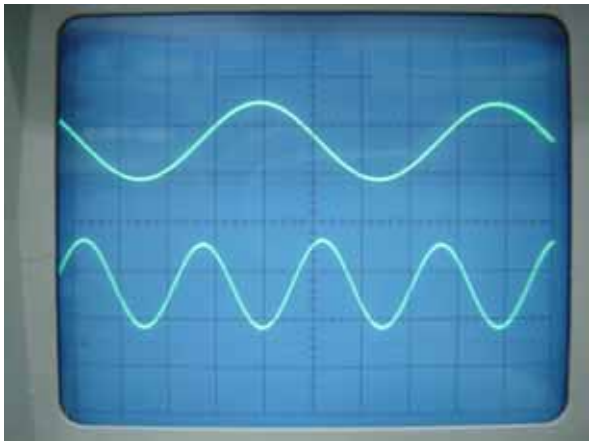


Fig. 10. The output waveform of frequency doublers (lower trace) when input is 800mVp-p,10 kHz-sinusoidal signal (upper trace)Volt/Div=0.5V, Time/Div=20μS.

IV. CONCLUSION

Squaring circuit, square-rooting circuit, and multiplier circuit using a voltage level shift buffer have been presented. The advantages of proposed circuits are simple structure, few devices, wide input range, and low voltage supplies. Simulation results show that all circuit can operate at ±1_V power supplies, the voltage input range of the squarer circuit is wide up ±1_V with 1.1% relative error, the current input range of the square-rooting circuit is about 100_μA with 1.2% relative error, the THD of the multiplier is less than 1.2% for a $800mV_{P\text{-}P}$ input signal at 1MHz fundamental frequency. These circuits are expected to be useful in many analog signal-processing applications.

B. Ultrasonic Signal Simulation

Ultrasonic signal can be modeled by gaussian function in Figure 2 and sine wave in Figure 3. $e(t)$ may be expressed in (2). F_0 is transducer center frequency. t is time. σ^2 is variance of gaussian function. t_0 is position of scatters in time domain. Figure 4 shows $e(t)$ at t_0 =2 μs. $h(t)$ is an impulse response of a scatter function used to convolute with $e(t)$ as described in (3).

$$e(t) = \exp[-2\pi^2\sigma^2(t-t_0)^2]\sin(2\pi F_0 t) \quad (2)$$

$$s(t) = e(t) * h(t) \quad (3)$$

For a medium of scatters, the echo signal $s(t)$ can be modeled in frequency domain as follows:

$$s(t) = e(t) * h(t) = \sum_M e(t) * h_a^2(M,t) * h_d(M,t) \quad (4)$$

where $h(t)$ is impulse response of scatters that relate to (5) and (6) in frequency domain. h_a^2 is the two ways impulse response of attenuation of a scatter in position M and $H_a^2(M,f)$ is frequency domain of h_a^2. $2Z$ is the total distance traveled by the ultrasound wave. $h_d(M,t)$ is a set of impulses in time domain that relate to position M in frequency domain as shown in (8). β is attenuation coefficient, which is estimated from FCS.

$$S(f) = E(f) \cdot H(f) \quad (5)$$

$$S(f) = \sum_M E(f) \cdot H_a^2(M,f) \cdot H_d(M,f) \quad (6)$$

$$H_a^2(M,f) = e^{-2Z\beta f} \quad (7)$$

$$H_d(M,f) = \delta(Z) \quad (8)$$

h_d is the scattering impulse function simulated by Dirac function. The position Z of a scatter is determined with function of object modeled. In this paper, two positions of Dirac function are utilized according to experimental system.

$$h_d(f,Z) = \delta(Z) \quad (9)$$

III. MULTINARROW BAND TECHNIQUE

MNB is one of strategies in Fourier statistics method that depends on the log-spectral estimation. The relation between incident wave and reflected wave in frequency domain can be described in (10).

$$S(f) = E(f) \cdot e^{-2Z\beta f} \quad (10)$$

E(f) is spectrum of incident wave from front surface and *S(f)* is the spectrum of reflected wave from back surface that is attenuated by factor $e^{-2Z\beta f}$ where 2*Z* is the propagation distance in material. With the classical assumption of linear with frequency attenuation, $\alpha(f)$ is attenuation expressed in dB/cm and β is the attenuation coefficient expressed in dB/cmMHz. The relation between $\alpha(f)$ and β can be expressed in (11).

$$\alpha(f) = \beta \cdot f \quad (11)$$

So, the βf in (10) is substituted by $\alpha(f)$ in (11) and get (12).

$$S(f) = E(f) \cdot e^{-2Z\alpha(f)} \quad (12)$$

The process to estimate the attenuation coefficient can be obtained by logarithm of (12) as shown in (13)-(16). Assuming, the sample is homogeneous. The attenuation $\alpha(f)$ may be estimated as a function of frequency from the slope of a linear regression fit to the log decay of spectra. The slope of ultrasonic attenuation coefficient, β, may be calculated via a linear frequency dependence of attenuation curve, $\alpha(f)$, versus frequency as shown in Figure 6. Equation (17) expresses unit conversion from Neper to dB.

$$10\log S(f) = 10\log E(f) - 20Z\alpha(f) \cdot \log e \quad (13)$$

$$10\log S(f) = 10\log E(f) - 20Z\alpha(f) \cdot \frac{1}{\ln 10} \quad (14)$$

$$10\log S(f) - 10\log E(f) = -20Z\alpha(f) \cdot \frac{1}{\ln 10} \quad (15)$$

$$\alpha(f) = \left(\frac{10\log S(f) - 10\log E(f)}{-20Z} \right) \ln 10 \quad (16)$$

$$\beta\,[\text{dB/cmMHz}] = 8.68 \cdot \beta\,[\text{Neper/cmMHz}] \quad (17)$$

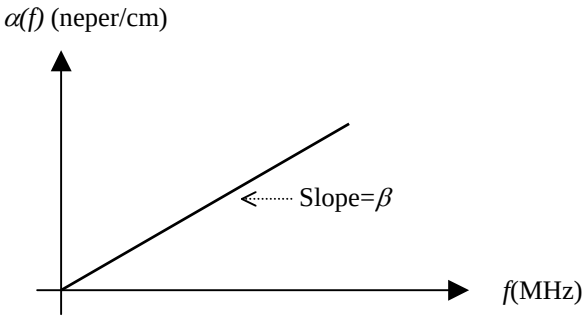

Figure 6. Slope of $\alpha(f)$

IV. NUMERICAL SIMULATION

According to ultrasonic transducer, 5 MHz of center frequency is selected to simulate ultrasonic signal with attenuation coefficient of brass = 0.50dB/cmMHz [6] as shown in Figure (7). The difference of time corresponds to Z=2.5 cm at *c*=4.430 mm/μs as described in Table I.

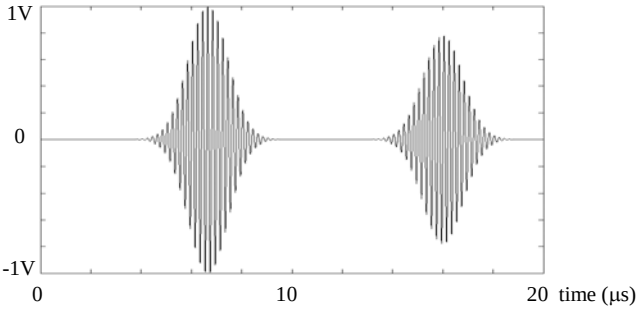

Figure 7. Simulation of Ultrasonic signal at 5 MHz

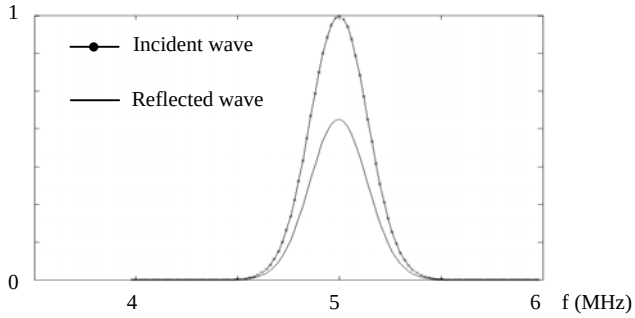

Figure 8. Spectrum of incident wave and reflected wave

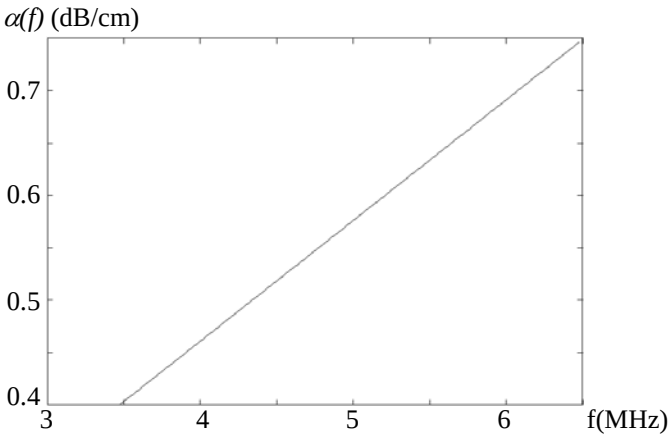

Figure 9. Attenuation versus frequency of simulated signal

From Figure 8, the spectrum of both incident wave and reflected wave is computed. The β in term of $\alpha(f)$ is estimated by (16) and plotted in function of frequency as shown in Figure 9. The slope of Figure 9 is 0.0576 Neper/cmMHz. To convert Neper unit to dB, equation (17) is applied by factor 8.68. Then, the result of the ultrasonic attenuation coefficient of simulated signal is 0.4999 dB/cmMHz. Additionally, other β values at 1 MHz and 5 MHz are tested and verified as shown in Table III.

TABLE III

ATTENUATION COEFFICIENTS COMPUTED BY SIMULATED SIGNAL

β (dB/cmMHz)	MNB		Error (%)	
	1 MHz	5 MHz	1 MHz	5 MHz
0.1	0.1020	0.1000	2.0000	0.0000
0.3	0.3001	0.3000	0.0333	0.0000
0.5	0.5021	0.5000	0.4200	0.0000
0.7	0.7021	0.7000	0.3000	0.0000
1.0	1.0021	1.0000	0.2100	0.0000
1.5	1.5021	1.5001	0.1400	0.0067
2.0	2.0021	2.0001	0.1050	0.0050
3.0	3.0022	3.0001	0.0733	0.0033

V. EXPERIMENTAL VALIDATION

The experimentation is built up as shown in Figure 10. The metal, brass, is immersed in Plexiglas water tank. Furthermore, the ultrasonic transducer is located at the top of water tank and linked to digital oscilloscope. The instruments and devices as shown in Table IV are setup to obtain an ultrasonic signal. Ultrasonic pulse generator and transducer are selected in same manufacturer, Panamatrics. The reflection mode is selected to measure the ultrasonic signal. The echo signal from transducer is digitized with digital oscilloscope and sent as a digital data set to personal computer by GPIB cable. The ultrasonic signal, *s(t)*, is digitized with a sampling interval $\Delta t = 1/F_s$ (F_s is the sampling frequency = 500 MHz), in 10,000 samples. Figure 11 displays a captured signal. The digitized data is computed to obtain β by MNB algorithm. So, β of measured signal is 0.4485 dB/cmMHz. The error calculated by (18) of β between simulation and experimentation is approximately 10.3%.

$$\text{Error (\%)} = \frac{\left|\beta_{theory} - \beta_{estimation}\right|}{\beta_{theory}} \cdot 100 \qquad (18)$$

VI. CONCLUSION

The primary goal of this paper is to establish the quantitative estimation for obtaining the ultrasonic attenuation coefficient in solid immersed in water. The MNB technique is the log-spectral estimation in frequency domain. The β is estimated by a linear frequency dependence of attenuation curve versus frequency. The ultrasonic reflection mode is selected to simulate and measure. The 5 MHz unfocused ultrasonic transducer and brass are selected and immersed in Plexiglas water tank. The data is acquired and computed by MNB algorithm. The result show that β from simulated signal is 0.50 dB/cmMHz while β from experimentation is 0.4485 dB/cmMHz. The error is approximately 10.3% because this work excludes the ultrasonic diffraction effect. However, the result in simulation and experimentation is in agreement with the experimental values To reduce the error, the Lommel diffraction correction method [7] will be compensated in future work.

***Abstract*–In this paper, we propose an electronically tunable high-value floating resistor by using CCCII with controlled output current gain. The very high-value resistor can be easily achieved by increasing the current gain of CCCIIs without changing the circuit configuration. The resistance value can be tuned electronically by bias current or current gain of CCCIIs. The proposed floating resistors were confirmed by using PSpice simulation.**

I. INTRODUCTION

The electronically tunable floating resistor is widely used in analog circuits. The application can be found in telecommunications, electronics and instruments such as active RC filter, oscillators, variable gain amplifiers, voltage or current to frequency converters etc. In VLSI technology, a resistor is formed on silicon wafer. However, resistors of practical values on silicon wafer suffer from limited values, high variability due to process variations and large temperature coefficients. Moreover, its resistance values are not variable. Therefore, they are generally replaced by active resistors. In the past, several electronically tunable resistors have been reported in the literatures with different techniques in literature [1]-[5]. However all of these reports are limited the resistance value. Recently, the high-value floating resistor using CMOS technology was reported in [6] enjoys electronically tunable and it is suitable for integrated circuits fabrication.

In this paper, a high-value electronically tunable floating resistor in bipolar technology has been presented. The proposed circuit bases second-generation current conveyors (CCCIIs) with controlled current gain. Our structure has more flexibility when the resistance value can be tuned by bias current or current gain of CCCIIs.

II. CIRCUIT REALZATION

The symbol of the relatively active element CCCII with controlled current gain is shown in Fig. 1(a), and is characterized by the relationship:

$$\begin{pmatrix} I_Y \\ V_X \\ I_Z \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 \\ 1 & R_X & 0 \\ 0 & k & 0 \end{pmatrix} \begin{pmatrix} V_Y \\ V_X \\ V_Z \end{pmatrix} \tag{1}$$

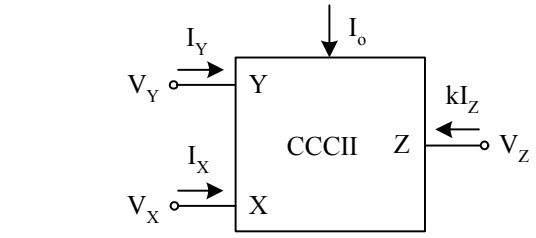
The input impedances for the ideal CCCII are infinite at terminal Y and R_X at terminal X, respectively. The terminal Z, that is equivalent to a current generator, possesses infinite output impedance. The schematic implementation for CCCII with current gain, implemented with bipolar technology is shown in Fig. 1(b). The intrinsic resistance R_X can be tuned by the bias current I_o, given by [7]

$$R_X = \frac{V_T}{2I_o} \tag{2}$$

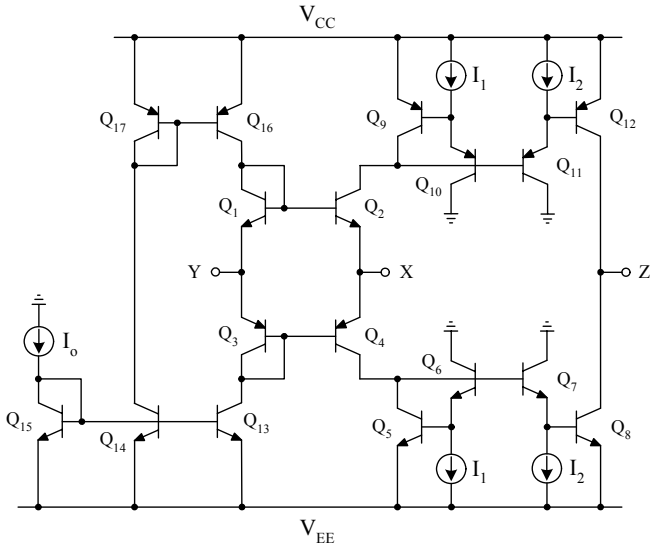
where V_T is the thermal voltage. The current gain k of this current conveyor is determined by the current ratio [8]. The current gain k can be changed by varying I_1 or I_2, expressed as [8]

$$k = \frac{I_1}{I_2} \tag{3}$$

The schematic in Fig. 1(b) is used to realize the high-value floating resistor.



(a)



(b)

Fig.1. Bipolar CCCII: (a) symbol and (b) schematic.

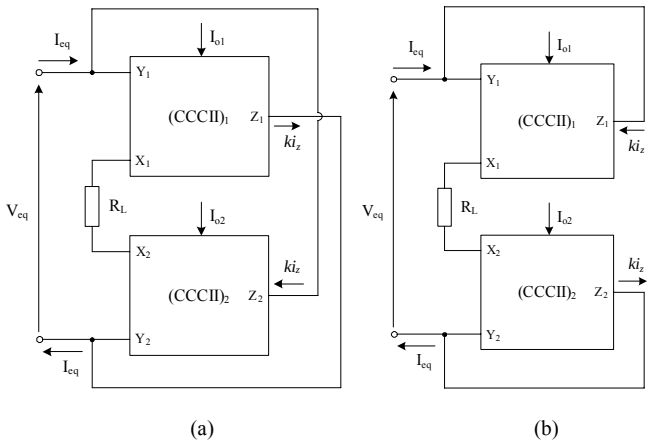


Fig. 2. Symbolic of proposed current controlled floating resistors: (a) positive floating resistor and (b) negative floating resistor.

Fig. 2 shows the proposed high-value current controlled floating resistor. The resistor R_X is an intrinsic resistance in each port X_1 and X_2. The load resistor R_L is connected between X_1 and X_2. The output of each CCCII is constituted by a current gain cell. Therefore, the output current on ports Z_1 and Z_2, they are equal to i_X/k. The outputs Z_1 is connected to Y_2 and Z_2 is connected to Y_1 to be the high-input positive floating resistor impedance as shown in Fig.2(a) or the outputs Z_1 is connected to Y_1 and Z_2 is connected to Y_2 to be the high-input negative floating resistor impedance as shown in Fig.2(b). Its floating resistance value can be given by

$$R_{eq} = \frac{1}{k}\left(2R_X + R_L\right) \tag{4}$$

Using (2)-(3), (4) can be rewritten as

$$R_{eq} = \frac{I_2}{I_1}\left(\frac{V_T}{I_0} + R_L\right) \tag{5}$$

From (5), it notes that the resistance value of proposed resistor can be tuned by bias current I_o. Moreover, the high-value of resistance can be adjusted by current gain ratio through I_1 and I_2. Note that by using CCCII with controlled current gain, resistance value of proposed resistor can be electronically tuned with both the bias current and current gain. Whereas the resistor circuit of Zouaoui-Abouda and Fabre [6] used CCCII with fixed current gain, thus only current bias can be tuned. Hence our structure has more flexibility than the resistor circuit of [6].

III. Simulation Results

The simulations were carried out at 27°C. Using the bipolar transistors NR100N and PR100N [9]. The floating resistor circuits in Fig. 2 are simulated. The DC supply voltage is ±2.5V. The results can be shown as follows. Figs. 3-4 show the variation of resistance of circuit in Fig. 2(a) with the current gain k=10 and R_L=0 and 1kΩ, respectively, against varies the current bias I_o. From Fig 3, the value of resistor decreases from 127 to 4.75kΩ when I_o varies between 2 and 50μA while the value of resistor decreases from 138.5 to 13.7kΩ when I_o varies between 2 and 50μA as shown in Fig. 4. Fig. 5 shows the variation of the negative resistance value of circuit in Fig. 2(b) as a function of I_o. With R_L=0Ω, the value of the resistor decreases from 90.2 to 7.2kΩ when I_o varies between 3 and 50μA. With R_L=1kΩ, the value of the resistor decreases from 104.5 to 16.4kΩ when I_o varies between 3 and 50μA, as shown in Fig. 6. From Figs. 3-6, all simulation results are confirmed with theoretical. Note that the proposed circuit can be provided high-value of resistance close up with theoretical results. To demonstrate the proposed resistor circuit has more flexibility than previous resistor circuit, the circuit in Fig. 2(a) is simulated again. Fig.7 shows the variation of the floating resistance value as a function of the load resistor R_L when I_o is 10μA and current gain is 10. The value of the resistor increases from 40 to 250.2kΩ when R_L varies between 1 and 20kΩ. Fig.8 shows the variation of the floating resistance value resistor as a function of the current gain (k) when I_o is 10μA and R_L=1kΩ. The value of the resistor increases from 7.2 to 92.3kΩ when k varies between 2 and 20.

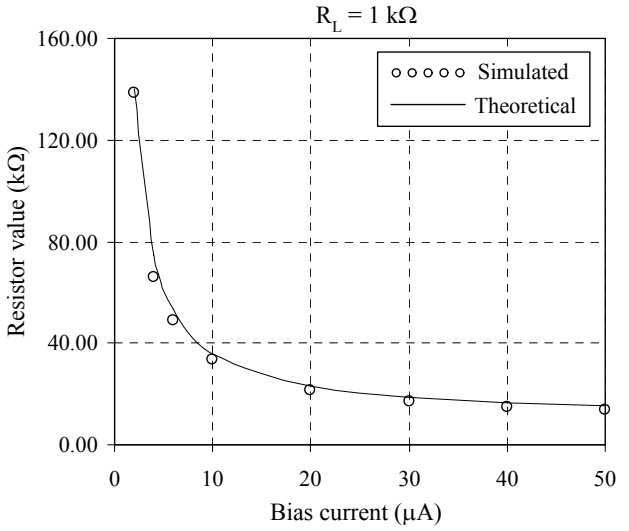

Fig. 4. Variation of positive resistance with DC bias current with R_L=1kΩ.

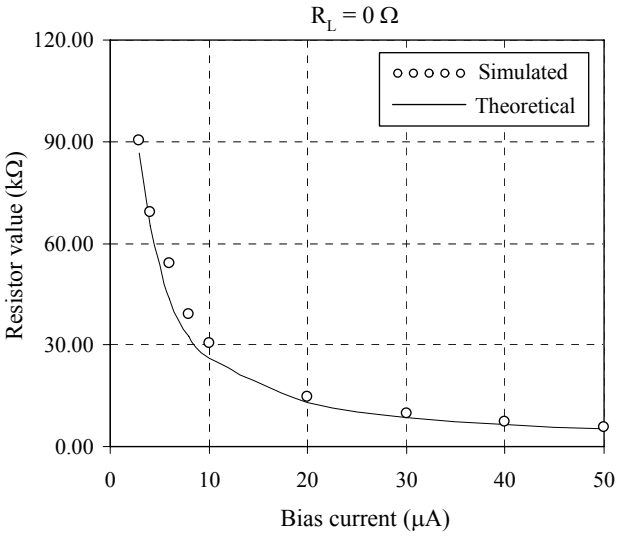

Fig. 5. Variation of negative resistance with DC bias current with R_L=0kΩ.

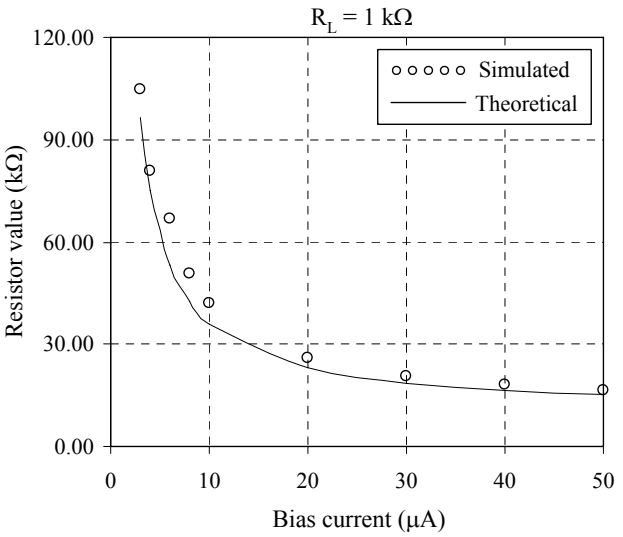

Fig. 6. Variation of negative resistance with DC bias current with R_L=1kΩ.

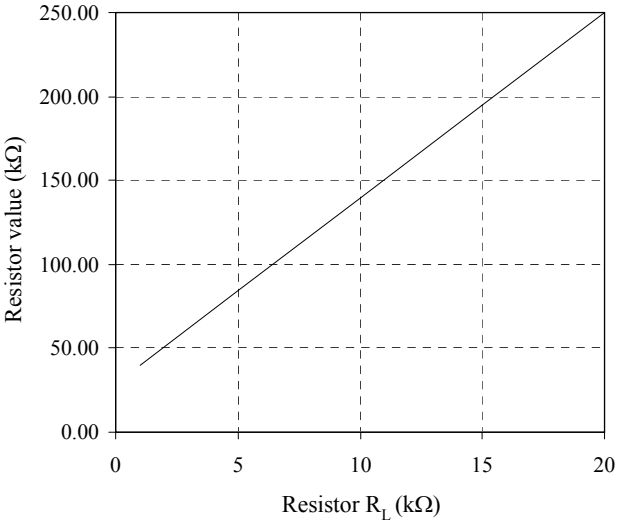

Fig. 7. Variation of resistance with the load resistor R_L.

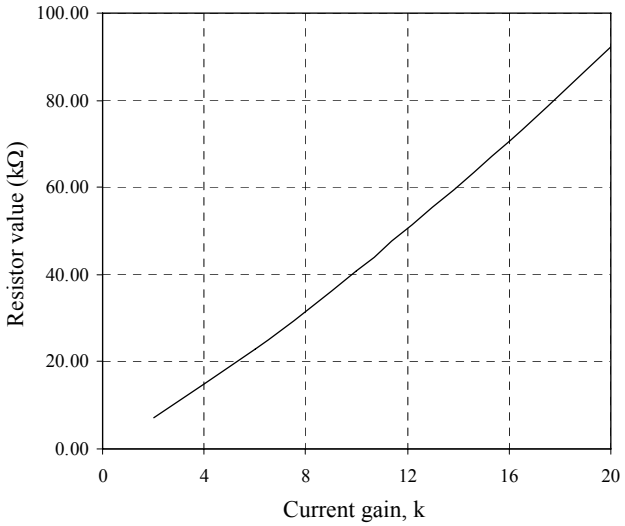

Fig. 8. Variation of resistance with the current gain k.

IV. CONCLUSIONS

A new technique for realizing the floating controlled resistor has been described. The high-value of resistance can be achieved and electronically tuned. It consists of two CCCIIs with controlled current gain, which can be fully integrated in bipolar technology. The resistance value can be electronically tuned by bias current or current gain. Moreover, by using CCCII with controlled current gain, the high-value or low-value range of resistances can be selected by varies the current gain. Simulation results have confirmed the performance of proposed circuits.

***Abstract*-This paper presents a fully-swing adiabatic circuit. The proposed circuit can reduce a non-adiabatic loss by completely returning charge at the output node during the recovery phase to the clocked supply. As a result, overall efficiency is improved toward its theoretical limit. In order to confirm its operation, circuit simulations of inverter/buffer chain are performed. Simulation results show that the proposed circuit achieves energy saving as much as 24% compared to 2N-2N2P adiabatic logic implementation at clock rate of 100 MHz.**

I. INTRODUCTION

Power dissipation has been a highly concerned issue in the performance of VLSI circuits. For high-speed digital CMOS circuits, there are several methods to achieve a low power dissipation such as reducing the supply voltage, the voltage swing, the load capacitance, and the switching activity. Although those methods try to minimize the power dissipation, still all of its energy drawn from its dc supply is completely dissipated in the circuit. Alternatively, adiabatic circuits can reduce power dissipation by utilizing ac power supplies to recycle the energy stored in the load capacitance instead of being dissipated in the circuits. Since their operation require slow transition of their ac supply voltage, adiabatic circuits lose their energy efficiency when operate at high frequency. However they still have some advantages over CMOS circuits for applications that do not require very high speed such as portable electronics.

The current adiabatic circuits can be classified as either partially adiabatic or fully adiabatic. In the fully adiabatic circuit, all the charge on the load capacitance is recovered by the power supply while in the partially adiabatic circuit, only some charge is recovered. The examples of the fully adiabatic circuits are Pass Transistor Adiabatic Logic (PAL)[1] and Split Rail Charge Recovery Logic (SCRL)[2]. This types of circuits however are difficult to implement due to its complexity of synchronization between cascading stages which limits its maximum operating speed. In contrast the partial adiabatic circuits can be designed based on a CMOS logic. The popular partially adiabatic families include 2N-2N2P[3], Efficient Charge Recovery Logic (ECRL)[4], Clock Adiabatic Logic (CAL)[5], and True Single Phase Adiabatic Logic (TSEL)[6]. The power supply for adiabatic operation is usually a trapezoidal or sinusoidal voltage source. This supply voltage also acts as a clock. Digital systems with multiple stages/cascades based upon the described adiabatic power clocking scheme usually require four clock phases when using a trapezoidal voltage source and two clock phases when using a sinusoidal voltage sources. The sinusoidal signal also can be considered as an approximation of the trapezoidal waveform with zero hold phase.

Although it is simple to implement and has a rather high operating frequency, the voltage output low of 2N-2N2P is not equal to GND but a threshold of PMOS. We proposed a partially adiabatic circuit based on 2N-2N2P structure which uses two complementary sinusoidal supply clocks. The circuit gives a full swing output while still possesses the advantages of 2N-2N2P. As a result, energy saving are improved. The paper is organized as follows. In Section II, the adiabatic switching and 2N-2N2P are discussed. Section III describes the operation of the proposed circuit. The performance comparisons of 2N-2N2P and the proposed circuit are presented in Section VI. Finally, we draw our conclusion in Section V.

II. ADIABATIC CIRCUITS

The dominant factor in the dissipation of static CMOS logic is the power required to charge capacitive node.

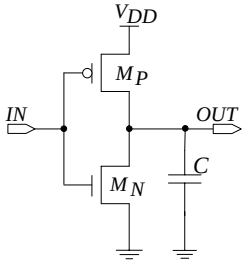

Figure 1. Static CMOS inverter.

In the CMOS inverter of Figure 1, when the output changes to high, the total energy drawn from the power supply is $E= CV^2_{dd}$, where C is the capacitance of the output node and V_{DD} is the supply voltage. Half of this energy is dissipation on the on-resistance R of the device MP, and the other half is stored in the output capacitance. When the output is driven low at a

later cycle, the energy stored in the output capacitor is dissipated on the on-resistance R of the device MN.

A. *Adiabatic Switching Theory*

The principle of adiabatic switching can be explained by its comparison to a simple RC circuit. Figure 2(a) shows current as a function of time during a switching of a static CMOS circuit. A low to high transition at node *out* can be modeled as a charging of load capacitor through a switch and its effective resistance. When the switch is turn on, *C* is charged up to V_{dd}. The current through the resistance decreases exponentially as the time passes. The energy dissipates is equal to $(1/2)CV^2_{dd}$ where V_{dd} is the voltage change at the node *out*. In an adiabatic circuit Figure 2(b), the transition is slowed down by using a time-varying voltage source instead of a static voltage supply. By spreading the transfer of charge to the capacitor over time, the current is greatly reduced. The overall energy dissipation is reduced to $(RC/T)CV^2_{dd}$ [7] if the current flow is maintained constant where *T* is total switching time. Ideally, with *T* approaching infinity, the energy dissipation for a switching will approach zero.

The power supply for adiabatic circuits produces a time-varying periodic signal, or *ac-supply*, that gradually swings between 0V and V_{dd}. The period of this signal is long enough to maintain a small potential drop V_R across the resistor. Alternatively, a simple form of adiabatic charging can also accomplished by using a power supply with a ramp output. Such a signal can be approximated as an oscillating signal from a resonant RLC circuit. The number of phase of *ac-supply* required to control cascaded gates is an important consideration in adiabatic logic design since it affects energy consumption, operating speed, and design complexity.

B. *2N-2N2P adiabatic logic*

The 2N-2N2P is a partially adiabatic circuit, as shown in figure.3. It uses a pair of cross-coupled NMOS(MN1 and MN2) to obtain non-floating output. To cascade 2N-2N2P circuits it needs four-phase *ac-supply*. Note that MP1 and MP2 are used for both charging the output node and return charge to the supply, thus its energy loss per cycle is

$$E = 2\left(\frac{R_P C_L}{T}\right) C_L V_{dd}^2 + C_L V_{tp}^2 \qquad (1)$$

Where C_L is the load capacitance, R_P is the turn-on resistance of PMOS, T is the transition time of the supply, V_{dd} is the peak voltage of the supply, and V_{tp} is threshold voltage of PMOS. In Eq. (1), the first term represent adiabatic energy, which can be reduced by lowering operation frequency and the second term represent non-adiabatic energy loss which is dependent on the load capacitance.

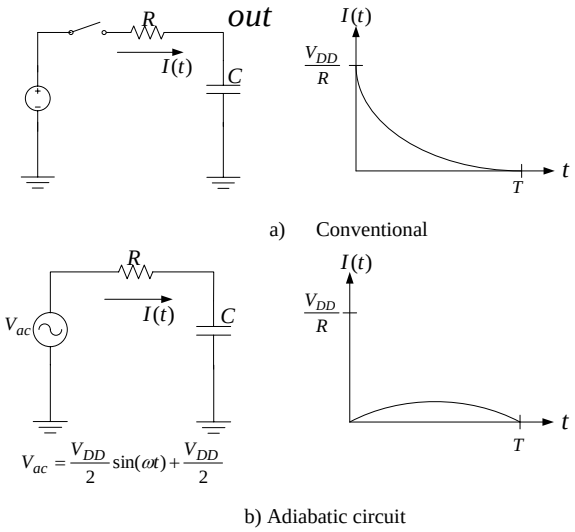

Figure 2. Modeling of the charging process in different circuit.

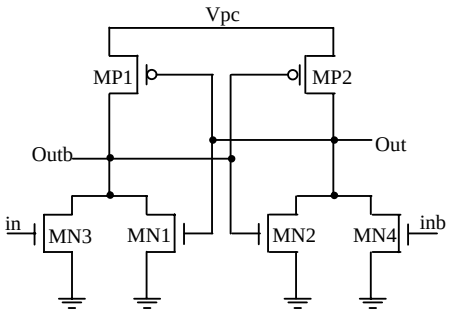

Figure 3. 2N-2N2P adiabatic logic.

III. PROPOSED ADIABATIC LOGIC

The proposed circuit is made up of a 2N-2N2P buffer/inverter and two additional pulse-controlled transistors (MN5, MN6) shown in the Figure 4. Pc and Pcb are the two opposite phases ac supply used for cascading stages as in Figure 5. The operation of the circuit can be explained as follows. While Pc ramps up from GND to V_{dd} if the input IN is high and INb is low, MN3 is turned on and MN4 is turned off. Therefore, the output node OUTb is discharged to ground by MN3. Consequently MP2 turns on. As a result the output node OUT increases as the supply (Pc) rises. When the supply (Pc) ramp down from V_{dd} to GND, the charge previously stored in the load capacitance at the OUT node returns to the supply. Due to the threshold voltage of PMOS, as the supply reaches about a threshold above GND MP1/MP2 stop conducting current. Hence, the output voltage cannot drop to GND. Therefore some of the charge remains in the load capacitance. To prevent this additional NMOS (MN5/MN6) are connected between the output nodes and the supply in the proposed circuit. As a result, when PULSE is high, MN5/MN6 are turned on the remaining charge at output node can be discharged to supply via MN5/MN6. Consequently, the output

voltage can reach GND. Thus, more charge can return to the supply.

The basic proposed circuit buffer/inverter logic gate can be expanded to other complex gates, such as AND/NAND, OR/NOR, and multiplexer, by using NMOS tree to replace MN3 and MN4. Then all these can build up various circuits, for example, adder, counter, and multiplier.

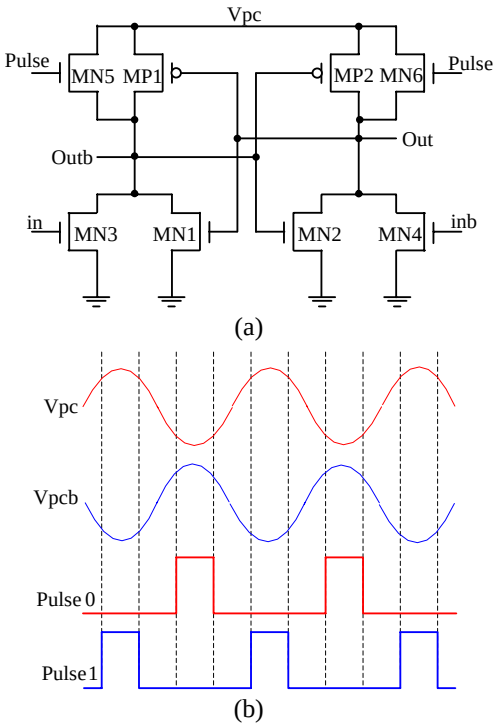

Figure 4. a) The proposed circuit b) Waveform and timing relationship between the supply voltage and pulse signal.

IV. SIMULATION RESULTS

The proposed circuit was simulated using 0.35 μm TSMC CMOS technology. A capacitive load of 20fF is placed at output nodes. The amplitude of sinusoidal power supply is 0.75V. Note that the PULSE signals can be obtained directly from the control signals used in a supply generator circuits. We discuss the result of HSPICE simulation of 4-stage pipeline using two-phase sinusoidal power supply shown in figure.5.

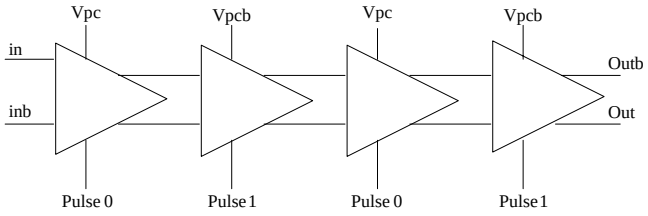

Figure 5. The 4-stage pipeline using two-phase sinusoidal power supply.

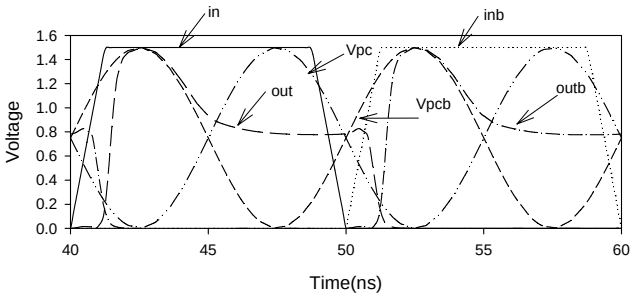
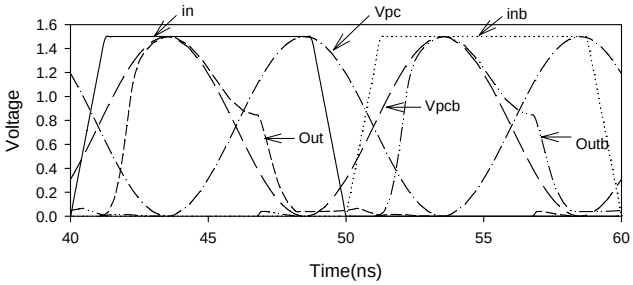
Figure 6 shows transient waveforms of the 2N-2N2P and the proposed circuit. In figure 6(a) the output voltages can not reach the ground level. In figure 6(b), when the supply is low and PULSE signal is active the MN5/MN6 are on and both of their output nodes (OUT, OUTb) are pulled to the same voltage level as the supply i.e., GND.



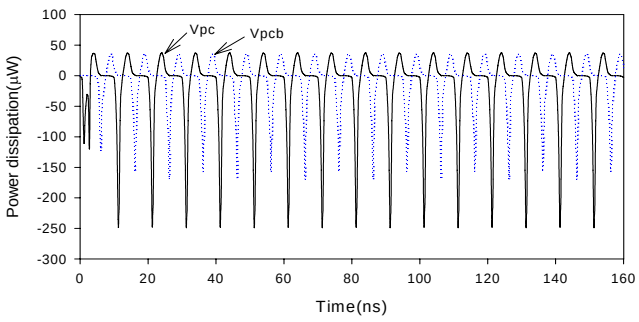
a) the 2N-2N2P circuit



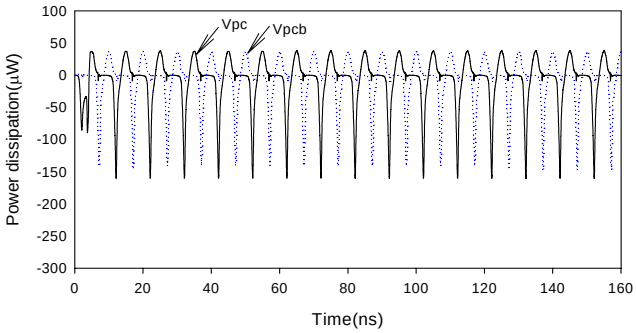
b) the proposed circuit

Figure 6. Transient waveforms of 2N-2N2P and proposed circuits at frequency 100MHz

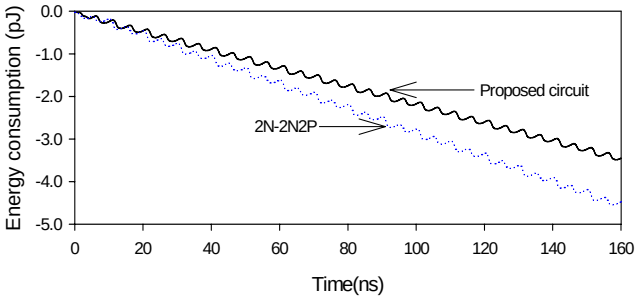
The Figure 7(a) and 7(b) shows plots of the power dissipation of the circuits at 100MHz. Negative and positive values indicate power flowing into and out of the circuit. Figure 7(c) shows the energy consumption during the transients of 2N-2N2P and proposed circuit. Clearly, the consumed energy of the proposed circuit is smaller than that of the 2N-2N2P circuit. Excluding power consumption used to generate the PULSE signal, the proposed circuit consumes 3.45 pJ, which is 76% of that of the 2N-2N2P (4.5 pJ).



a) Power dissipation of power clocks, Vpc, and Vpcb in 2N-2N2P circuit.



b) Power dissipation of power clocks, Vpc, and Vpcb in proposed circuit



c) Energy profiles

Figure 7. The power profiles of the simulation circuits at 100MHz

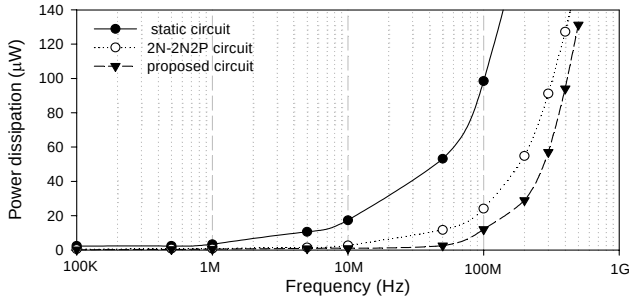


Figure 8. Power dissipation against operating frequency

Figure. 8 shows the power dissipation against the operating frequency of the 2N-2N2P, the proposed circuit, and static circuit at a supply voltage 1.5V ac and dc respectively . At 100MHz, the 2N-2N2P circuit consumes 26 μW, the static circuit consumes 98 μW, and the proposed circuit consumes 19 μW.

The setup of the complete system is shown in Figure. 9. The pulse generator circuit produces two non-overlapsing clocks, *Pulse0* and *Pulse1* from the system clock *Clk*. These two pulses control oscillation frequency of the sinusoidal supply as well as allow outputs of each stages to reach GND

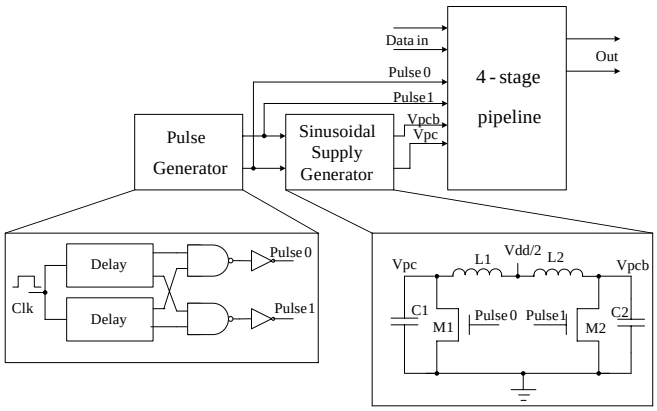

Figure 9. Simulation setup for buffer/inverter chain

V. CONCLUSION

We present a low power adiabatic circuit based on a 2N-2N2P adiabatic circuit. The proposed circuits is able to eliminate the non-adiabatic loss. The simulation results show that at operation frequency of 100MHz the proposed circuit consumed 76% of the energy of a conventional 2N-2N2P adiabatic circuit. The circuit is suitable for the low power applications such as portable devices where speed is not a critical factor.

***Abstract*-This paper presents the effect of resonances in enclosure with apertures. An analytical formulation has been employed for the shielding effectiveness. The factors such as the size and shape of aperture, sum of apertures are important to shielding performance. To improve the shielding, the use of metal piece inside enclosure is studied for removing the lowest resonance frequency. Results show that the place of metal piece can be used to evaluate shielding effectiveness for design purposes.**

I. INTRODUCTION

The shielding enclosure has already been studied many times. It is frequently used to reduce the emission or to improve the immunity of the electronic equipment. Electromagnetic compatibility (EMC) of enclosures of electronic equipment is a key issue that must be taken into account in the early stages of design. The integrity of shielding enclosures is compromised by slots and apertures for heat dissipation, CD-ROMs, I/O cable penetration or other possibilities. These apertures tend to become the coupling route of Electromagnetic Interference (EMI) from interior to outside hence degrade the Shielding Effectiveness (SE) of the enclosure. This parameter is defined as the ratio between the incident field in absence of the shield and the field in the same position when the effect of the enclosure is taken into account, the definition of Electrical Shielding Effectiveness (SE_E) will be as [1]:

$$SE_E = 20log(E_2/E_1) \quad (1)$$

E_1: Electrical field with shielding;
E_2: Electrical field without shielding.

There are two methods to calculate the shielding effectiveness[2], numerical simulation and analytical formulation. For numerical method that have been researched and used to calculate the shielding effectiveness include transmission line matrix (TLM)[6], finite difference time domain[7] (FDTD), method of moments (MoM) and finite element method (FEM)[8]. These methods can model complex structures but often require a relatively large amount of computer memory and computation time to give reasonable accuracy. Although they are good at predicting the shielding of a particular enclosure, it is difficult for designers to use them to investigate the effect of design parameters on SE and SM. For analytical formulation, it provides a much faster calculating shielding effectiveness. Analytical methods include transmission line analogy and circuit theory. A simple a rectangular enclosure with an aperture at one face can be modeled by an equivalent circuit, to predict the shielding effectiveness as a function of the frequency and the size of the aperture. The size of the enclosure is often expressed in units of the wavelength of the radiation, commonly known as the electrical size of the enclosure. The apertures can behave like antennas, and their electrical size can be defined analogously to that of antennas. We employ the analytical formulation[3]. It can be calculated as functions of frequency, aperture dimensions, enclosure dimensions, wall thickness and position within the enclosure. Results show that shielding effectiveness related to the parameters above.

In this work, we present the technique to improve the shielding by metal piece. The enclosures will produce resonance frequencies. These resonances are possible to suppress or remove by resize the enclosure dimensions. While almost enclosures dimensions are fixed, the use of metal piece inside the enclosures is studied for removing the lowest resonance frequency. We found the distance from the back wall of enclosure to the metal piece influence to shielding effectiveness.

II. THEORY

A rectangular enclosure with a rectangular aperture is represented by the equivalent circuit which is shown in Fig. 1. The electric shielding, a distance p from the aperture is obtained from the voltage at point P in the equivalent circuit, while the current at P gives the magnetic shielding. The radiating source is represented by voltage V_0 and impedance $Z_0 \cong 377\,\Omega$ and the enclosure by the shorted waveguide whose characteristic impedance and propagation constant are Z_g and k_g. According to Robinson *et al.*[3], the first process is finding an equivalent impedance for the slot and then using simple transmission line theory to transform all the voltages and impedances to point P.

First, the slot impedance is calculated. The aperture is represented as length of coplanar strip transmission line. For aperture impedance Z_{ap}, it is calculated from the short circuits at the ends of the aperture through a distance $l/2$ to center. This is represented by point A in the equivalent circuit and include a

factor *l/a* to account for the coupling between the aperture and the enclosure. The aperture impedance Z_{ap} is defined in

$$Z_{ap} = \frac{l}{2a} jZ_{0s} \tan\frac{k_0 l}{2} \quad (2)$$

where $k_0 = 2\pi/\lambda$ and Z_{0s} is characteristic impedance which given by Gupta *et al*[5].

According to Robinson *et al.*, to calculate the electric and magnetic shielding effectiveness, it is defined from voltage and current at point *P*, respectively.

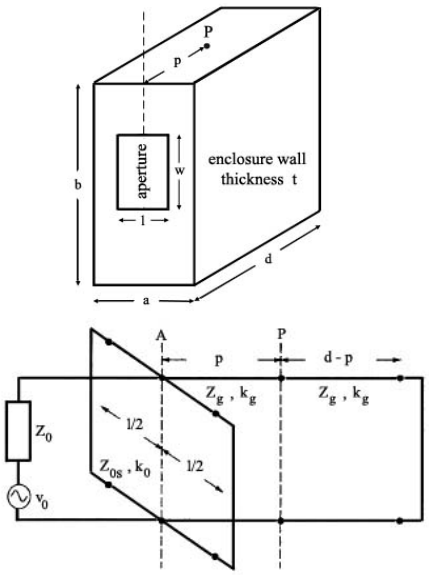

Fig. 1. Rectangular enclosure with aperture and its equivalent circuit.

Here we employ the analytical formulation for calculate the shielding effectiveness in difference parameters to show that the enclosure resonance. We set the enclosure dimension at 20x40x45 cm, aperture sizes are 1x18 cm, 2x9 cm and 3x6 cm, thickness at 0.2 cm and distance from the aperture *p* is 5 cm. All apertures are the same area at 18 cm^2. We will compare the shielding effectiveness with the aperture of different shape. The result is shown in Fig. 2.

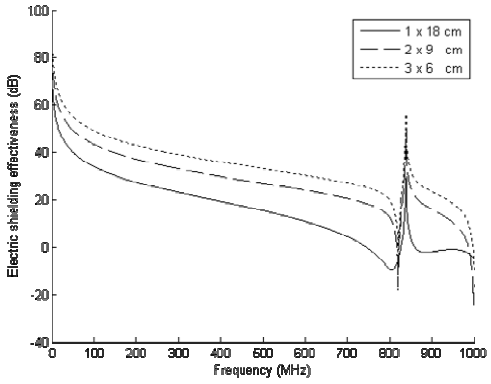

Fig. 2. Calculate SE_E at 5 cm of 20x40x45 cm enclosure with 1x18, 2x9, 3x6 cm apertures.

The calculation shows that the shielding effectiveness of the 3x6 cm aperture is better than 2x9 and 1x18 cm apertures. Shielding effectiveness decrease from low frequencies to high frequencies and resonate at the same point. We concentrate in resonance frequencies, all of them resonate at approximately 800 MHz.

Now we investigate the influence to resonance frequencies by changing the dimension of enclosure. We keep the same aperture size at 2x9 cm and measurement point *p* at 5 cm from aperture, while we change the parameter 'a', 'b' and 'd'. The results are shown below.

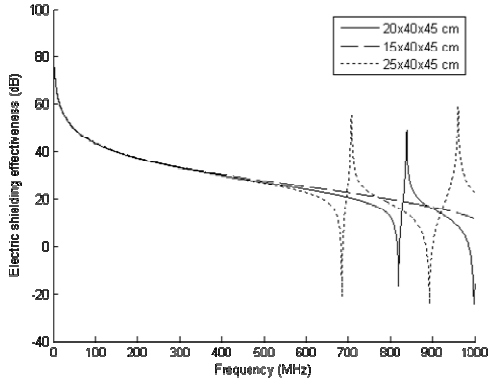

Fig. 3. Calculate SE_E of difference parameter 'a' enclosures.

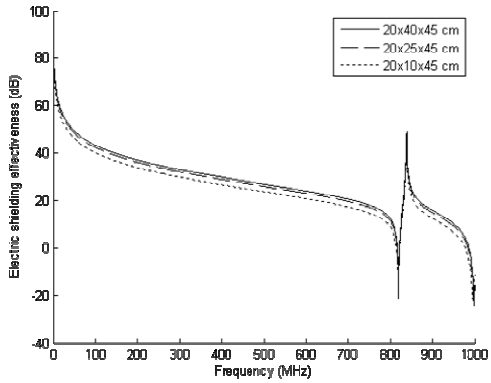

Fig. 4. Calculate SE_E of difference parameter 'b' enclosures.

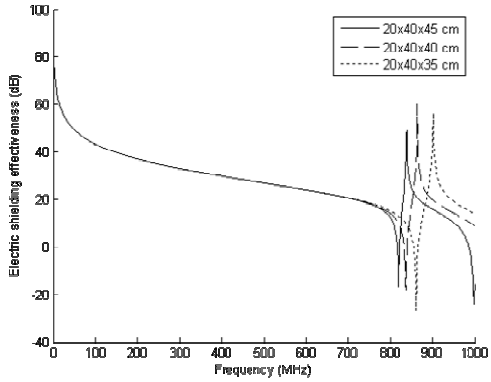

Fig. 5. Calculate SE_E of difference parameter 'd' enclosures.

Fig. 3 shows the results which difference resonance frequencies. For ‘a’ = 20 cm, the resonance is 800 MHz. While we decrease ‘a’ to 15 cm, the resonance frequency has been shifted over 1000 MHz. When ‘a’ is increased to 25 cm, the resonance frequencies are 700 MHz and 900 MHz. In Fig. 4, the resonance frequencies are the same point at approximated value of 800 MHz. The results show difference shielding effectiveness. The 20x40x45 cm enclosure is better than 20x10x45 cm enclosure. Fig. 5 shows the results when we change ‘d’ parameter. We found that while the ‘d’ is decreased, the resonance frequency is increased.

In case of ‘d’, the parameter influences to the resonance frequency. While almost enclosures dimensions are fixed, to resize enclosures is uncomfortable. The use of metal piece inside the enclosures is studied for removing the lowest resonance frequency. It is possible to do that because these resonances will be absorbed by the metal piece inside the enclosure and it is more comfortable than changing enclosure dimension.

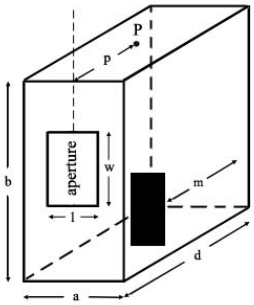

Fig. 6. Measurement set up with a metal piece inside the enclosure.

III. MEASUREMENTS

We set up the 20x40x45 cm aluminium enclosure for test. A rectangular 1x18 cm aperture is placed at the front face of the enclosure. There is a metal piece in the enclosure with the distance *m* from the back wall. Fig. 6 shows a metal piece inside the enclosure. The measurements are performed in a semi anechoic chamber. The experimental equipment are an EMI receiver with Bi-log antenna in the range of 30 MHz – 1000 MHz, signal generator, dipole antenna and ferrite clamps. A signal generator produces frequencies from 30 MHz to 1000 MHz with a step frequency of 10 MHz and 5 V peak-to-peak amplitude. We set the dipole antenna in the box for electromagnetic source. The measurement configuration is shown in Fig. 7.

IV. RESULTS

The shielding effectiveness for the enclosure under study can be observed in Fig. 8 with comparison analytical formulation and measurement. The result shows that for lower frequencies differ from expected. At range of low frequencies from the simulation result and actual measurement are different because

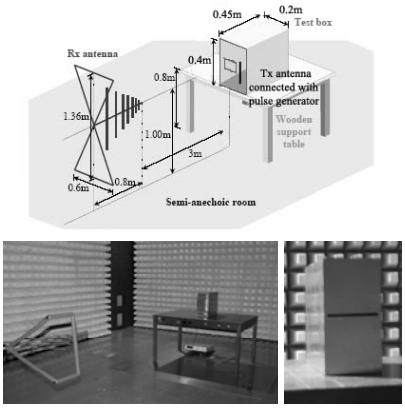

Fig. 7. Configuration of measurement.

the simulation base on free space condition but in actual base on reflection effect which depend on the size and characteristic of the chamber. In frequency range 300 MHz – 1 GHz, the both results are in good agreement. For resonance frequency, both results also agree with an approximated value of 800 MHz.

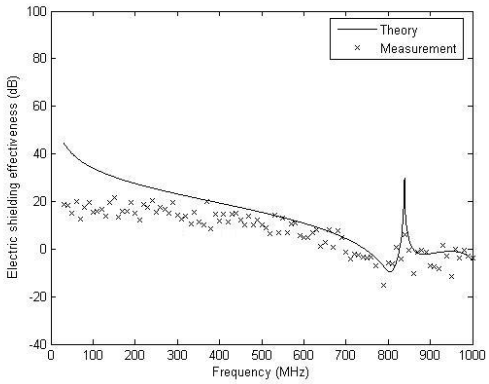

Fig. 8. Shielding effectiveness for enclosure with aperture.

We concentrate in removing the lowest resonance frequency by metal piece inside enclosure. According to Fig. 5, we found the smaller enclosure has higher resonance frequency. Introducing a metal piece as shown in Fig. 6 produces a frequency shift due to the reflection effect. We set up the 10x20x0.2 cm metal piece inside the enclosure with 1x18 cm aperture. The difference distances from back wall *m* are 5, 10 and 15 cm. The result is shown in Fig. 9

For *m* = 5 cm, the resonance frequency is about 820 MHz. When we increase distance to 10 cm, the resonance has been shifted to approximately 870 MHz. The enclosure with metal piece placed at 15 cm produces the resonance about 900 MHz. We found the results are similar from the Fig. 5. In that results show the resonances have been shifted to higher when the enclosure decrease dimension. According to Fig. 9, the increase distance from back wall is like decrease the dimension of the enclosure. The results show the metal piece inside enclosure can be removing the lowest resonance frequency.

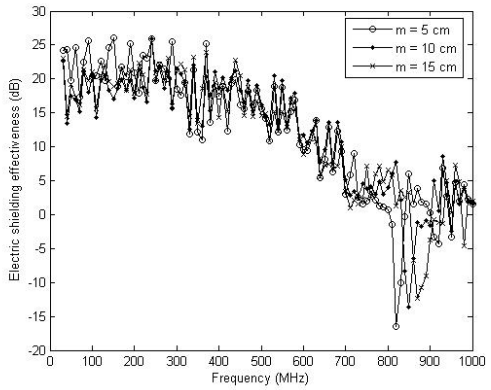

Fig. 9. Shielding effectiveness for enclosure with a metal piece inside.

V. CONCLUSION

In this paper, we propose the improvement of shielding effectiveness. The use of metal piece inside enclosure is studied for removing the lowest resonance frequency. Obtained results point out the metal piece as one of important design parameter. The effect of the placing metal piece is well seen at the resonance. When the distance from the back wall is longer, the resonance frequency will increase. Placing metal piece becomes a partial solution as long as they are designed to remove the lowest resonance frequency. Further investigations in variation of conductivity and orientation of metal piece are still needed.

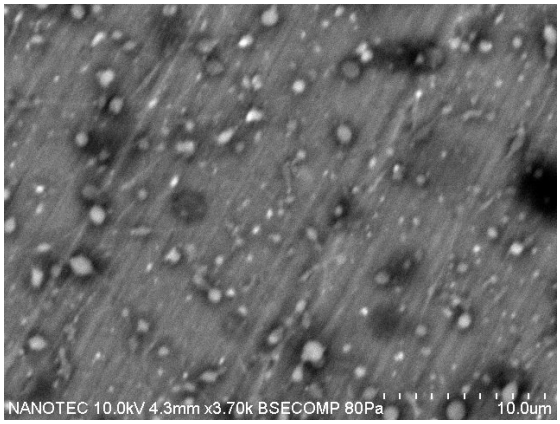

Figure 2. SEM Image of PANI coated QCM electrode surface.

distilled aniline was mixed in a polymerization vessel that was cooled at 0 ℃. In a separate flask, 1 N HCl was combined with ammonium peroxidisulfate and cooled to 0 ℃. Thereafter, the aqueous ammonium persulfate solution was added slowly to the aniline/HCl solution with both solutions being precooled to 0 ℃. The mixture was stirred for about 3.5 h at –5 to 0℃. The desired green emeradine hydrochloride precipitate was extracted by filtration and washed first in water and then in methanol until the filtrate became colorless. The precipitate was then treated in aqueous ammonium hydroxide solution for about 3 h to obtain the powder of polyemradine hydrochloride salt. Next, the green emeradine salt was washed by distill water and filtered until the filtrates were neutral. Finally, the obtained powder was dried in vacuum at 50 ℃ for 48 h and then stored in a vacuum desiccate.

For protonation doping, 2 Molar (M) maleic acid was prepared by adding 236.89 g maleic acid to 1000 ml of distilled water [10]. In order to obtain maleic acid doped polyaniline at mole ratio of 1000:1, 0.35 g of emeradine base was immersed in 2 M maleic acid solution at particular volume of 425.36 ml. The mixture was vigorously stirred and allowed to reach equilibrium for 48 h. The doped powder was filtered and dried at 60 ℃ for 40 h in a vacuum oven. Polyaniline doped powder was dissolved in N-Methylpyrrolidone (NMP) with the ratio of 0.5 g: 10 ml [11].

For the PANI coating process, the electrospinning of PANI solvent is used. The PANI solvent is loaded into electrospin syringe and syringe to QCM substrate distance is approximately 5 cm. The electrospinning was conducted at a high voltage in the range between 10-20 kV. The photograph of a QCM sensor which used in the experiment is shown in Figure 1. It is a low-cost commercial quart crystal resonator with silver electrode. The scanning electron micrograph (SEM) showing the surface morphology of PANI coated electrode is demonstrated in figure 2. It shows that the electrospun surface is covered with mixture of micro and nano particles with diameter less than 2 μm.

IV. EXPERIMENT

The diagram of experimental system is shown in Figure 3. The humidity control system is a sealed high-quality plastic chamber with low humidity absorption. The QCM sensor and the commercial humidity sensor are placed in the chamber at the same level. The data of frequency and humidity are sent to the computer via USB port every second, the frequency output, humidity and temperature will be then recorded in the computer.

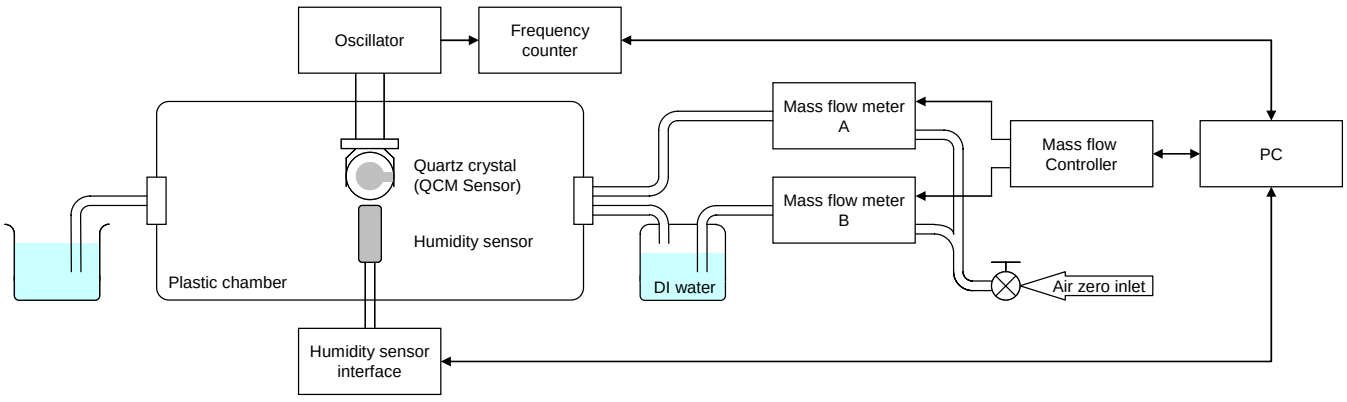

Figure 3. Diagram of data acquisition system.

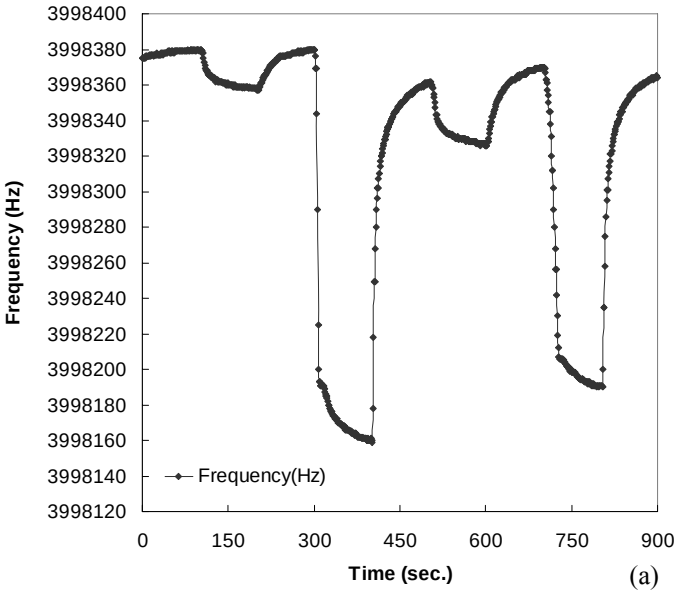
For the humidity control, water bubbler system is used. Air zero, pure and low humidity air, is split into two lines. The first line is passing through mass flow controller A and directly flown into the chamber. The second one is passing through mass flow controller B and bubbled through deionized water before entering the chamber. Initially, the chamber is filled with air zero flowing at the rate of 1000 sccm. Next, the desired humidity is input into the chamber by turning on the water bubbled air zero at a predetermined flow rate and turning off air zero from mass flow controller A. After the humidity is stabilized and the sensing response is recorded, the humidity is then dislodged by turning off the air zero flowing through the bubbler and restoring the air zero from mass flow controller A. The same procedure is repeated for different humidity by varying water bubbling flow rate.



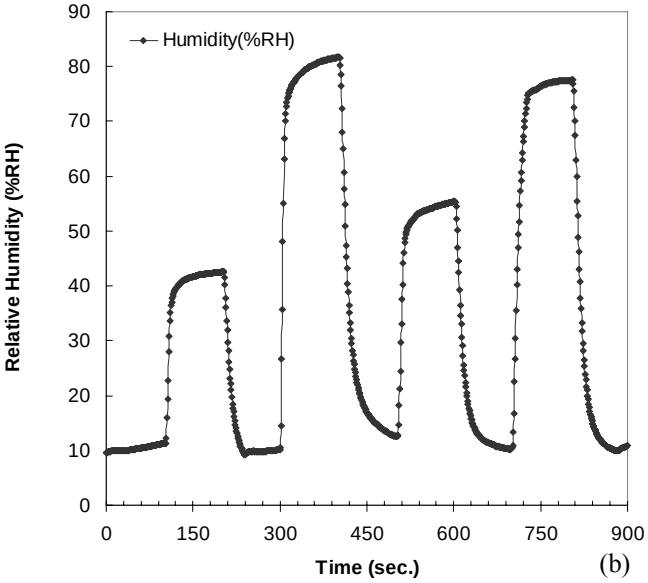


Figure 4. Typical dynamic response of (a) frequency change vs. time of PANI coated QCM humidity sensor and (b) relative humidity measured by the commercial humidity sensor

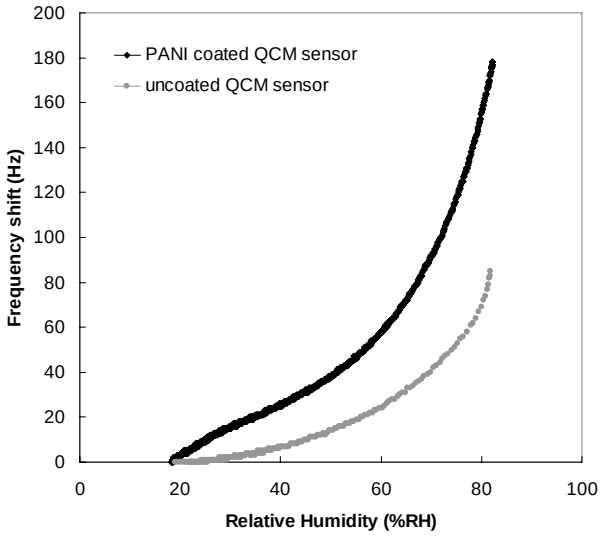

Figure 5. Frequency shift vs. relative humidity at ambient temperature of 21.6°C

V. Results and Discussion

Typical dynamic response of the PANI coated QCM humidity sensor and the corresponding dynamic humidity measured by the commercial humidity sensor are shown in Figure. 4 (a) and (b), respectively. From the figure, it can be seen that the PANI coated sensor can respond well to the controlled relative humidity of 40% to 80%. In addition, it has short response and recovery times. The response time is measured to be between 3 and 10 seconds depending on relative humidity while the recovery time is determined to be between 40 and 200 seconds. The humidity response is found to be stable and reversible over whole range of relative humidity between 20% and 80%.

Figure 5 show the measured results of frequency change of uncoated QCM sensor and PANI coated QCM sensor as a function of relative humidity. It is clear that the frequency shift of QCM sensor at a given humidity is considerably increased after PANI coating. The increase of humidity sensitivity is more that the factor of 2.2 for relative humidity between 20% and 80%. The result confirms that the PANI electrospun thin film considerably increase water vapor absorption.

VI. Conclusion

In conclusion, we have developed a low-cost humidity sensor made by coating a commercial quartz crystal resonator with Polyaniline (PANI) thin film. The electrospinning technique is used to coat the PANI nanometer-scale thin film to the electrode of quartz crystal. From experimental results, it

was found that PANI coating on the QCM electrode is an effective way to improve humidity-sensing characteristic of QCM sensor. The PANI coated sensor has good response to the humidity with short response and recovery times. The humidity-sensitivity of PANI coated QCM sensor is increased by more than factor of 2 compared to uncoated QCM sensor.

***Abstract*-Electronic nose devices are of increasing interest to the quality control of alcohol and food processing. Optical gas sensors that require low electrical power are in great need to such devices. The zinc (II) -2,9,16,23-tetra-*tert*-butyl-29H,31H-phthalocyanine (ZnTTBPc) and zinc (II) -5,10,15,20-tetraphenyl-porphyrin (ZnTPP) organic thin film sensors have been produced by spin-coating onto glass substrates for detecting specific alcoholic volatile organic compounds (VOCs). Responses of the films to various alcohols and Thai whisky were monitored by optical absorption spectroscopy. The classification of alcohol volatile organic compounds (VOCs) using these fabricated optical gas sensors were obtained by Principle Component Analysis (PCA). The system is able to distinguish ethanol, methanol and Thai whisky. This results are in good agreement with the Density Function Theory (DFT) calculations whereby the interactions of ZnTTBPc and ZnTPP to methanol (MeOH), ethanol (EtOH) and iso-propanol (IPA) have been investigated by using B3LYP/6-31G* method. The presence of zinc atom in the center of both ZnTTBPc and ZnTPP molecules causes an increase of positive NBO charge while the oxygen atom in the alcohol molecules leads to a decrease. NBO charge calculations shows that the interaction of zinc atoms both in ZnTTBPc and ZnTPP with the oxygen atom in alcohol occurs by charge transfer.**

I. INTRODUCTION

Metal-phthalocyanines (MPc) and metal-porphyrins (MP) are organic semiconductor materials with technological importance [1]. The electrical and optical properties of MPc and MP are strongly influenced by electron donor and acceptor with gas [2]. This makes MPc and MP a natural choice of gas detection for VOCs. Examples for their gas sensing applications include lutetium bisphthalocyanine (LuPc) films for detecting VOCs from olive oil or wine [3], Manganese phthalocyanine (MnPc) for detecting trimethylamine as an indication for the freshness of fish [4], Zinc Tetraphenyl porphyrin (ZnTPP) for sensing 4-aminophenyl, which is an environmental contaminant from various industry sectors and from municipal wastewater treatment plants [5]. Responses of MPc and MP opto-chemical gas sensors to organic vapor are presented by the change of some physical properties [1], for example, electrical conductance [6], capacitance, work function, refractive index [7] and optical absorbance [8].

In the present work, we report the fabrication of ZnTTBPc and ZnTPP spin-coated thin films as an alcohol vapor sensing device with the optical absorbance response in the UV-visible spectral range. The absorbance change induced by exposure to various alcohol vapors including Thai whisky has been analyzed by Principle Component Analysis. In addition, quantum mechanical calculations have been conducted in parallel to investigate the interaction of ZnTTBPc and ZnTPP with alcohol molecules (MeOH, EtOH and IPA), in termsof interaction energy, charge transfer and energy gap.

II. QUANTUM MECHANICS COMPUTATIONAL METHOD

Initial structures of ZnTTBPc, ZnTPP, MeOH, EtOH and IPA models were constructed by a molecular mechanics force field program. The optimized geometries were obtained by using the DFT calculation based on B3LYP/6-31G* level. The calculations were performed by using the Gaussian 03 program. The potential interaction energy was calculated by varying the distance between oxygen in OH group of alcohol molecules and zinc atom in the center of ZnTTBPc and ZnTPP molecules.

III. EXPERIMENTAL METHOD

Zinc(II)-2,9,16,23-tetra-*tert*-butyl-29H,31H-phthalocyanine (ZnTTBPc) was obtained from Sigma-Aldrich, while zinc(II)-5,10,15,20-tetraphenylporphyrin (ZnTPP) has been synthesized by our research group using a standard method. ZnTTBPc and ZnTPP thin films were prepared by the spin-coating technique on cleaned glass slides. For ZnTTBPc, its chloroform solution at 0.015 molar concentration was spin-coated onto glass substrates at 1000 rpm for 30 sec. For ZnTPP, the same method was applied for its chloroform solution (0.007 molar). An improvement in the ZnTTBPc sensing properties has been achieved by thermal annealing in a furnace under a

flow argon gas and heated at the heating/cooling rate of 5°C/min until reaching 340°C [9]. The optical absorption spectra of sensor films were recorded at room temperature and at normal incidence in the range of 340-795 nm by Jenway UV-Vis Spectrophotometer.

The alcohol sensing capability of the ZnTTBPc and ZnTPP films has been investigated under dynamic conditions by using a home-built stainless steel chamber with quartz windows for optical measurements. The test was conducted under a flow system at a constant rate of 755 mL/min by using 99.9% nitrogen as both a carrier and a reference gas. The dynamic optical response was monitored by recording the absorbance intensity at fixed interval of 10 min during alcohol exposure and another 10 min during recovery under a nitrogen flow.

IV. Results and Discussion

A. *Quantum Mechanics Calculation*

The quantum mechanics calculations of ZnTTBPc and ZnTPP with different types of alcohols are illustrated in Figure 1. In particular, ZnTTBPc indicated the strongest interaction with methanol and the weakest interaction with iso-propanol, whereas the results for ZnTPP showed intriguingly the opposite. Table 1 compares the interaction energies at the optimized distance, the change in HOMO-LUMO (Energy Gap ; Eg) and the change in the NBO charge of zinc and oxygen atoms. The results indicates a possible charge transfer mechanism for the interaction of ZnTTBPc and ZnTPP with the alcohol molecules. This also suggests a possibility for detectable changes in the optical absorbance in the presence of alcohol vapour flow the alcohols vapour.

TABLE I
CALCULATED INTERACTION ENERGY ; E(kcal/mol) AT THE OPTIMIZED DISTANCE ; D(Å), CHANGE IN HOMO-LUMO ENERGY GAP ; △Eg(meV), CORRESPONDING WAVELENGTH ; λ(nm) AND THE CHANGE IN NBO CHARGE AT ZINC AND OXYGEN ATOMIC SITE ($\times 10^{-3}$a.u.)

Interaction	E	D	$\triangle E_g$	$\triangle\lambda$	Zinc	Oxygen
ZTTBPc-MeOH	7.13	2.50	+13.88	+3.61	+26.89	-41.79
ZnTTBPc-EtOH	5.37	2.63	+ 5.17	+1.35	+19.91	-31.65
ZnTTBPc-IPA	4.18	2.88	+ 3.54	+0.92	+14.01	-25.92
ZnTPP-MeOH	4.49	2.75	-30.75	-4.78	+26.42	-30.67

ZnTPP-IPA	5.96	2.63	-34.02	-5.29	+27.13	-31.53

(E_g and λ of ZnTTBPc, ZnTPP are 2.18, 2.84 eV and 569.47, 436.62 nm)

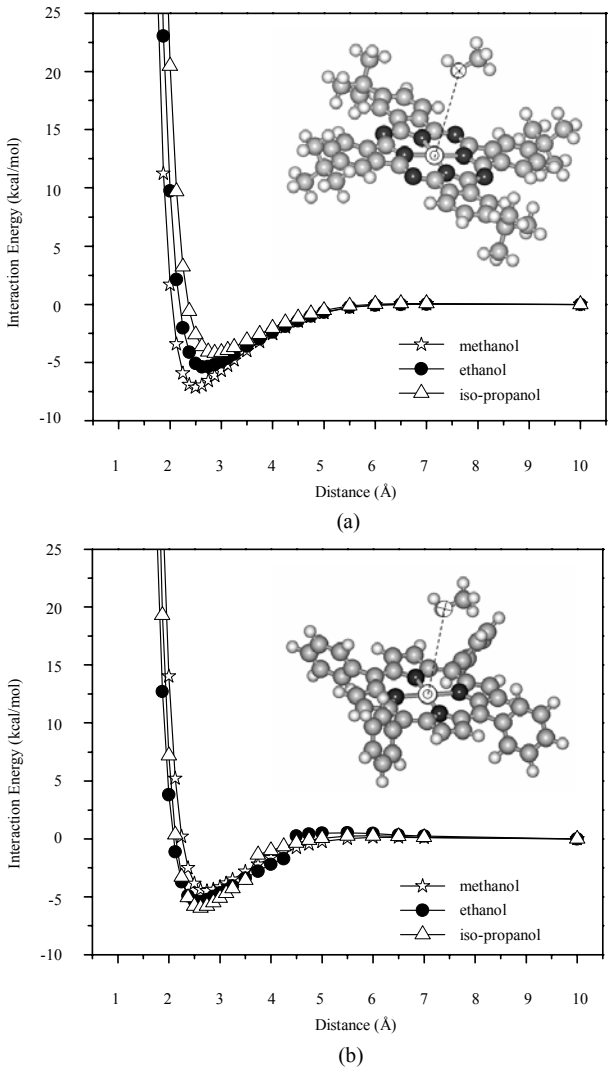

Figure 1. The interaction energy between (a) annealed ZnTTBPc and (b) ZnTPP with alcohols as a function of the intermolecular distance. Inset: (a) ZnTTBPc and (b) ZnTPP (Zn atom) interacting with MeOH (O atom) as shown by the dot line. Representation: Zn-double, N-black, C-grey, H-white and O-cross balls.

B. *Optical Absorption Measurements and Optical Sensing Characteristics*

The ZnTTBPc, ZnTPP spectra are signified by the intense B band at 330, 433 nm and Q band at 621, 551 nm, as shown in Figure 2. The delocalized π-electron system near central metal atom in MPc and MP is an important feature for VOC vapor detection. This comprises a highly polarized electron cloud and weakly bound π-electrons. Thus ZnTTBPc and ZnTPP are a relatively good electron donor. For the interaction mechanism, the electrons are likely to transfer to alcohol molecules, acting as an electron acceptor. This is also supported by the quantum mechanics calculated results.

The results of dynamic response test to alcohol vapors are illustrated in Figure 3, for which the optical absorption spectrum was selectively divided into five intervals, covering

the entire range for observable changes, as R1:340-415, R2:415-565, R3:565-625, R4:625-635 and R5:635-795 nm. The optical absorption response $\Delta A/A_{ZnTTBPc}$ and $\Delta A/A_{ZnTPP}$ for each interval was calculated from $(A-A_0)/A_{ZnTTBPc}$ and $(A-A_0)/A_{ZnTPP}$, where A and A_0 are the area integrals measured during alcohol vapor exposure and during the nitrogen gas flow, respectively, and $A_{ZnTTBPc}$ and A_{ZnTPP} are the initial area integral of ZnTTBPc and ZnTPP.

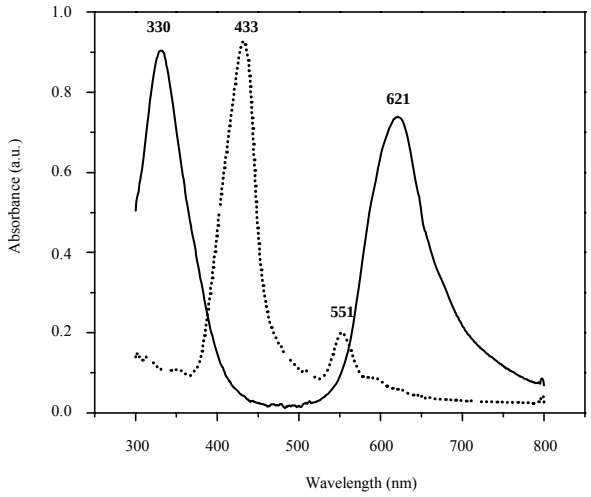

Figure 2. Optical absorption spectra of ZnTTBPc and ZnTPP (dotted line) thin films.

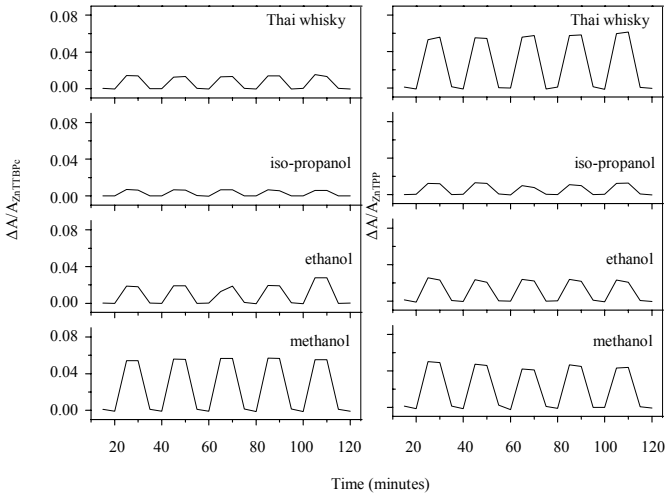

(a) (b)

Figure 3. The typical dynamic responses in the presence of alcohol vapors of (a) ZnTTBPc-R5 and (b) ZnTPP-R3

Figure 4 illustrates a histogram comparing the optical responses of ZnTTBPc and ZnTPP films to alcohols. The average response ΔS was calculated from the average of $S-S_0$ for all observable response pulses, where S is the dynamic sensor signal during alcohol vapor exposure and S_0 is the base sensor signal in nitrogen gas flow.

Overall, the responses of ZnTTBPc films to alcohols produce the strongest response with methanol in R5 (635-795 nm) for ZnTTBPc, whereas for ZnTPP the strongest response was observed in R3 (565-625 nm) for the Thai Wisky. Note that the strongest response for ZnTTBPc corresponds to the Q band at 621 nm for π-π* transitions of phthalocyanine ring [1]. The result is consistent with the expected change in the delocalize π-electron system, in good agreement with the calculations.

Figure 4. The average responses of (a) ZnTTBPc and (b) ZnTPP thin films

C. *Principle Component Analysis*

To evaluate the alcohol identification performance of the sensor array based on phthalocyanines and porphyrins, a simple statistical chemometric technique has been used, namely the Principle Component Analysis (PCA). PCA operates data by reducing abundant information into limited data space dimensions [10]. The data sets for ZnTTBPc and ZnTPP have been analyzed independently by PCA. The principle components were computed iteratively such that the first Principle Component (PC) carried the most variance, hence, information. Figures 5 and 6 show the 3D score plots of PCA analysis for the first three PCs. The results for ZnTTBPc and ZnTPP films evidently illustrate distinctive clustering of the data corresponding to methanol, ethanol and iso-propanol. This suggests that a sensor with only a single type of organic molecules may already be sufficient as an electronic nose [5]. We have also applied our optical gas sensor to test a

commercial brand of Thai whisky. Figure 6 shows the PCA results for the ZnTTBPc sensors, which indicates the Thai whisky is probably closer to ethanol than methanol. The discrepancies may originate from the lower alcoholic percentage in the Thai whisky than the pure ethanol. Further investigations will be required to assess the performance of our optical gas sensors.

V. CONCLUSION

We have demonstrated that ZnTTBPc and ZnTPP thin films can be used as gas sensors, capable of classifying different types of alcohol. The interaction of the sensing molecules with alcohol vapor molecules has been studied by the quantum mechanical calculations, which indicates a charge transfer mechanism between the oxygen atom in alcohol and the central Zn atom in the sensing molecules. The strong sensor signal of methanol is attributed to strong interaction between the sensing molecules and methanol as depicted in Fig. 1 together with higher vapor pressure (30 kPa which is higher than ethanol 9 kPa and iso-propanol 2.4 kPa at 20 ^{o}C). The potential application in the food industry of our gas sensor array has been demonstrated in the classification of the Thai whisky in comparison to ethanol and methanol.

***Abstract*— Microcantilever sensors have been modeled and characterized for biosensor applications. The stress induced on gold surface with polysilicon piezoresistive sensing is demonstrated. In principle, an adsorption of biochemical species on a functionalized surface of the microfabricated cantilever will cause a surface stress and consequently the cantilever bending. The sensing mechanism relies on the piezoresistive properties of the polysilicon wire encapsulated in the beam. The sensitivity of the sensing technique could be measured by external read-out circuit as a balanced Wheatstone bridge configuration. The resistance change output of the cantilever is directly proportional to the amount of bending in the MEMS cantilever. Compensation by resisters on the substrate significantly reduces the temperature dependence.**

I. INTRODUCTION

Microcantilever has been widely used as chemical and biological sensors [1]-[3], atomic force microscopes [4] and data storage devices [5]. The deflection of these cantilever beams apply various techniques same as the techniques for atomic force microscopy AFM technology such as optical reflection, piezoresistive, piezoelectric, capacitive, and electron tunneling [6]. Microcantilever acts as a surface stress sensor which sensitivity of detection based upon the adsorption induced force when a specific biochemical species adsorbed on a functionalized surface of the cantilever beam [7]. These biosensors can be applied as a patient classifier for the presence of various diseases with faster responses, higher accuracy and lower cost.

In this paper, the model and characterization of our microfabricated cantilever have been described. The temperature dependence of microcantilevers has been studied and compensated by symmetric Wheatstone bridge configuration with on-chip resistors.

TABLE I
All dimension of MEMS cantilever beam

Material layer	Wide (μm)	Long (μm)	Thickness (μm)
Nitride	40	100	0.5
Polysilicon	10	400	0.5
Silicon dioxide	40	200	2.5
Gold	40	200	0.5

II. EXPERIMENTAL

A. *Microcantilever Fabrication*

The cantilever-based sensors have been developed with the integrated piezoresistive read-out with the integration of a full and symmetric Wheatstone bridge on chip with two resistors placed on the cantilevers and two resistors on chip as shown in Fig. 1. The piezoresistive cantilever can be functionalized with biochemical materials to perform antigen-antibody reaction or DNA hybridization while the other bare cantilever can be applied as a reference beam, thus there is a possibility to perform differential measurements through the subtraction of signals from two cantilevers. The background noises from thermal drift and fluid turbulence effects were minimized. Commercial available Multi-users MEMS Process (PolyMUMPs) was used to fabricate this device. The cantilever beam comprised of four structural layers, silicon nitride, polysilicon, silicon dioxide and gold. We have previously reported the fabrication process of cantilever beam with piezoresistive read-out [8], which can be operated in gas phase and consisted of a large array of cantilever sensors. The polysilicon wire forms a piezoresistive element that runs down the length of the beam and back. Silicondioxide layer fills the gap between polysilicon and top gold layer. The AFM picture of top gold layer acts as a reactive or adsorption layer was shown in inset of Fig.1.

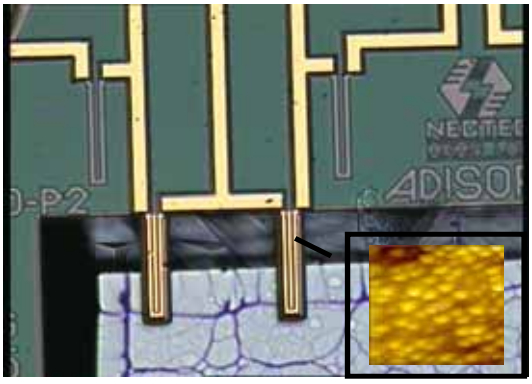

Figure 1. Scanning electron micrograph (SEM) of fabricated cantilever array sensors and gold layer surface.

The beam has a length of 200 micrometers with 40 micrometers width. All layers dimension including thickness was shown in Table I.

B. Device Modeling

This methodology is conducted to analyze the beam deflection due to surface stress after the device was adsorbed by biochemical molecules. The adsorbed layer can attempt to expand or may try to contract know as a compressive surface stress and a tensile surface stress, respectively.

MEMS cantilever is bending due to mechanical force generated by molecular adsorption. Adsorption-induced stress sensors have a sensitivity range based on adsorbed mass which proportional to molecular size. In addition, MEMS cantilever bending is also ideal for liquid-based biosensor applications.

The mechanical design of piezoresistive polysilicon wire encapsulated in MEMS cantilever is optimized for detecting changes in surface stress upon analyzes surface adsorption. The fractional change of resistance ($\triangle R/R$) in a piezoresistive wire is described by the following expression,

$$\frac{\Delta R}{R} = 3\beta\pi_L \frac{(1-v)}{t}\Delta\sigma \qquad (1)$$

where π_L is the piezoresistive coefficient of polysilicon , $\Delta\sigma$ is the difference of the longitudinal stress and the transverse stress, t is the thickness of the cantilever, and β is a factor that is adjusted for the thickness of the piezoresistor. From the above expression, the $\triangle R/R$ ratio is proportional to the stress difference, $\Delta\sigma$ is the stress difference distribution depends on the geometric factors of the layers and the reaction forces between the gold surface and the biochemical molecules. Therefore, maximizing the stress difference in the way of changing the geometric factors can increase the deflection signals.

C. Device Simulation

A piezoresistive simulation is performed using Coventorware. Firstly, the tip deflection was varied from 0 to 4 micrometers to verify the resistance change due to beam deflection. The simulation result of tip deflection shows in inset. The plot of normalized resistance change versus beam tip deflection was shown in Fig. 2. From the simulation, the resistance of the beam has increased about 2% when the tip of the cantilever beam was increasingly deflected of 1 micrometer.

The relationship of resistance change (piezoresistivity) with beam deflection is in linear manner with a constant slope (sensitivity).

D. Characterization (Temperature Dependence)

Microcantilever beam has been tested at room temperature to study the change of piezoresistive by various external temperatures. The Wheastone Bridge with built-in offset and consisting of four identically behaving resistors was shown in Fig. 3, the output signal will vary linearly with supply voltage [9-12].

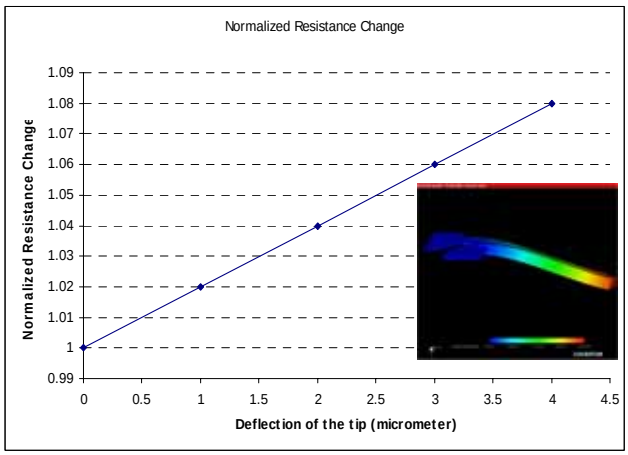

Figure 2. Plot of normalized resistance change in relative with beam deflection.

To characterize temperature dependence, the beam was placed on an adjustable PID hot plate in chamber and varied temperature up to 80 degrees.

The output voltage of uncompensated and compensated beam varied with temperature as shown in Fig. 4. The diagram of amplifier circuit for amplifying the output signal from the Wheatstone bridge was shown in Fig. 5. The four part of low power J-FET OPAMP TL064 are used to be the differential amplifier. Input A and B are connected to Wheatstone bridge output Vo- and Vo+ respectively. Each input signal will buffering by one part of OPAMP and then amplifies with differential amplifier. Voltage gain of this circuit will be controlled by feedback signal from the last OPAMP, we can control it by varies the variable resistor 1MOhm.

From the experimental results, the temperature sensitivity of uncompensated cantilevers is at 28 mV/degree C (Celsius) compared to feedback compensated cantilevers which is less than 0.0015 mV/degree C. From this result, compensation by resisters on the substrate significantly reduces the temperature dependence, therefore this microcantilever sensors can be operated at various temperature ranges and suitable to implement for nano-biosensor applications.

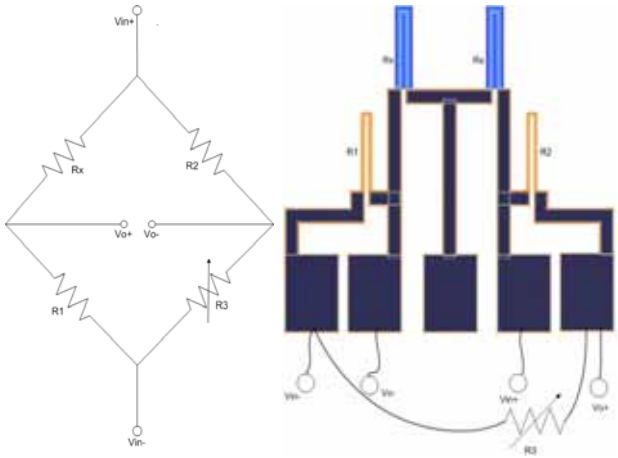

Figure 3. The cantilever beam series act as Wheatstone bridge that fabricated on sensor chip.

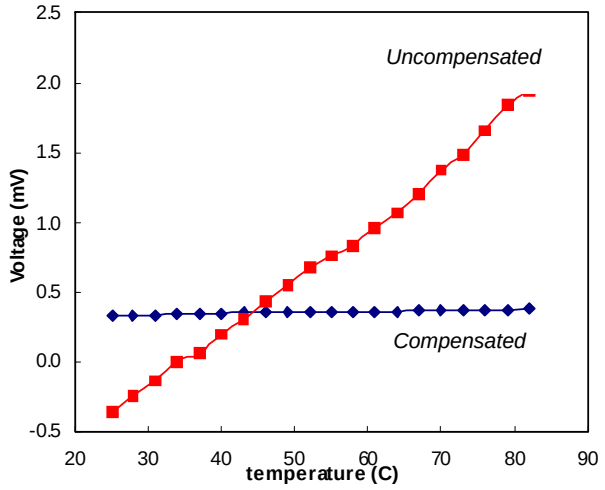

Figure 4. Plot of temperature dependence of cantilever beam non-compensate temperature (A) and compensate temperature (B).

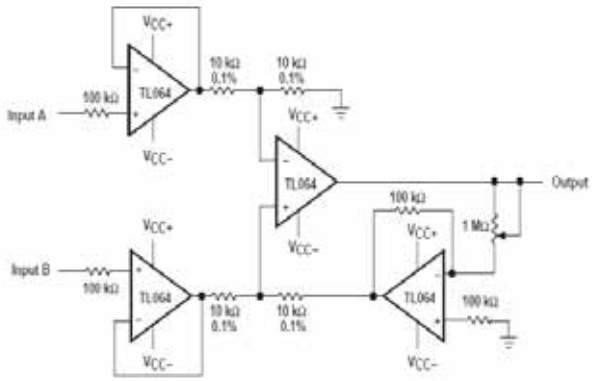

Figure 5. Diagram of amplifier circuit used in the experiment.

III. Conclusion

Microcantilever sensors have been modeled and characterized for biosensor applications. The stress induced on gold surface with polysilicon piezoresistive sensing is demonstrated. In principle, an adsorption of biochemical species on a functionalized surface of the microfabricated cantilever will cause a surface stress and consequently the cantilever bending. The sensing mechanism relies on the piezoresistive properties of the polysilicon wire encapsulated in the beam. The sensitivity of the sensing technique could be measured by external read-out circuit as a balanced Wheatstone bridge configuration. The relationship of resistance change (analogous to piezoresistivity) with beam deflection is in linear manner with a constant slope (analogous to sensitivity). Therefore, the resistance change output of the cantilever is directly proportional to the amount of bending in the MEMS cantilever and can be measured by piezoresistive read-out. Compensation by resisters on the substrate significantly reduces the temperature dependence. The temperature sensitivity is reduced from 28 mV/degree C (Celsius) of uncompensated cantilevers to 0.0015 mV/degree C in case of feedback compensated cantilevers. Therefore this microcantilever sensors can be operated at various temperature ranges and suitable to implement for nano-biosensor applications.

***Abstract*- Recently, a wide variety of polymeric materials have been widely used to construct micron-sized channels on a glass or silicon chip. In particular, polydimethylsiloxane (PDMS) has been used extensively, because it is robust, optically transparent, nonpolar, and impermeable to aqueous solutions. In addition, it allows the easy, fast, and inexpensive fabrication of devices by using micromolding techniques. The microchannel was formed by complex 2-dimensional (2-D) patterned PDMS layers using microfabrication technique. The micromolding technique was used to fabricate PDMS slabs with micro-sized grooves, and then the completed microchannel was formed by bonding PDMS slab with glass with oxygen plasma treatment. The contact angle and the flow leak test of microchannel are studied under various conditions of oxygen plasma treatment including RF power and treatment time. The proper condition for plasma treatment to achieve optimal surface hydrophilicity and bonding strength is at RF power of 6.8 Watt for 1-5 minute.**

I. INTRODUCTION

Microfluidic systems increasingly gain importance in modern life sciences as well as in diagnostic and therapeutic biomedical engineering and under development to address a variety of medical problems. Key advantages of micro total analysis systems based on microfluidic technology are the promise of small size and the integration of sample handling, measurement functions within a single, automated device and having low mass-production costs.

The most development of these technologies is named "lab-on-a-chip", and is poised to provide chemistry and biochemistry professionals with a powerful new tool. Lab-on-a-chip applications, especially in polymerase chain reaction (PCR) [1-4] and Capillary electrophoresis (CE) [5-8] need a development for microfluidic channel fabrication. Thus microfluidic technology plays the important role because it can make a rapid prototype and reduce the reagent including sample.

Polydimethylsiloxane (PDMS) is one of the materials that widely used as the materials of choice for microfluidic molding due to its easy and low cost fabrication, good optical transparency and easy sealing to other materials etc. In this paper, the molding procedure on silicon wafer, PDMS microchannel fabrication and surface treatment by oxygen plasma are reported. Moreover, surface treatment condition is varied to optimize bonding strength between PDMS and glass substrate. The bonding strength between PDSM structure and glass substrate is examined by the leak test of microfluidic channel.

II. EXPERIMENTAL

Silicon wafer were cleaned in piranha solution (mixture of 1: 4 of 50% H_2O_2 and 97% H_2SO_4) at 120 ^oc for 10 minutes, then carefully rinsed several time in deionized water and dried with gentle stream of air. After that silicon wafer were dehydrated by bake at 150-200 ^oC for 10 minutes. SU-8 photoresist was spin-coated on silicon wafer using a spin coater (Laurell technologies corp. model WS–400A–6NPP), then soft baked to remove all the solvent in the layer. The photoresist coated wafers were exposed using MJB4 mask aligner (SUSS microtec) then post-baked in order to selectively cross-link the exposed portions of the film. The sample was left in the desiccators to cool down slowly at room temperature for more than 13 hours. Finally sample was developed and cleaned with deionized water and isopropyl alcohol, and then it was gently dried with air. Spin speed, exposure time, baked time and developing time were optimized to achieve a smooth surface on mold. SU-8 mold was checked by microscope CX41 (Olympus) and the mold thickness was investigated by surface profiler measurement (Veeco model dektak^3 series).

Fig. 1. PDMS on SU8 master mold

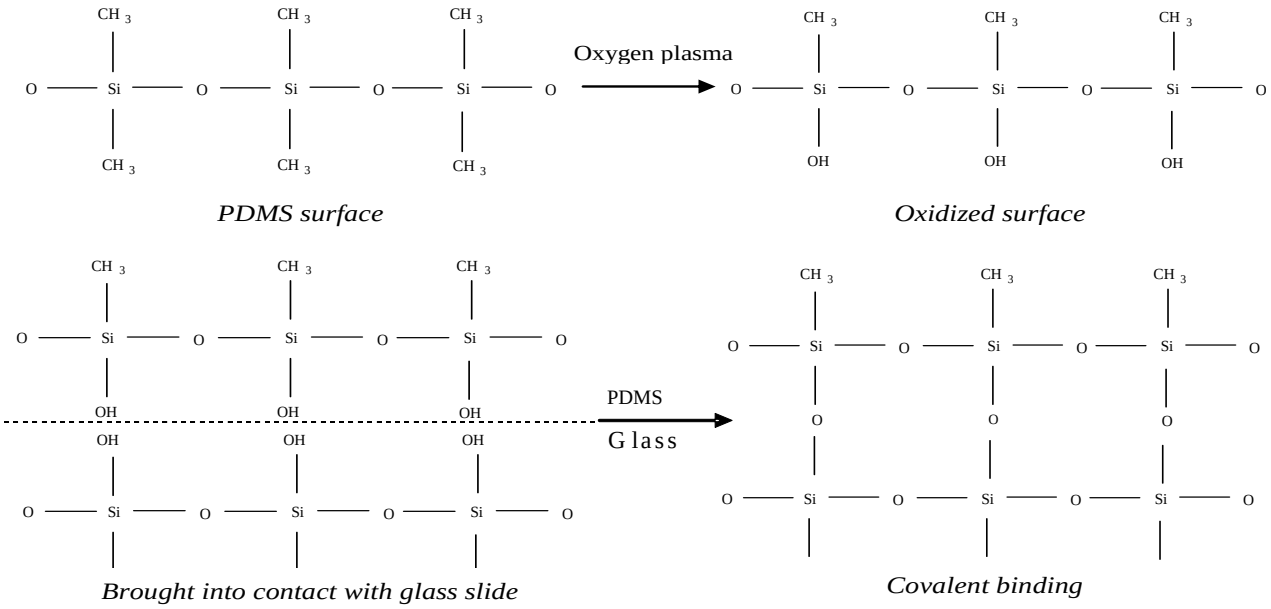

Fig. 2 Binding procedure of the modified surface of PDMS with glass slide.

Sylgard 184 Silicone Elastomer kit (Dow Corning), consisting of PDMS was prepared by mixing the precursors sylgard with a curing agent at a ratio of 10:1 by volume. The prepolymer mixture was degassed at 20-50 mTorr in ambient temperature desiccators with a mechanical vacuum pump for 10 minutes to remove any air bubbles in the mixture. PDMS mixtures were gradually poured onto the SU8 master mold to the height over the depth of designed channels as shown in Fig. 1. After the PDMS is cured at 100 ^{o}C for 30 minutes on a SU-8 mold, the molded polymer samples are peeled.

PDMS and glass slide were treated under oxygen plasma in a commercial plasma system (Harrick scientific corp. model PDC –32 G). The PDMS and glass substrate were then attached together to complete the microchannel. The procedure occurred in binding process of PDMS and glass substrate was shown in Fig.2. Treatment of PDMS in oxygen plasma result in the formation of hydroxyl groups at the surface which is changed to hydrophilic property through a dehydration reaction. Then the hydrophilic PDMS can form covalent bond with glass substrate. In order to find the optimum plasma treatment conditions for PDMS-glass bonding, the RF power and treatment time were varied. Water contact angle measurement and leak test of treated microchannel were conducted for each treatment condition. Contact angle measurements were performed by using contact angle measurement system (Rame'- hart instrument co. model 200). For leak test, deionize water was flown into the microchannel at various flow rates by using micropump (New era pump systems Inc. model NE-1000). The experimental setup for leak test is shown in Fig. 3. The flow rates that cause the leakage of the microchannel were observed.

III. RESULT AND DISCUSSION

The microchannel thickness and profile of microfabricated mold has been characterized by Dektak surface profile. Nice profile and the slight variation of thickness have been observed. The thickness variation may due to the viscosity change of the photoresist during spinning process.

PDMS were treated under oxygen plasma and then taken into contact with glass substrate to complete microchannel structure. For contact angle measurement, PDMS were immersed in methanol for 10 minutes and dried under the compress dry air. The photo of water contact angle of PDMS and PDMS treated under oxygen plasma are shown in Fig. 4. The water contact angle of untreated PDMS is about 117 degree. The water contact angles of PDMS treated versus treatment time at various conditions are shown in Table 1. It can be seen that PDMS surface treated under the low RF power at 6.8 Watt for 1 minute has the lowest contact angle at about 9 degree. For PDMS treated under high RF power of 10.5 Watt, the minimum water contact angle is 10 degree at 10 seconds treatment time. The results indicate that optimum contact angle of PDMS treated by low RF power of 6.8 Watt is better than that treated by high RF power at 10.5 Watt.

TABLE I
FLOW RATE THAT CAUSE LEAKAGE OF MICROCHANNEL THAT TREAT UNDER OXYGEN PLASMA

Exposure time (second)	Contact angle (degree)	
	6.8 Watt RF power	10.5 Watt RF power
5	57	13
10	45	10
20	24	12
30	22	16
40	20	16
50	12	20
60	9	22
300	33	48
600	40	65
900	49	79
1200	60	80

The microchannel for the leak test in this experiment consists of chamber, microchannel, inlet and outlet as show in Figure 6. The dimension of microchannel are 2 cm. x 100 µm x 100 µm. and chamber's dimension is 0.4 mm. x 0.9 mm x 100 µm. Leak test of the microchannel were performed by gradually increasing the flow rate of deionized water into microchannel and observed the flow rate that cause the leakage. The result of leak test is shown in Table 2. The microchannel treated at RF power 6.8 Watt for 60 and 300 seconds can endure the flow rate more than 10 ml/min. It can be indicated that the attachment of the low water contact angle of PDMS lead to the good adhesion between glass and PDMS. In contrary, the microchannel treated for a longer time was leaked at a lower flow rate. This can be explained by considering the effect of RF power and treatment time to the bonding strength between PDMS and glass. For PDMS treated under high RF power, the kinetic energy of ion incident on the substrate is high. Thus the siloxane backbone on the PDMS surface should be damaged and consequently reduced the Si-OH available for bonding with glass slide [4]. The effect of plasma treatment time on PDMS has been reported by Owen and Smith [5]. The report mentioned that the long treatment time will lead to the crack of the surface, which results in the poor bonding between glass and PDMS.

IV. CONCLUSION

We have successfully fabricated PDMS based microfluidic channel. PDMS slab with micropatterned grooves is bonded with glass substrate to complete microchannel. The good bonding between PDMS and glass substrate is obtained by treating PDMS and glass surfaces into hydrophilic state in order to provide covalent binding between glass and PDMS. Surface treatment can be done by commercially available oxygen plasma cleaner. The various conditions for oxygen plasma treatment including RF power and treatment time have been studied to optimize surface hydrophilicity and bonding strength. The proper treatment condition for optimize surface hydrophilicity is at RF power of 6.8 Watt for 1 minute or at RF power of 10.5 Watt for 10 seconds. The results indicate that the low contact angle of the treated PDMS surface lead to the good bonding strength between glass and PDMS. The proper treatment condition that leads to the best boding strength of microchannel is treatment at 6.8 Watt for the time between 1 to 5 minutes.

Abstract- **In this work, we study the effect of nanometer-scale thickness and annealing temperature on gas sensing behaviors of TiO2 nanocrystalline thin films prepared by electron beam evaporation with ion-assisted deposition (IAD). TiO_2 thin film has been prepared with different thicknesses from 30 nm to 100 nm and annealing temperatures upto 400 °C. From structural characterization by X-ray diffraction (XRD) and atomic force microscopy (AFM), the as-deposited TiO_2 thin film has amorphous structure with smooth surface. After annealing above 300 °C, the TiO_2 film becomes polycrystalline anatase structure with increased roughness and porosity. The ethanol-sensing characterization shows that as-deposited film has moderate sensitivity, which is increased with the film thickness and temperature. In addition, TiO_2 thin films annealed at 400 °C exhibit higher sensitivity, which is relatively insensitive to the film thickness and operating temperature. The results suggest that the effective region for gas sensing of TiO_2 thin film is only within a few tens of nanometers from the surface and only very thin film with thickness as small as 30 nm may be sufficient for gas sensing.**

Keywords: **Titanium dioxide, thin film, semiconductor gas sensor, nanometer scale thin film**

I. INTRODUCTION

Semiconductor gas sensors have been widely investigated for gas sensing applications due to their low cost, good performances and easy implementation [1]. The principle of operation consists of a variation of the resistivity of the sensing material when its surface is exposed to different kind of reducing or oxidative gases. Usually, the behavior is based on an n-type electronic conduction, in which the resistance of the sensing layer decreases when exposed to reducing gases, such as CO or hydrocarbons. Transition metal oxides, such as SnO_2, WO_3, ZnO, ITO and TiO_2 have been proposed as candidates for gas detection [2-4]. Titanium dioxide (TiO_2) is a versatile material, which has been used in many applications such as, solar cell, electrical insulution, photocatalytic layer for self-cleaning glass, optical coating for filters and waveguides, etc. For gas sensing applications, TiO_2 is used in anatase phase that has lower resistance and higher sensitivity to gas adsorbents than the rutile phase, which is stable at higher temperature. TiO_2 nanocrystalline thin films are desired because of stable and good gas-sensing characteristics at operating temperature below 400 °C [5-6]. In the last application, it's clearly reported in the literature that the physical and gas-sensing properties of the sensor depends considerably on the method and the condition of the sensitive film preparation [7].

Electron-beam evaporation is one of preferred techniques for thin film gas sensor fabrication because of ease of batch fabrication and ability to form high-quality multilayer thin film structures. In addition, the properties of the thin film material can be manipulated to enhance the gas-sensing characteristics of e-beam evaporated thin film with ion-assisted deposition (IAD). In this work, we prepared TiO_2 nanocrystalline thin film by ion-assisted e-beam evaporated for gas-sensing applications. The gas-sensing performance of ion-assisted electron beam evaporated TiO_2 thin film has been characterized with different thickness in nanometer scale.

II. HELPFUL HINTS

The starting gas sensitive material is an analytical grade titanium oxide (TiO_2) pellets (99.99%). The substrates for thin film coating were (100) silicon wafers and 200 µm-thick Alumina sheets. The gas sensors were then fabricated from a series of thin film deposition using Denton's ion-assisted e-beam evaporator system. The gas sensor fabrication process started with the deposition of chromium (Cr) and gold (Au) interdigitated electrodes on alumina substrates. Chromium and gold layer were then successively e-beam evaporated over the alumina substrates through electroplated-Ni shadow masks having an interdigitated pattern. The thickness of Cr and Au layer were ~200 and ~100 nm, respectively. Next, the TiO_2 layer was evaporated over interdigitated electrode through another electroplate shadow mask with square window pattern aligned to interdigitated area. For this study, the depositions were conducted with different thickness in nanometer scale

from 30 nm to 100 nm. The deposition rate, oxygen flow rate, and substrate temperature were ~ 0.2 nm/s, 25 sccm, and 200 °C, respectively. The ion driving voltage and ion flux current are ~400 V and ~0.15 A. The films were then annealed at different temperatures up to 400 °C. The microstructure of the TiO_2 films at different temperature annealing was studied by means of atomic force microscopy (AFM) and X-ray diffraction (XRD). The surface morphology was observed by field emission scanning electron microscopy (FESEM).

For gas sensing measurements, the gas sensors were mounted in a stainless steel gas-testing chamber and the electrode to connect with probe. Inside the chamber there is a heating stage to achieve a certain sensor operating temperature. The gas-sensing experiments were done in the temperature range from 200 to 400 °C. For gas testing, purified air (99.999% Air Zero) and Air containing gas sample were mixed with different ratio and flow with mass flow controller into the testing chamber.

III. UNITS

X-ray diffractograms and AFM images of TiO_2 thin films with 30 nm thick TiO_2 thin film with different annealing temperatures are shown in Fig. 1 and 2, respectively. It can be seen that the as-deposited TiO_2 thin film has amorphous structure with smooth surface. After 2 hour-annealing at 300 °C and 400 °C, the TiO_2 thin film becomes polycrystalline structure with nanometer grain size and anatase phase with (101) preferred orientation [6]. It is interesting that the polycrystalline structure of TiO_2 thin film can be observed by XRD even though the thickness is very small in nanometer scale. In addition, it was found from AFM data that the root mean square (rms) surface roughness of the film increases from 1 nm to 2 nm as the annealing temperature increases up to 400 °C. Furthermore, the film becomes more porous with nanometer pores after annealing above 300 °C.

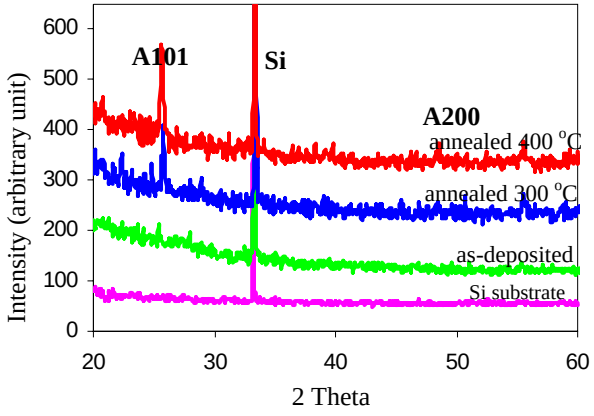

Figure 1. X-ray diffractograms of 30 nm thick TiO_2 thin film with different annealing temperatures.

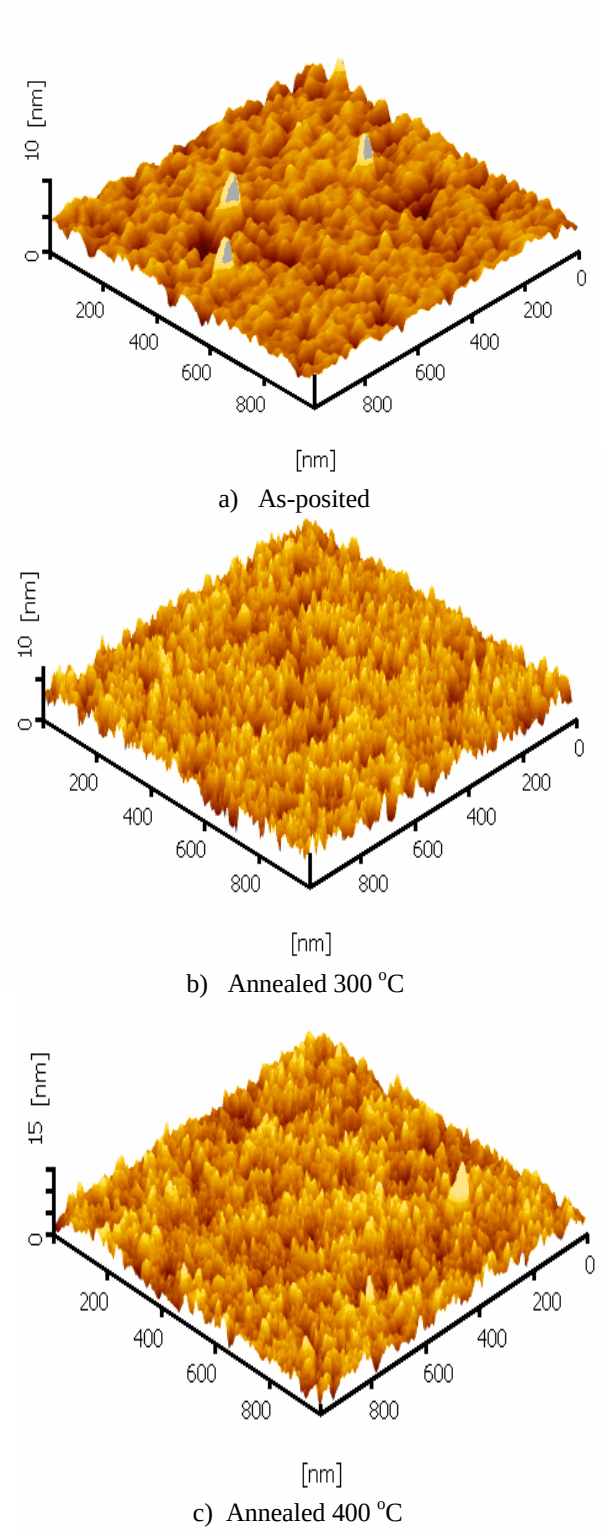

Figure 1. AFM images of TiO_2 thin films with 30 nm thick TiO_2 thin film with different annealing temperatures.

The gas sensing characteristics of the gas sensors are characterized in term of gas-sensing response. The resistance of the TiO_2 thin films was reduced upon the exposure to reducing gas, indicating that it is n-type semiconductor. In

addition, the resistance of the TiO_2 thin films is decreased as thickness and annealing temperature increases. The gas sensing response of n-type semiconductor gas sensor to a reducing gas is normally defined as the ratio of the background resistance to the resistance with gas sample, (R_o/R_g), while the response to an oxidizing gas is defined in the reverse way. The gas-sensing response was calculated time response data and plotted versus various parameters including gas concentration and temperature.

The gas-sensing responses of TiO_2 e-beam evaporated thin films before and after annelaing toward ethanol are shown in Figs. 3 and 4, respectively. It shows that the responses to ethanol of the as-deposited films tend to increase with operating temperatures. In addition, the response is slowly increased with the film thickness. After annealing at 400 ^oC, the response to ethanol of all TiO_2 thin films are improved and become almost independent of the film thickness. Moreover, the effective operating temperature ranges become wider with maximized response at around 350 ^oC.

The improved response after annealing is attributed to the improvement in surface roughness, porosity, and crystallinity of the TiO_2 thin films as is evident from structural characterization. In addition, the observed thickness independence of the response after annealing at sufficiently high temperature suggests that the effective region for gas sensing of TiO_2 thin film is only within a few tens of nanometers from the surface and only very thin film with thickness as small as 30 nm is sufficient for gas sensing. However, the resistivity of very thin film is very high, complicating electrical measurement. It should be noted that the TiO_2 thin films still can sense ethanol at lower operating temperature than 250 ^oC, however the background current is not sensible at these temperature.

IV. CONCLUSION

In conclusion, we study the gas sensing behaviour of TiO_2 thin film prepared by electron beam evaporation with ion-assisted deposition (IAD). TiO_2 thin film has been characterized for structural and gas-sensing characteristics as a function of IAD deposition parameters with thickness in nanometer scale. From structural characterization by X-ray diffraction (XRD) and scanning electron microscope (SEM), the as-deposited TiO_2 thin film has amorphous structure with smooth surface. After annealing at or above 300 °C, the TiO_2 film becomes polycrystalline structure with nanometer grain size and anatase phase with (101) preferred orientation. The experimental results show that 30 nm-thick TiO_2 thin films annealed at 400 °C exhibit high sensitivity to low concentration ethanol in the range of 300 ppm with high response at operating temperature above 250 °C and maximized response at around 350 °C.

Maskless Etching of Microfabricated Structures with Low-Power Focused Ion Beam

Peerasak Chantngarm
Department of Electronics and Telecommunication Engineering,
Pathumwan Institute of Technology, Bangkok 10330, Thailand

Abstract - **Characteristics of the structures microfabricated by 20-keV Ga^+ FIB on Si have been investigated with AFM images and photographs from a Nomarski microscope. The images from AFM show redeposition effect inside and near the edges of the holes etched by FIB. The images also show great damages of the as-implanted structures induced by the high current density of FIB. The relationship between the dose of ion beam and the structures fabricated by FIB was studied. The results indicated that the depth of the structures is directly proportional to the dose of the ion beam with sputtering rate of 132 nm/minute, when the beam current is 28 pA. The line width is also directly proportional to the dose, when the implanting time does not reach the critical value. The experimental results revealed the discrepancies between the beam diameter and the width of the microfabricated structures, which is considered to be the results of combined effects from surface charging effects, vibration, and the part of ion beam with weaker intensity.**

I. INTRODUCTION

Nanoelectronics, including Micro-Electro-Mechanical Systems (MEMS) and Nano-Electro-Mechanical Systems (NEMS), has become one of research areas that attracts a lot of attentions. At the same time, the technologies to fabricate nanoscale structures have been developed rapidly. One of key technologies is photolithography; however, there are many difficulties to be resolved to make further progress. Focused ion beam (FIB) is one of alternative technologies for photolithography in some applications [1-2]. With a very small ion beam diameter, about 0.1 μm, FIB is suitable for maskless etching, maskless implantation, and maskless ion-assisted deposition, etc.

In order to properly fabricate devices, it is essential to fully understand the fundamental characteristics of FIB system itself, and of the structures fabricated with FIB. Although conventional microscopy method such as scanning electron microscopy (SEM) is good enough to acquire images showing topography of the microfabricated structures, atomic force microscope (AFM) is known to provide more detailed information for very small structures. With a probe placed very close to the sample, AFM can acquire a detailed image of the sample over a small area by measuring the attractive forces or repulsive forces between the tip and the sample [3]. The forces are then processed by software to show color images on a screen where the color of images represents the friction between a tip and the sample.

In this study, we investigated fundamental characteristics of the structures microfabricated by 20-keV Ga^+ FIB. AFM was used to examine the surface topography and the depth of the etched specimens, which gave us very detailed information. A Nomarski microscope was also used in our experiments to acquire optical images of microfabricated structures. Three experiments have been done with Si in this study. The first experiment is to examine the surface topography of Si after being bombarded with FIB in dot-mode and area-mode. The second experiment is done to find the relationship between the dose and the depth of holes etched by FIB. The last experiment is to find out the correlation between the implanting time and the width of lines.

The rest of the paper is organized as follows. Section II briefly introduces the fundamentals of stopping mechanisms in solids as well as the redeposition effect associated with ion beam etching. Section III describes the experimental procedures, FIB system, and beam diameter which is an important parameter. Section IV discusses the experimental results and we draw out conclusion in section V.

II. THEORY

A. Stopping Mechanisms

When charged particles are implanted into solids, they collide with atoms of the target and lose energy until stop. There are two kinds of stopping mechanisms for ions implanted into targets, nuclear stopping and electronic stopping. The dominant mechanism is determined by the mass and the energy of the accelerated ions, as well as the mass of the target atoms. Generally, when the energy is relatively low, the stopping is dominated by nuclear stopping, the elastic collisions with nuclei or whole atoms which absorb the impact. On the other hand, when the energy is relatively high, the stopping is dominated by electronic stopping, the inelastic collision with bound electrons of the target atoms so that the atoms of target are excited or ionized. Hence, on the assumption that both mechanisms are independent, the energy loss per distance unit could be expressed as follows:

$$-\frac{dE}{dx} = N\left|S_n(E) + S_e(E)\right| \tag{1}$$

where N is the atomic density of the target atoms, $S_n(E)$ and $S_e(E)$ are nuclear-stopping and electronic-stopping cross-sections, respectively. In the case of implanting 20-keV Ga^+ into Si, the major part of energy loss is due to nuclear stopping which contributes to cascade collision and sputtering [4].

B. Redeposition Effect

One characteristic of etching by ion beam is that the etching and the redeposition of nonvolatile etch product species have taken place simultaneously [5]. Hence, the final net sputtering is the result of combined effects between the etching and the redeposition. Other factors that affect the sputtering are the incidence angle of ion beam, the structure of target materials whether it is an amorphous or a crystalline structure, and the orientation of the crystalline structure, etc. Although FIB has much higher beam current density, the similar redeposition effect is expected.

III. Experimental

Three experiments have been done. First, Si was bombarded with FIB in dot-mode and area-mode, and the surface topography was observed with AFM. In dot-mode, standing ion beam was implanted into just one point for 1 minute. In area-mode, ion beam was raster scanned into area of 5x5 μm^2 for 2 minute 23 seconds. The distance between the center of adjacent holes and areas was 10 μm. The beam current was 28 pA. In the second experiment, FIB was used to etch holes on Si with different dwell time: 1 minute, 2 minutes and 3 minutes. The objective is to find out the relationship between dwell time and the depth of holes. The beam current and the distance between adjacent holes are the same as in the first experiment. The third experiment is to find the correlation between implanting time and the line width on Si. The implanting time was 8 and 82 seconds, while the beam current used in this experiment was 33 pA. We used AFM from Seiko model SPA300 to examine the surface topography and to measure the depth of each holes. A Nomarski microscope was used to acquire the optical images in the last experiment. In all experiments, Czochralski (CZ) grown *n*-type Si substrates of (100) orientation were used. The size of substrates was 2x2 cm^2. The FIB system is introduced in subsection A, and the definition of beam diameter used in the experiments is described in subsection B.

A. FIB System

The FIB system used in this study is model EFIB-2000S from Eiko Engineering. The ion source was needle-type liquid metal ion source (LMIS) which provides Ga^+ ions. When an ion beam hits a target, atoms of the target are sputtered off, secondary electrons and ions are emitted, and the primary ions are implanted. Hence, FIB could be used as a scanning ion microscope (SIM) to provide high-contrast images during ion bombardment [6]. Prior to using FIB in each experiment, the ion beam was adjusted to get well-conditioned beam and stable beam current.

B. Beam Diameter

There are several methods to find out a beam diameter, such as the knife-edge method, the $1/e^2$ optical intensity criterion, and the 1/e electric field strength criterion. In reality, the beam diameter of FIB is affected by several factors, such as beam energy, beam current, etc [7]. In our study, instead of measuring the beam diameter directly, we derived the beam diameter from beam energy and beam current based on the specification from the manufacturer. Assuming that the beam energy is 20 keV, when the beam current is 100 pA the beam diameter is about 0.15 μm, and when the beam current is 30 pA the beam diameter is about 0.1 μm [7]. The beam current used in our experiments is around 30 pA. Hence, the beam diameter should be about 0.1 μm by specification. One way to make sure that the beam is focused enough is by viewing the SIM image of a standard sample provided with the FIB system. The standard sample has an Al layer on the top with LATEX particles, which is a type of polymer. Fig. 1 shows the SIM image of LATEX particles, and lines generated by FIB. The diameter of LATEX particles is 1 μm and the width of the line generated by FIB is about 0.2 μm. Once we get the image of the LATEX particles clearly, it means that the beam ion beam is well conditioned. However, it is not unusual that the minimum line width of the structure etched by 0.1-μm-diameter FIB would be larger than 0.1 μm. The wider minimum line width is caused by the part of ion beam with weaker intensity. It is reported that the minimum line width on Si etched with 0.1-μm-diameter FIB could be 0.5 μm [8]. The discrepancies between the beam diameter and the line width would be further discussed in section IV.

IV. Results And Discussion

It is known that ion bombardment causes damages to the targets due to elastic collisions with nuclei of target atoms. With beam current density 10^5 times higher than conventional ion beam [8], it is expected that FIB could cause more damages to the targets. The reason that Ga^+ ions were used in our study is due to the large sputtering yield, as well as the stability and the ability to operate at room temperature of the Ga^+ ions LMIS. Fig. 2 is the AFM images showing the surface topography of Si after ion bombardment with FIB in the first experiment. The diameter of two holes in the middle of Fig. 2(a) is 2 μm and the size of implanted areas in Fig. 2(b) is 5x5 μm^2. From the images, it could be seen that the roughness on the edges of holes in Fig. 2(a) and on the implanted areas in Fig. 2(b) is nonuniform. This phenomenon is considered to be the combined effect of cascade scattering and redeposition effect, which were explained in section II.

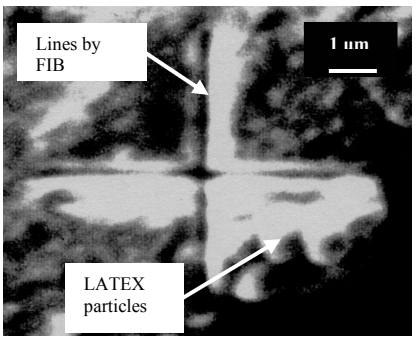

Fig. 1. The SIM image of LATEX particles and lines generated by FIB.

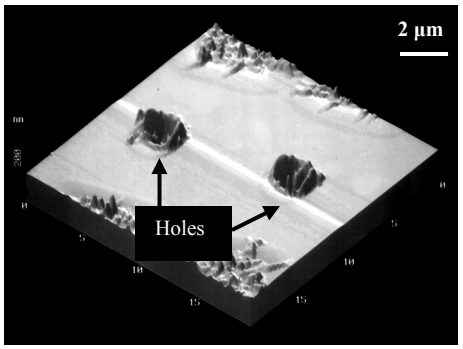
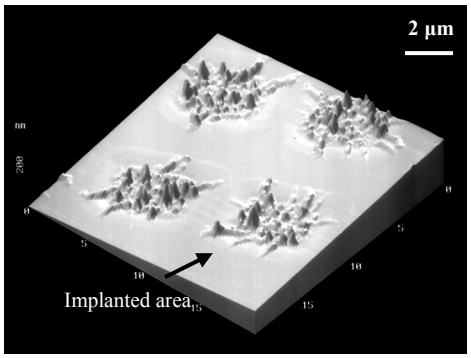
Fig. 3 is the AFM images showing top view and cross section of the holes on Si in the second experiment. The line above holes in the middle of Fig. 3(a) is a reference line to display the cross section of the holes. Here, the holes under the line could be separated into three groups: two on the left, three in the middle, and two on the right. The dwell time for each group is 1 minute, 2 minutes and 3 minutes, respectively. The rough areas near the holes in Fig. 3(a) are the same damages at the implanted areas as in Fig. 2. Two vertical lines in the middle of Fig. 3(b) are also reference lines used to measure the depth of the holes. The cross section in Fig. 3(b) shows some interesting characteristics. First, the feature profile of the holes is not anisotropic, but conical. This is due to the energy distribution profile of ion beam, which has the highest current density at the center, combining with the redepostion effect taking place near the bottom of the holes [9]. Second, the two holes with the shortest dwell time have a two-peak feature profile. This could be explained with the AFM image in Fig. 2(b). When the dwell time is not long enough, the sputtering process is continuing at the surface and the area could be nonuniform. Third, there are two hones at the edges of the holes with the height of left hones directly proportional to the dwell time. These hones are also considered to be the result of redeposition effect. The same effect also caused faceting near the edges of two holes with the longest dwell time. Fourth, the diameter of the holes on the surface of Si substrate is about 2 μm, which is the same for all holes.

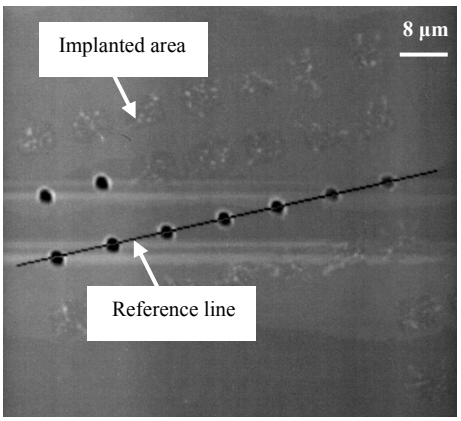


(a)

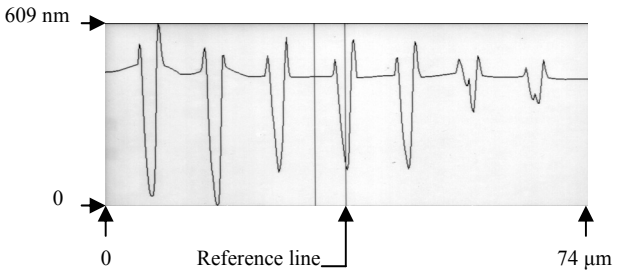


(b)

Fig. 2. AFM images showing FIB ion bombardment results on Si. (a) Two holes with 2μm diameter. (b) Implanted area with size of 5x5 μm^2.



(a)



(b)

Fig. 3. Holes examined with AFM. (a) Top view. (b) Cross-sectional view.

Fig. 4 shows the relationship between dose and the depth of holes. The depths of holes were measured by AFM. Dose is used instead of dwell time, because the beam current is hard to precisely control and make it continuously stable. Fig. 4 indicates that the depth of the holes is directly proportional to the dose. This is because when the number of ions bombarded the target increases, the number of target atoms sputtered out also increases. In this case, when the beam current is 28 pA, the sputtering rate of 20-keV Ga^+ FIB ion etching with normal incident angle beam is 132 nm/minute.

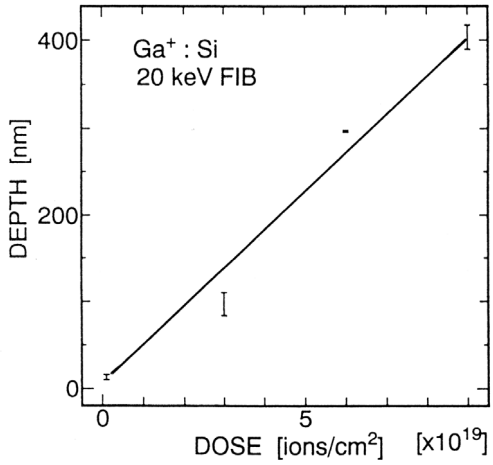


Fig. 4. The relationship between dose and the depth of holes.

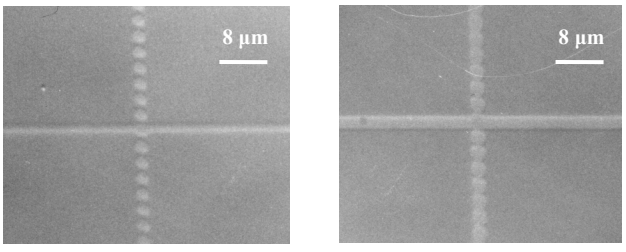
In the third experiment, we used FIB to draw lines in vertical and horizontal directions on Si with different implanting time, as shown in Fig. 5. The objective is to find out the correlation between implanting time and line width. When the implanting time is 8 seconds, the line width is 1.3 μm. The line width increased to 2.7 μm, when the implanting time is 82 seconds. The dots in vertical direction are caused by the line-drawing mechanism of the FIB system, which uses a raster scan. Fig. 5(a) shows that the scan mode used in this experiment has large space between lines. With longer implanting time, each dot increases the size and connects to each other; however, the trace of raster scan still remains.

The results from all three experiments show one common issue. The size of pattern on Si is much larger than the beam diameter in specification, 0.1 μm. Although we expected that the size of pattern could be up to 0.5 μm, the results from experiments went beyond that. Hence, we need other explanations in addition to contribution from the part of ion beam with weaker intensity. Here, there are few experimental results that gave us some insight. First, the holes in Fig. 3(a) and the dots in Fig. 5(a) are not complete circles, which could make the beam diameter larger in some directions. This might be the results of beam adjustment or might be the surface charging effect caused by ion bombardment on Si, a low-conductivity material. One way to avoid the surface charging effect is by depositing thin layer of metal on the Si. Second, the line widths in the third experiment increase with the implanting time. There are two possible reasons for this. One is small vibration of the equipment, and the other is the part of ion beam with weaker intensity. In fact, it might be the combined effects of both. Due to small feature size fabricated in our experiment, even small amount of vibration might affect the line width. Third, the diameters are the same for all holes in Fig. 3. This might look contradictory to the previous fact; however, there is an explanation for this. With a few seconds of short implanting time, only the central part of beam could etch the target, so the line width is narrow. When the implanting time also increases, the part of beam with weaker intensity shows accumulated effects on the target, so the line width increases. On the other hand, when the implanting time is long enough to reach the critical value, for example, more than 1 minute for etching a hole, the diameter of the hole does not increase any further. This is because the weaker part of ion beam has already played the role.



(a) (b)

Fig. 5. Lines drawn on Si with FIB. (a) Implanting time is 8 seconds. (b) Implanting time 82 seconds.

V. Conclusion

Three experiments have been done to investigate the fundamental characteristics of the FIB system and the structures on Si microfabricated with 20-keV Ga^+ FIB. The first experiment is to examine the surface topography of Si after being bombarded with FIB in dot-mode and area-mode. The results show nonuiformity on the implanted area and at the edges of the holes due to the combined effect of cascade scattering and redeposition effect. The second experiment is to find the relationship between dose and the depth of holes etched by FIB, which indicates that the depth is directly proportional to the dose. The results also show the conical shape of the holes, except when the dwell time is not long enough which the bottom of the holes would not be smooth. In addition, there were evidences of redeposition effect causing hones and faceting near the edges of the holes. The last experiment is to find out the correlation between implanting time and the width of lines, which shows that the line width is also directly proportional to the dose. However, further analysis suggests that the line width is directly proportional to the dose only when the implanting time is shorter than the critical value. In other words, the hole diameter and the line width should remain the same beyond the critical value. In addition, our analysis suggests that the discrepancies between the beam diameter and the size of fabricated structure are possibly due to surface charging effect, vibration, and the part of ion beam with weaker intensity. Further studies shall be done on other kinds of materials to confirm the analysis and obtain deeper insight in FIB system and the structures fabricated with FIB.

Acknowledgment

I would like to express my deep appreciation to Prof. H. Matsunami and everyone in Matsunami Laboratory for very fruitful discussions and providing equipments used in this research.

htshandiz@shahroodut.ac.ir

Abstract- **Inverse solution of robot kinematics has many Answers. In order to have a unique solution using other criteria such as cost function for optimal situation is necessary. The task is more difficult if the assumption of rigid body not acceptable as it is in practical world. In this work a fuzzy controller is proposed to overcome the above mentioned problems. The new part of this work is using geometric error which make implementation of fuzzy controller more efficient than other methods. The result shows rapid convergence in inverse solution of robot kinematics.**

I. INTRODUCTION

Desired trajectory of robot manipulator is usually given in the Cartesian space. Whereas, the controllers are designed in joint space. It means mapping between these two spaces are necessary. This mapping for manipulator, when the joint space is converted to the Cartesian is known as kinematics. The mapping is called inverse kinematics if Cartesian space is mapped to joint space.

There are two difficulties in kinematics mapping, first due to intensive computational complexity because of coupling effects of the robots and the second is obtaining closed form solution of inverse kinematics. Differential relationship which is called Jacobian can be used to avoid solving the closed form kinematics and the inverse kinematics. The Jacobian matrix related the changing in Cartesian position or orientation and changing in joint angle. The following equation shows this relation:

$$dx = J(q).dq \qquad (1)$$

In which x is the Cartesian vector, q is the joint vector and $J(q)$ is Jacobian matrix.

Many industrial robots are like human arm. For moving hand no body solve the complex kinematics or inverse kinematics equation which related position of the links to rotation of the joints. It is the clue which led the researcher to use fuzzy logic and fuzzy controller for robot manipulator.

S. w. Kim and J. J. Lee proposed a solution method in which they have found a rough solution based on gradient method and then refine it by introducing the fuzzy logic through the extension principle [1].

Y. Xu and M. Nechiba use fuzzy method in different way to solve inverse kinematics [2]. These two groups are first researchers who start to use fuzzy method to find a fast solution of inverse kinematics.

M. T. H. Beheshti and A. K. Tehrani based on Kim and Lee work developed an adaptive fuzzy method for a robot with extra degree of freedom. They continue their work by solving the inverse kinematics of redundant robots in an environment with obstacles. Their PD fuzzy controller has been improved by considering distance from singularity points and updating the rule base [3-5].

Y. Xia and J. A Wnag, proposed a dual neural network for solving inverse kinematics differential equations [6].

E. Oyama et all, used a modular neural network to solve inverse kinematics for robot with extra degree of freedom [7].

In this work a new method based on geometrical error and fuzzy logic is proposed. The result is compared with other methods.

II. PROBLEM FORMULATIONS

Figure one shows the two links robot, which is used in this work.

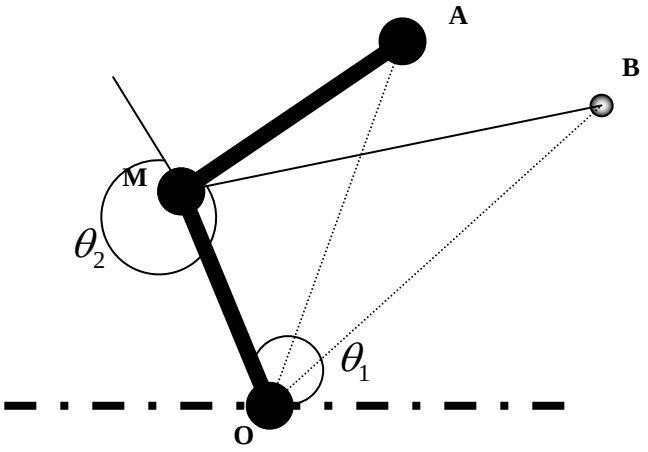

Figure 1. Two links robot

In the figure O is origin of robot, M joints two links, A is the place for actuator, B is the desired target, θ_1 and θ_2 are the joint variable for link one and two, respectively.

There are three errors which are used in this work as follow. First error is actuator error in Cartesian space, which is given by following formula:

$$\varepsilon_0 = \left| x_d(t) - x(t) \right| \quad (2)$$

In which $x_d(t)$ is desired trajectory and $x(t)$ is the position of actuator in time t. It is obvious that the smaller ε_0 means less difference between desired trajectory and real place of actuator. The second error is difference between the length of vector between origin - actuator and origin – target. The following formula explains this error in mathematics language:

$$\varepsilon_1 = \left| OA \right| - \left| OB \right| \quad (3)$$

Where $\varepsilon_1 = 0$ occurs in two situations. First the actuator is in desired place if $\varepsilon_0 = 0$ and the second by changing θ_2 it reaches to the asked position, if $\varepsilon_0 \neq 0$. The following formula shows the amount of this change:

$$\Delta\theta_2 = Arc\tan\left(\frac{AB}{2MA}\right) \quad (4)$$

Third error is difference between the length of vector between point M - actuator and point M – target. The following formula explains this error in mathematics language:

$$\varepsilon_2 = \left| MA \right| - \left| MB \right| \quad (5)$$

Where $\varepsilon_2 = 0$ occurs in two situations: the actuator is in desired place if $\varepsilon_0 = 0$ or the by changing θ_1 it reaches to the asked position, if $\varepsilon_0 \neq 0$. The following formula shows the amount of this change:

$$\Delta\theta_1 = Arc\tan\left(\frac{AB}{2OM}\right) \quad (6)$$

The output of controller increases or decreases the distance between actuator real and desired position.

III. FUZZY CONTROLLER

The basic configuration of fuzzy logic controller (FLC) in figure 2 is used in this work [8]. It has four principle parts as: fuzzification interface, a knowledge base, decision making logic and a defuzzification interface.

Fuzzification interface changes the process output errors ε_1 and ε_2 which are crisp to fuzzy data. It is mapped the inputs data into suitable linguistic values. In other word the input data is viewed as labels of fuzzy set. This is based on membership function.

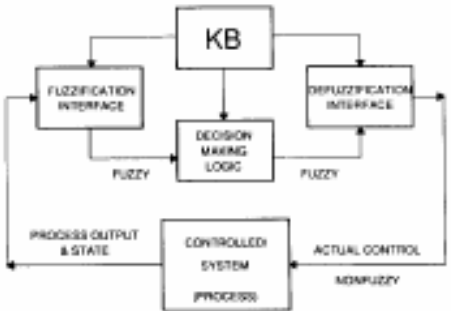

Figure 2. Basic configuration of FLC

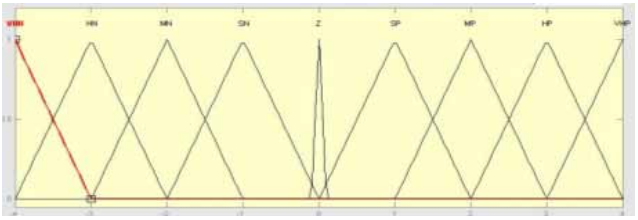
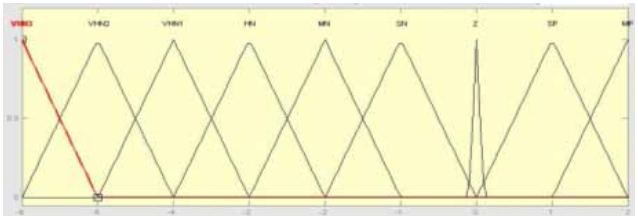
Our experience due to simulation and reviewing other researchers work shows the triangular membership function is the best. In this work span of ε_1 is [-4 , 4] and ε_2 is [-6 , 2]. There are 9 levels for each variable as shown in figure 3.



(a)



(b)

Figure 3. Membership function of (a) ε_1 and (b) ε_2

The knowledge base consists of a data base and a linguistic or fuzzy control rule base. With conditional statements all output of fuzzification are related to a set of linguistic control rule.
The two control variables which are used in rule base have the membership function as shown in figure 4.
After rejecting the redundant rule the following rules are used in this work.

If (ε_1 Is VHN) then ($\Delta\theta_2$ Is VHP)

If (ε_1 Is HN) then ($\Delta\theta_2$ Is HP)

If (ε_1 Is MN) then ($\Delta\theta_2$ Is MP)

If (ε_1 Is SN) then ($\Delta\theta_2$ Is SP)

If (ε_1 Is Z) then ($\Delta\theta_2$ Is Z)

If (ε_1 Is SP) then ($\Delta\theta_2$ Is SN)

If (ε_1 Is MP) then ($\Delta\theta_2$ Is MN)

If (ε_1 Is HP) then ($\Delta\theta_2$ Is HN)

If (ε_1 Is VHP) then ($\Delta\theta_2$ Is VHN)

If (ε_2 Is VHN3) then ($\Delta\theta_1$ Is VHN3)

If (ε_2 Is VHN2) then ($\Delta\theta_1$ Is VHN2)

If (ε_2 Is VHN1) then ($\Delta\theta_1$ Is VHN1)

If (ε_2 Is HN) then ($\Delta\theta_1$ Is HN)

If (ε_2 Is VHN3) then ($\Delta\theta_1$ Is VHN3)

If (ε_2 Is HN) then ($\Delta\theta_1$ Is VHN3)

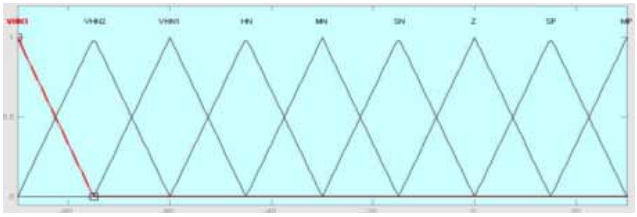
If (ε_2 Is MN) then ($\Delta\theta_1$ Is MN)

If (ε_2 Is SN) then ($\Delta\theta_1$ Is SN)

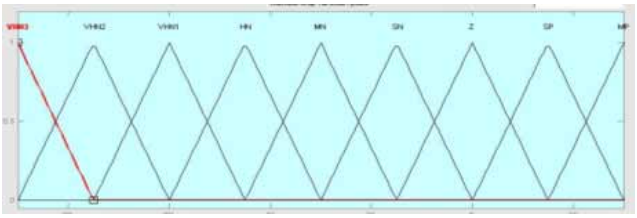
If (ε_2 Is Z) then ($\Delta\theta_1$ Is Z)

If (ε_2 Is SP) then ($\Delta\theta_1$ Is SP)

If (ε_2 Is MP) then ($\Delta\theta_1$ Is MP)



(a)



(b)

Figure 4. Membership function of (a) $\Delta\theta_1$ and (b) $\Delta\theta_2$

Decision making logic is a part in FLC which has the capability of simulating human decision making. The decision is in fuzzy form.

The last part is defuzzification part. The task of this part is exactly vice versa of fuzzification part. This part changes the fuzzy value to crisp value. In this work the center of area is used for defuzzification task.

$$\Delta\theta_i = \frac{\sum_{j=1}^{9} \mu_{\Delta\theta_i}(w_j).w_j}{\sum_{j=1}^{9} \mu_{\Delta\theta_i}(w_j)} \qquad i = 1, 2 \tag{6}$$

In which $\mu_{\Delta\theta_i}(w_j)$ is membership function of $\Delta\theta_i$ and w_j is center of jth membership function.

IV. EXPERIMENTAL RESULTS

The robot motion is simulated by using MATLAB. In order to comparing the result of proposed method with other methods sinusoidal input for Cartesian space is used. In this work 2.5 present flexibility for link and joint is considered. Figure 5 shows our result and other researcher results in best situation.

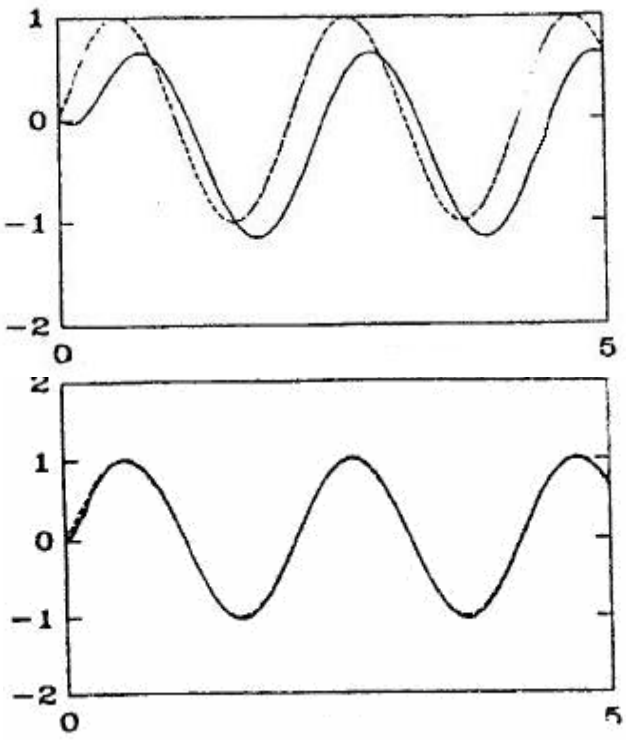


Figure 5. Researcher result (above) our result (below)

V. CONCLUSIONS

As simulation result shows our method is more accurate and faster than other method. In our simulation we considered 2.5 percent flexibility whereas other researchers assume the links and joints are rigid.

Fuzzy Logic Based Embedded Controller for Control System Education

N. Jasungnuen, P. Janchaichanakun, and P.Koseeyaporn
Department of Teacher Training in Electrical Engineering
King Mongkut's Institute of Technology North Bangkok, 1518 Bangkok, THAILAND

***Abstract*-This paper presents an education tool of fuzzy logic control in embedded microcomputer applied to an undergraduate control laboratory course. A control script interpreter is implemented on the embedded side allowing flexibility in changing control algorithm so that controller design skill can be achieved in training program. To simplify the usability for undergraduate level, graphic user interface for PC is developed. Therefore, the controller parameters such as membership functions and rule base can be designed with less effort. Communication between PC and embedded module provides transferring information of controller to the embedded side and retrieving the control result from embedded part to the PC for graphically observation. The system model implementation for testing the controller in embedded module is based on operational amplifier circuit. The results show that the implemented software and hardware is suited for control system training.**

***Index Terms*-Embedded microcomputer, fuzzy logic controller.**

I. Introduction and Background

Fuzzy logic, or fuzzy set theory, was fist present by Zedah [1]. Since then, many applications of fuzzy logic have been revealed continuously. Fuzzy logic controller is also widely used especially for imprecise and nonlinear systems [2]. As in academic part, classical control is rather been focused. Mathematical model of the system has to be known in order to design a well-matched controller. On the other hand, mathematical model of the system is not required for designing of fuzzy logic controller. Instead, the well-knowledge of system behavior is needed. In order to allow academic training program to catch up the recent technology, a laboratory tool of fuzzy logic control for DC brushless motor has been introduced [3]. For undergraduate level, migrating knowledge of linear control to the complex approach may have some difficulty. Simplification of the gap between linear and nonlinear control is needed. Another aspect is that the cost of laboratory tool for training program is high. For these reasons, an effortless and low cost training tool is required. As described in [4], one choice of implementing such a low cost computation tool for control system is embedded system. It has the capability that is similar to personal computer (PC). There is one benefit of using embedded module for academic program. Because the embedded system has already been employed in industrial sector, the training program that uses embedded module will make the students get familiar to this kind of technology.

In this paper, an ease-of-use tool for designing of fuzzy logic controller is introduced. A set of training tool for undergraduate control laboratory based on embedded system is implemented.

II. Embedded Microcomputer

Embedded module is compact and low cost. As almost the same capability as PC, embedded module is widely used in manufacturing. Engineering training of embedded module is, therefore, required. The training covers programming and interfacing skill. The embedded module consists of CPU, RAM, and communication ports. The embedded module employed here is the Mity Mite CPU 386XS module, which can be operated under MS-DOS operating system. The program implemented in this embedded module can be achieved by using C++ compiler under DOS operating system. Communication port provides sending and receiving data between PC and embedded module via general SOCKET communication. Fig.1 shows the embedded module applied in this work.

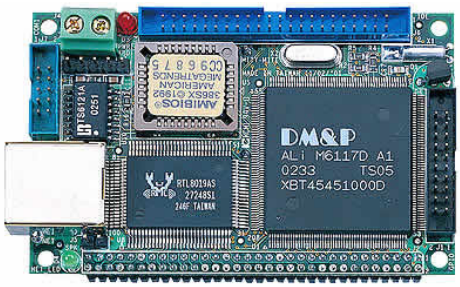

Figure 1. Embedded system module.

III. Fuzzy Logic Controller

Unlike classical control scheme, fuzzy logic control use linguistic terms to represent quantity of the inputs and outputs. In addition, mapping between input and output is another important part. To this, a well understanding between input and output is needed. Fuzzy logic controller is composed of three parts; fuzzification, inference engine, and defuzzification part as can be seen in Fig. 2. Fuzzfication behaves as an interpreter. It interprets the numerical quantity into fuzzy meaning. Fuzzy meaning can be composed of several levels.

Each level, so called fuzzy membership function, may cross the boundary of another fuzzy membership function. Each membership function may be a form of triangle, a trapezoid, or bell shape. For simplicity, triangle is often chosen as

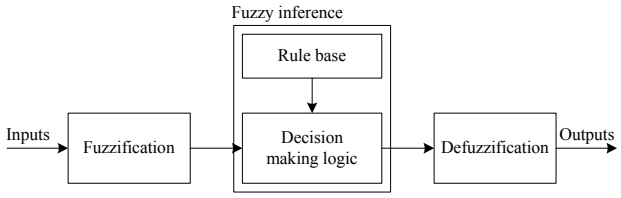

Figure 2. Fuzzy logic controller block diagram

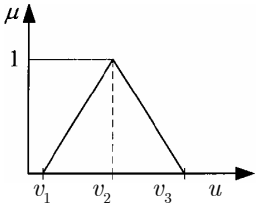

Figure 3. Triangle membership function

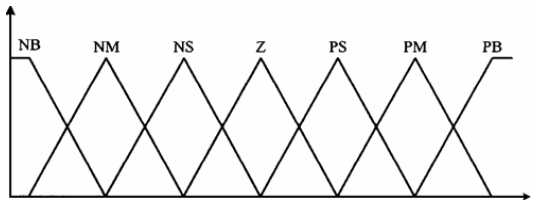

Figure 4. Seven levels of fuzzy membership function.

$$\mu(u_i) = \begin{cases} \dfrac{u_i - v_1}{v_2 - v_1}, & v_1 \le u_i \le v_2 \\ \dfrac{v_3 - u_i}{v_3 - v_2}, & v_2 \le u_i \le v_3 \\ 0, & otherwise. \end{cases} \quad (1)$$

where the graphical view of this function is shown in Fig. 3.

To fuzzify input quantity to linguistic terms, a set of membership function as in Fig. 4 is used. Each membership function represents the fuzzy level of input such as negative big (NB), negative medium (NM), negative small (NS), zero (Z), or positive small (PS). Based on this fuzzy linguistic, fuzzy inference will map the relation between inputs and output linguistic in term of database provided by expert. The evaluation of this process is based on logical decision-making scheme. The database in this inference engine is so called rule-base. The rule-base is typically a text or linguistic format which is in logical form such as "and" or "or" relation. Finally, defuzzification will transfer the linguistic output to the numerical format. The output (u_o) is generally evaluated by averaging of the individual centroid corresponding to their weight as

$$u_o = \frac{\sum_{i=1}^{n} u_i \mu(u_i)}{\sum_{i=1}^{n} \mu(u_i)} \quad (2)$$

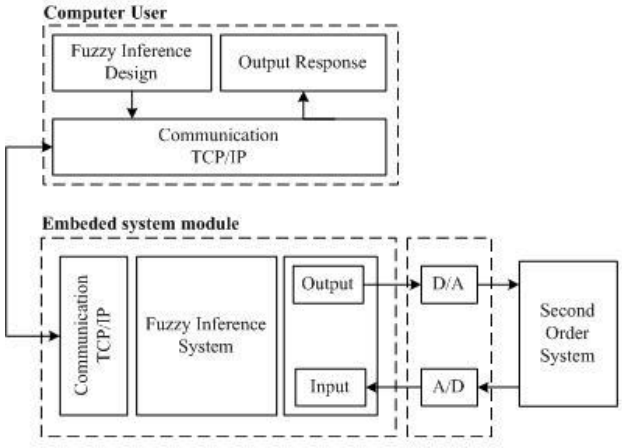

Figure 5. System communication

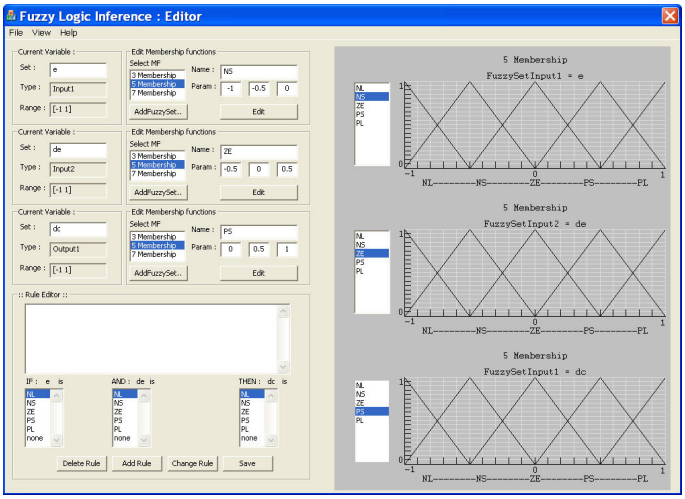

Figure 6. FLC setup window.

IV. Design of System and Program

As shown in Fig. 5, the designed system is composed of three parts, PC program, embedded module, and linear system model in operation amplifier circuit. The PC part allows user to conveniently design FLC. This can be done by providing a Graphic User Interface (GUI) implemented by using Visual C++ compiler as the result shown in Fig. 6. The user can specify number of membership function and the details of the membership function. Rule base can be also added by simply selecting the membership functions at both input and output sides. The results of design FLC can be exported into file and displayed as shown in Fig. 7.

The second part is the embedded module, which receives the information setting of FLC in text format file from PC side where the communication between embedded module and PC is based on SOCKET communication. After the file is loaded into the embedded module, the embedded module is ready to provide the output the system via digital to analog interface as shown in Fig. 8 (right). The systems as shown in Fig. 8 (left) consist of first-, second-, and third-order circuits built from operational amplifiers. The parameters of the system models can be adjusted so that the students can practice different type of system characteristic. An example of system step response

is illustrated in Fig. 9. Additionally, the input and output ports of the embedded system allows user to choose the program to run according the laboratory instruction. The result at the embedded side can be sent back to the PC side so that the user can observe the result graphically as shown in Fig. 10.

V. Experimentation Procedure

The procedure of experiment performing is based on learning objective orientation including controller design and embedded interfacing skill. The students are assigned to adjust controller parameters based on different types of system in actual circuit models. By using the graphical tool described previously, the controller can be designed rapidly resulting in saving time while the understanding is still permitted. The second step is to save the designed result to the embedded module. After that, the module will be ready to plug into the system circuit models. The result of testing of output is then ready to be loaded into the PC side for observing the response. Finally, the discussion and report will be made or more experiment can be performed repeatedly.

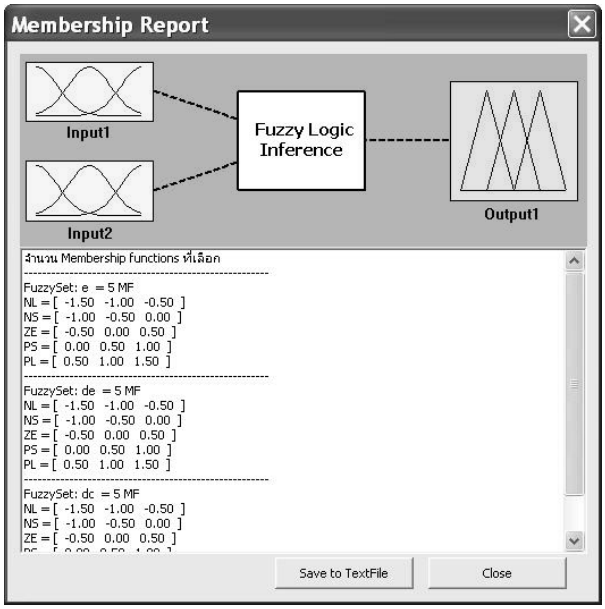

Figure 7. Window showing the results of the designed FLC.

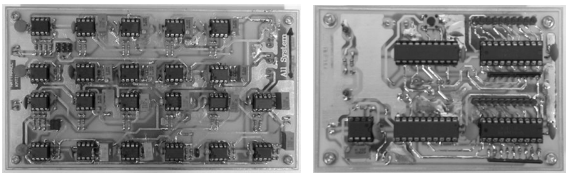

Figure 8. System model (left) and A/D, D/A circuit board (right).

VI. Conclusion

A tool for training of fuzzy logic controller and embedded system is presented. It has the benefit of low cost and effective training tool. The learning objectives cover programming skill, controller design, and embedded application. The students are motivated to link their knowledge of linear control system to the fuzzy type of controller resulting in broader knowledge. The laboratory allows gaining in experience in recent technology. The flexible structure of the embedded system provides higher efficiency in training tool, reusability in different type of controller design training.

Electromagnetic Flux Density Controlled by Fuzzy Logic Method

Satean Tunyasrirut and Santi Wangnipparnto
Faculty of Engineering, Pathumwan Institute of Technology,
833 Ram 1 Rd, Pathumwan, Bangkok, 10330, Thailand.

***Abstract*- This research studies on the electromagnetic flux density controlled by fuzzy logic method as well as to control a working process with the utilization of aISA-A57 interfacing card. Regarding to control a personal computer is used through DOS operational system. Spontaneously, the aISA-A57 card (D/A, A/D & I/O Interfacing Board) with the utilization of Borland C++ 5.0 programming language. From the experiment shown that the design fuzzy logic control at 0-5 volt able to control the electromagnetic flux density in 0-90 millitesla by using the response time less than 0.23 second and has steady error less than ± 3 % of error over all.**

I. INTRODUCTION

Nowadays, the various parameters in the process of industrial are controlled such as temperature, level, and etc. Some process needs to keep the electromagnetic flux for control the position, force, and speed of the equipments such as the motor, solenoid valves, electric train, and etc. The objective of the controller is to maintain a electromagnetic flux set point at a given value and be able to accept new set point values dynamically. The conventional proportional-integral-derivative (PID) is commonly utilized in control, but the parameter of its must be turned by tuning method either in time response of frequency response to meet their required performances[1],[2]. On the other hand, the fuzzy controller is also popularly implemented in many practical industrial automation applications. In this paper presents design and implements the fuuzy logic controller for control electromagnetic flux. The aim of this paper is two-fold. The first is shown the dynamics response of system when changes the step set point and see the steady state errors. The second shown the phenomena effect of the iron powder under the magnetic flux density.

II. THEORY

Magnetic flux density(B)

When a electric current flows through a conductor (copper wire), it generates a magnetic field. Arrangement the conductor on the magnetic materials such as the soft iron as shows in Fig. 1, the magnetic material's atomic parts will align in a certain direction and send the magnetic field is perpendicular to the direction of current flow and its direction is given by the right hand rule. The flux density(B) is given by the flux passing

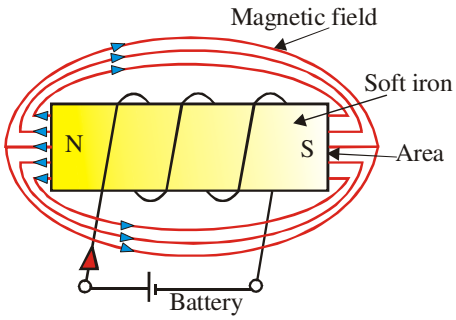

Fig. 1. Magnetic flux density.

per unit area through a place at right angle to the flux as defined as

$$B = \varnothing/A \quad (1)$$

The unit of magnetic flux density is called gauss or Tesla. 1 Tesla is10,000 gauss and using the letter for Flux is "B"

The relationship between B and H may be written

$$B = \mu H = \mu_0 \mu_r H \quad (2)$$

Where: μ_r is the relative permeability of the material. and μ_0 is the magnetic permeability of free space [$4\pi x10^{-7}$ H/m].
H is the field strength at any point within a magnetic field and it is a function of input current so we can control the flux density by adjust the current that passing the conductor.

Fuzzy logic controller

The structure of the proposed magnetic flux control system is shown in Fig. 2.

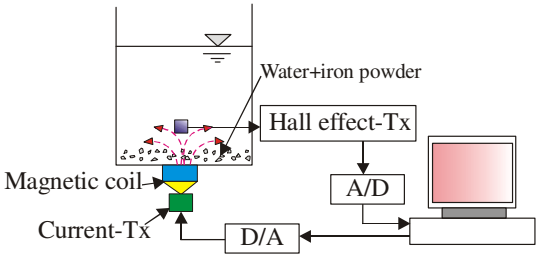

Fig. 2. The proposed magnetic flux system.

The input of fuzzy logic controller is the magnetic flux density error(e) between the set point and the process variable. The fuzzy logic controller consists of fuzzification, fuzzy inference,and defuzzification stages as shown Fig. 3. The number of membership functions for each input variable is designated in five ranges and the names of them are positive large /positive small/zero/negative small/ negative large. The fuzzy controller output has 25 membership functions. The form of all input and output membership functions are selected to be triangle-shaped functions for simplicity. In fuzzification stages, the input variables, the position is converted into fuzzy variables using the membership function as shown in Fig. 4. The linguistic rules of e and ce of temperature are shown in Table 1.

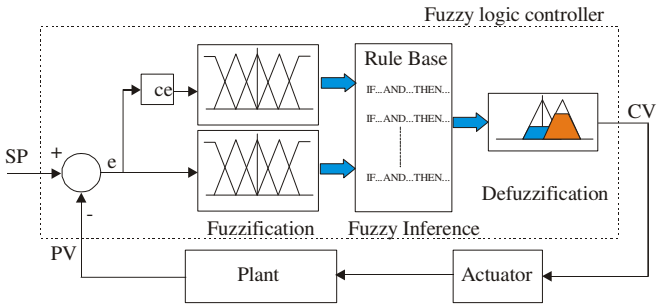

Fig. 3. Block diagram of fuzzy logic controller.

The defuzzificating operation, in this paper, uses the centroid defuzzification method because of its implementation simplicity.

III. EXPERIMENTAL SETUP

The experimental set up consists of the hardware such as personal computer, the aISA-A57 card (D/A, A/D & I/O Interfacing Board), the beaker size 1000 ml that filling the water and the iron powder, hall effect sensor, V to I transmitter, and magnetic flux density generator as shown in Figure 5 and the software programming language using the Borland C++ 5.0. The calibration of the hall effect sensor is shown in Fig. 6.

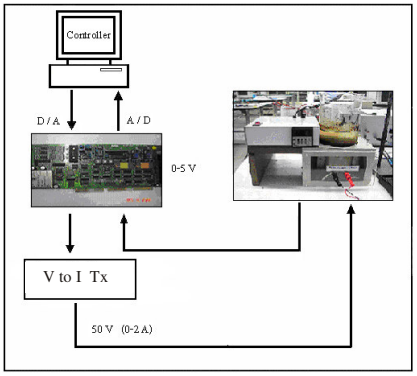

Fig. 5. The experimental setup.

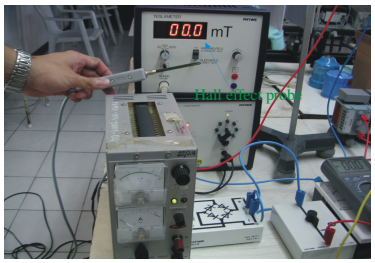

Fig. 6. The calibration of the hall effect sensor setup.

IV. Experimental Results

The experimental results in this paper can be divided in two parts, the first shows performance of the fuzzy logic controller, the second shows the effect of iron power under maagnetic field.

A. Tthe magnetic flux density control by fuzzy logic controller

The responses time and steady state error of the temperature control when changing the step set point from 20mT to 90mT and 90mT to 20mT are shown in Fig. 7. and Figure.8 respectively. The Table 2 shows the responses time and steady state error at another the step set point and found that the response time less than 0.23 second and has steady error less than ± 3 % of error over all.

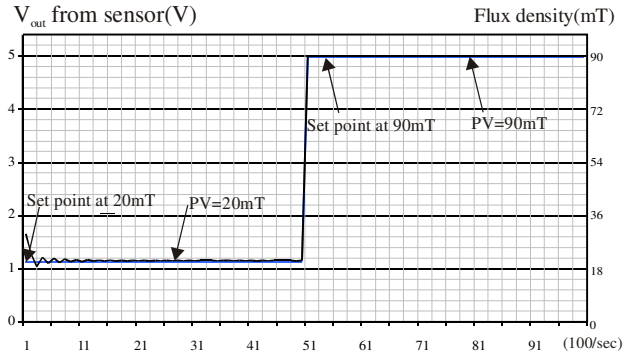

Fig. 7. Changing the step set point from 20mT to 90mT.

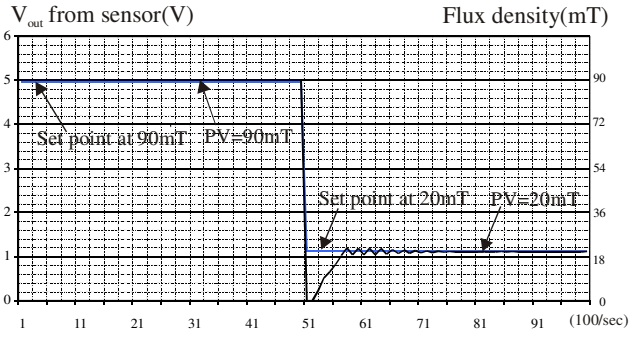

Fig. 8. Changing the step set point from 90mT to 20mT.

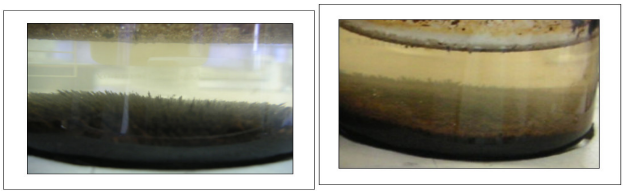
TABLE 2.
Performance of the fuzzy logic controller when changing the flux density step set point.

Step set point [mT]	Response time [sec]	Steady state error [%]
20-30	0.23	1
20-40	0.18	0.125
20-50	0.2	0.54
20-60	0.19	1
20-70	0.18	0.17
20-80	0.18	0.112
20-90	0.01	0.02
90-20	0.22	2
90-30	0.2	0.66
90-40	0.2	1
90-50	0.21	1.4
90-60	0.16	1
90-70	0.16	0.28
90-80	0.21	0.375

B. Effect of iron power under maagnetic field.

When applied the maagnetic flux density 90 mT on the iron powder that mixed with the water in the beaker size 1000 ml, we found that the iron powder will extend following the magnetic line and after cut off magnetic flux density, the iron powder will falling to the bottom of the beaker by gravity force, so we can be using this effect to enhancement heat transfer in the beaker.



a,) b.)

Fig. 9. The phenomena of iron powder under magnetic field.
a.) has maagnetic flux density b.) no maagnetic flux density

V. Conclusion

The fuzzy logic controller has been proposed control the electromagnetic flux density passing the beaker to the water that mixed the iron powder. It has been shown that when changing the flux density set point, the response time less than 0.23 second and has steady error less than ± 3 % of error over all. The effect of magnetic field force can be done the the magnetic materials movement in the liquid so we can apply its to enhancement heat transfer in the system or another applications.

ACKNOWLEDGMENT

The authors gratefully acknowledge the Mr. Teerawat Maneedang and Mr. Attapon Panyo who testing the experimental apparatus hardly.

***Abstract*-This paper presents a fuzzy I-PD controller for two-link robot manipulator. The proposed controller consists of a Mamdani fuzzy I and a Mamdani fuzzy PD controller and its parameters are adjusted to make the manipulator follow to desired trajectory. The experimental results in controlling the two-link robot manipulator by using the proposed fuzzy I-PD controller with the same parameters (proportional gain, integral gain and derivative gain) as the conventional I-PD controller are also shown in this paper.**

I. INTRODUCTION

The most well-known and widely used controllers in the industries are the conventional PID-family controllers. The good points of the PID type controllers are the simple in adjusting their parameters to meet the desired control system performances by using the tuning method such as Zeigler-Nichols' (Z-N) tuning formula or coefficient diagram method (CDM) [1-2]. However, when the PID controller is used to control the nonlinear system such as a manipulator system, it is difficult to achieve the desired trajectory, since the manipulator systems contain uncertain components.

Recently, the fuzzy logic controller has been used in control system when the mathematical model of the process is vague or exhibits uncertainties or when PID-family controller can not generate the satisfactory performance [3]. However, due to popularity and simplicity of PID type controller, fuzzy PID-family controllers have been also employed in control system by combining the merits of both controllers.

It is known that I-PD controller has a property to avoid large changes in control signal due to the proportional and derivative actions when there is a sudden change in the reference input. Therefore, a fuzzy I-PD controller, which is the modification of conventional I-PD controller structure, is presented in this paper. Firstly, the conventional I-PD controller is divided into I controller part and PD controller part. After rearranging the structure of I and PD controllers, they will be constructed as a Mamdani fuzzy I controller and a Mamdani fuzzy PD controller. The inputs of Mamdani fuzzy I controller will consist of two inputs, error and change of error, and Mamdani fuzzy PD controller will consist of two inputs, output and change of output. The control signal of the controller is the subtraction value of the output of Mamdani fuzzy I controller and Mamdani fuzzy PD controller. The proposed controller is implemented to control two-link robot manipulator. The experimental results are shown that the parameters of Mamdani fuzzy I-PD controller can be adjusted to make the manipulator follow desired trajectory. The experimental results are also shown by comparing the proposed fuzzy I-PD controller to the conventional I-PD controller where the values of proportional gain, integral gain and derivative gain of fuzzy and conventional controllers are identical.

II. TWO-LINK ROBOT MANIPULATOR

In Fig. 1, when the effect of gravity is negligible, the Lagrange dynamics of the two-link robot manipulator is [4]

$$M(q)\ddot{q} + V(q,\dot{q}) + F(\dot{q}) + \tau_d = \tau \tag{1}$$

where $q, \dot{q}$ and $\ddot{q} \in R^2$ are joint angle, velocity and acceleration vectors, $M(q) \in R^{2x2}$ is the inertia matrix, $V(q,\dot{q}) \in R^2$ is the Coriolis/centripetal torque vector, $F(\dot{q})$ is the friction, τ_d and $\tau \in R^2$ are disturbance and input torque vectors. The term $M(q)$ and $V(q,\dot{q})$ in dynamic equations (1) are given by

$$M(q) = \begin{bmatrix} J_1 + J_2 + 2rC_2 & J_2 + rC_2 \\ J_2 + rC_2 & J_2 \end{bmatrix} \tag{2}$$

and

$$V(q,\dot{q}) = \begin{bmatrix} -rS_2(2\dot{q}_1\dot{q}_2 + \dot{q}_2^2) \\ rS_2\dot{q}_1^2 \end{bmatrix} \tag{3}$$

where $J_1 = I_1 + m_1 a_1^2 + m_2 \ell_1^2$, $J_2 = I_2 + m_2 a_2^2$, $r = m_2 \ell_1 a_2$, $C_2 = \cos q_2$, $S_2 = \sin q_2$ and $q = [q_1 \; q_2]^T$. $F(\dot{q})$ is assumed to be zero.

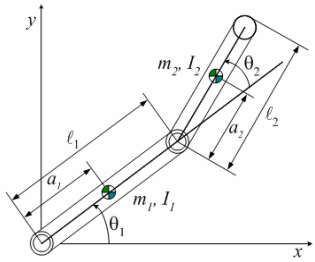

Figure 1. Structure of two-link robot manipulator (top view).

Fig. 2 shows the SCARA type robot manipulator which will be used in the experiments. The mass and the length of robot arms are m_1 = 4.37 kg, m_2 = 1.24 kg, $\ell_1 = \ell_2 = 200$ mm,

$a_1 = 63$ mm and $a_2 = 80$ mm. Maximum torque of the 1st and the 2nd joint are 70 Nm and 15 Nm when the maximum torque commands are produced at ±8 V by 2 channels 24 bits D/A PC interface card. Optical encoders of the 1st joint and the 2nd joint are 614,400 and 507,904 pulse/rev.

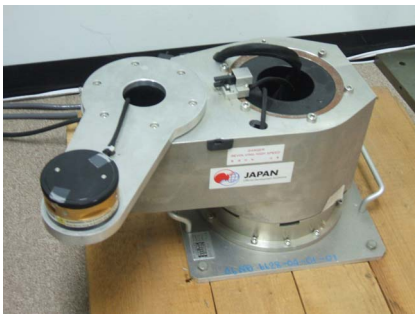

Figure 2. SCARA type robot manipulator.

III. FUZZY I-PD CONTROL SYSTEM

The conventional I-PD controller and fuzzy I-PD control system structure which composes of a Mamdani fuzzy I controller and a Mamdani fuzzy PD controller, will be describe in this section.

A. Conventional I-PD Control System Structure

The conventional I-PD control system which consists of a plant, an integral controller and a PD feedback controller, is shown in Fig. 3. Here, K_i is the integral gain of the integral controller, and K_p and K_d are the proportional gain and derivative gain of the PD controller respectively.

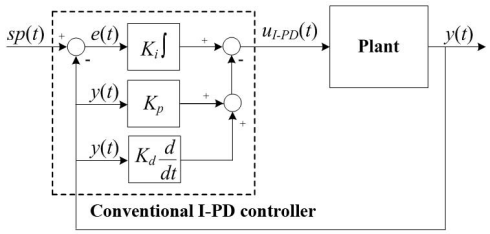

Figure 3. Conventional I-PD control system structure.

The control signal of the conventional I-PD controller of the control system shown in Fig. 3 can be expressed as

$$u_{I-PD}(t) = K_i \int_0^t e(t)dt - K_p y(t) - K_d \frac{dy(t)}{dt} \tag{4}$$

where $e(t)$ is the error signal and $y(t)$ is the output signal of the control system. After rearranging (4), it can be rewritten as

$$u_{I-PD}(t) = u_I(t) - u_{PD}(t) \tag{5}$$

where

$$u_I(t) = K_i \int_0^t e(t)dt \tag{6}$$

and

$$u_{PD}(t) = K_p y(t) + K_d \frac{dy(t)}{dt}. \tag{7}$$

The control signal of the system $u_{I\text{-}PD}(t)$ in (5) can be transformed into discrete time as

$$u_{I-PD}(nT) = u_I(nT) - u_{PD}(nT) \tag{8}$$

where T denotes the sampling time.

B. Fuzzy I-PD Control System Structure

The structure of the fuzzy I-PD control system shown in Fig. 4 consists of a process and a fuzzy I-PD controller which is the modification of the conventional I-PD controller. The control signal of the fuzzy I-PD controller $u_{I\text{-}PD}(nT)$ is the subtraction of Mamdani fuzzy I control signal and Mamdani fuzzy PD control signal.

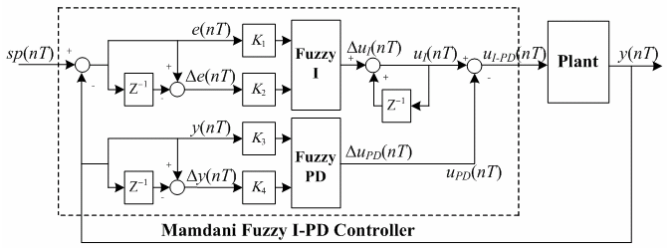

Figure 4. Fuzzy I-PD control system structure.

The output of Mamdani fuzzy I controller $u_I(nT)$ can be computed from (6) by approximating the integral term with the trapezoidal summation. Therefore

$$u_I(nT) = K_1 e(nT) - K_2 \Delta e(nT) + u_I(nT - T) \tag{9}$$

where the error $e(nT) = sp(nT) - y(nT)$, the change of error $\Delta e(nT) = e(nT) - e(nT\text{-}T)$, $K_1 = K_i T$ and $K_2 = K_i T/2$. When the term $K_1 e(nT) - K_2 \Delta e(nT)$ is replaced by $\Delta u_I(nT)$, the new output of Mamdani fuzzy I controller can be obtained as

$$u_I(nT) = \Delta u_I(nT) + u_I(nT - T) \tag{10}$$

where $\Delta u_I(nT)$ is the output change of fuzzy I controller whose inputs are $K_1 e(nT)$ and $K_2 \Delta e(nT)$.

In the same manner, the output of Mamdani fuzzy PD controller $u_{PD}(nT)$ can be directly computed from (7) by approximating the derivative term with two-point difference form. Then

$$u_{PD}(nT) = K_3 y(nT) + K_4 \Delta y(nT) \tag{11}$$

can be obtained, where $y(nT)$ is the output, $\Delta y(nT)$ is the change of output, $K_3 = K_p$ and $K_4 = K_d/T$. Define $\Delta u_{PD}(nT)$ to be $K_3 y(nT) + K_4 \Delta y(nT)$, the new output of Mamdani fuzzy PD controller becomes

$$u_{PD}(nT) = \Delta u_{PD}(nT). \tag{12}$$

IV. FUZZY I-PD CONTROLLER DESIGN

In this section, the Mamdani fuzzy I controller and the Mamdani fuzzy PD controller design will be described. The fuzzification, fuzzy rules and defuzzification are needed for designing the fuzzy controllers.

A. Fuzzification

In fuzzification, $K_1e(nT)$ and $K_2\Delta e(nT)$ are the Mamdani fuzzy I controller inputs and $K_3y(nT)$ and $K_4\Delta y(nT)$ are the Mamdani fuzzy PD controller inputs. Input scaling uses two input membership functions (n : negative and p : positive). Since the fuzzy I and fuzzy PD controllers have similar structure, the membership functions of all inputs are similarly selected with the adjustable constant L as shown in Fig. 5.

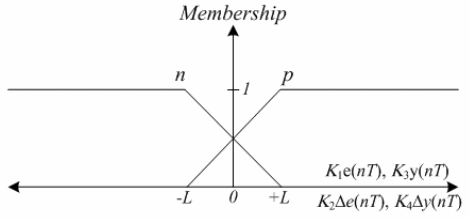

Figure 5. Input membership functions.

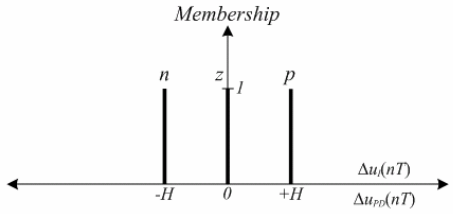

Figure 6. Output membership functions.

B. Fuzzy Rules

The output membership functions for Δu_I and Δu_{PD} are shown in Fig. 6. Three output membership functions are used (n : negative, z : zero and p : positive), where H is the adjustable constant. Based on the input membership functions in fuzzification stage and these output membership functions, the fuzzy control rules for the Mamdani fuzzy I controller are

R^1: IF $K_1e(nT)$ is n & $K_2\Delta e(nT)$ is n THEN $\Delta u_I(nT)$ is n
R^2: IF $K_1e(nT)$ is n & $K_2\Delta e(nT)$ is p THEN $\Delta u_I(nT)$ is z
R^3: IF $K_1e(nT)$ is p & $K_2\Delta e(nT)$ is n THEN $\Delta u_I(nT)$ is z
R^4: IF $K_1e(nT)$ is p & $K_2\Delta e(nT)$ is p THEN $\Delta u_I(nT)$ is p.

Similar rules are also applied for assigning the Mamadani fuzzy PD controller. Hence,

R^1: IF $K_3y(nT)$ is n & $K_4\Delta y(nT)$ is n THEN $\Delta u_{PD}(nT)$ is n
R^2: IF $K_3y(nT)$ is n & $K_4\Delta y(nT)$ is p THEN $\Delta u_{PD}(nT)$ is z
R^3: IF $K_3y(nT)$ is p & $K_4\Delta y(nT)$ is n THEN $\Delta u_{PD}(nT)$ is z
R^4: IF $K_3y(nT)$ is p & $K_4\Delta y(nT)$ is p THEN $\Delta u_{PD}(nT)$ is p.

C. Defuzzification

The centroid defuzzifier is used to calculate the output change $\Delta u_I(nT)$ of the Mamdani fuzzy I controller and $\Delta u_{PD}(nT)$ of the Mamdani fuzzy PD controller. The defuzzification results are respectively obtained from

$$\Delta u_I(nT) = \frac{\sum_{r=1}^{4} \mu_{I_r} \Delta u_{I_r}}{\sum_{r=1}^{4} \mu_{I_r}} \text{ and } \Delta u_{PD}(nT) = \frac{\sum_{r=1}^{4} \mu_{PD_r} \Delta u_{PD_r}}{\sum_{r=1}^{4} \mu_{PD_r}}, \qquad (13)$$

where μ_{I_r} and μ_{PD_r} are the membership values at the r^{th} rule, Δu_{I_r} and Δu_{PD_r} are the singleton outputs at the r^{th} rule.

Fig. 7 and Fig. 8 show the input spaces of Mamdani fuzzy I and Mamdani fuzzy PD controller that can be decomposed into 12 different input spaces (ICs). The results of $\Delta u_I(nT)$ and $\Delta u_{PD}(nT)$ are obtained by applying defuzzification algorithm (13) to each membership area. The expressions of $\Delta u_I(nT)$ and $\Delta u_{PD}(nT)$ in IC1 to IC12 are shown in Table 1.

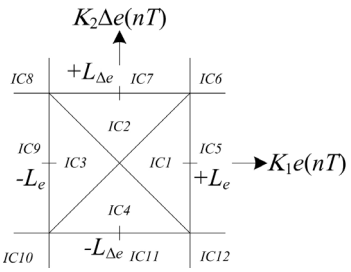

Figure 7. Input spaces of fuzzy I controller.

V. EXPERIMENTAL RESULTS

In this section, the proposed Mamdani fuzzy I-PD controller is implemented to control the two-link robot manipulator shown Fig. 2 in order to demonstrate the effectiveness of the proposed the controller. In the experiments, the sampling time T is chosen to be 0.001 second.

First, the parameters K_i = 25.0, K_p = 25.0 and K_d = 10.0 of the conventional I-PD controller are found from the CDM tuning method when the stability index $\gamma_2 = 4$ [5] and then they will be used for designing the proposed Mamdani fuzzy I-PD controller as stated in section III. Consequently, the gains for the Mamdani fuzzy I controller are K_1 = 0.025 and K_2 = 0.0125, and for the Mamdani fuzzy PD controller are K_3 = 25.0 and K_4 = 10000, respectively. The adjustable constants for 1st joint are chosen as L_e = 600, $L_{\Delta e}$ = 50000, L_y = 85000, $L_{\Delta y}$ = 85000, $H_{\Delta u_I} = 20400$ and $H_{\Delta u_{PD}} = 11400$. The adjustable constants for 2nd joint are chosen as L_e = 7500, $L_{\Delta e}$ = 500000, L_y = 850000, $L_{\Delta y}$ = 650000, $H_{\Delta u_I} = 14600$ and $H_{\Delta u_{PD}} = 12600$.

The experimental results of the Mamdani fuzzy I-PD and the conventional I-PD control systems are shown in Fig. 9 to Fig. 14. It is seen from Fig. 9 and Fig. 12 that the Mamdani fuzzy I-PD controller can control the robot manipulator rapidly follows the desired cubic polynomial trajectories [6] than the conventional I-PD controller. Both control systems can reach to the desired angular position at 90 degrees without steady-state error as shown in Fig. 10 and Fig. 13 where the smaller error of both links of the Mamdani fuzzy I-PD control system can be noticed. Furthermore, it can be seen that the magnitude of the control signals of the 1st link and the 2nd link of the fuzzy I-PD control system are smaller than the control signals of the conventional I-PD control system as shown in Fig. 11 and Fig. 14. Thus, the effectiveness of the Mamdani fuzzy I-PD controller for the two-link manipulator is confirmed by the experimental results.

VI. CONCLUSIONS

The Mamdani fuzzy I-PD controller has been proposed in this paper and has been implemented to control the angular position of the two-link robot manipulator. The proposed Mamdani fuzzy I-PD controller can control the robot manipulator to rapidly follow the desired trajectories without steady-state error. In conclusion, the proposed controller has the efficiency to handle the robot manipulator.

***Abstract*- The tower building categories used in the energy breakdown are HVAC, lighting, computers and diverse equipment. The HVAC system has the greatest energy saving potential as it is the major energy consumer. It consumes approximately 64 percent of the total building energy. Good HVAC control in buildings helps reduce energy use and maintain occupant comfort. To this end, there are many design conditions to observe HVAC systems. Such as the heat exchanger, connecting ductwork, damper, mixing air components, and PI, PID, Fuzzy, EMC, QUICK control systems. This paper critically examines indoor climate control technologies. A new modal of variable air volume diffuser can control room air velocity, mixing of supply air and room air for thermal comfort based on fuzzy logic control. Constant air supply and variable air room volume can convert maximum heat from surface 20 percent increase.**

Keywords: HVAC; PMV; Fuzzy control; Diffuser

I. INTRODUCTION

The consumption of energy by heating, ventilating, and air conditioning (HVAC) equipment in industrial and commercial buildings constitutes 50 percent of the world energy consumption [1]. It is impact on the development of new control methodologies for HVAC systems aiming at improving their energy efficiency. The design of HVAC control system capable of maintaining comfort conditions within a thermal space and reduce energy wastes regardless of the thermal loads acting upon the system[2]. Optimal control strategies for time-scheduled operation of heating, ventilating and air conditioning systems are showing the optimal mass flow rates to the zones, air and water supply temperatures[3].

A large number of thermal comfort indices have been set up for the analysis of indoor climates[4,5,6,7]. Such as the new fuzzy PMV calculation does not require an iterative solution and can be easily adjusted depending on the specific thermal sensation of users. The fuzzy PMV is as accurate as Fanger's PMV [8]. The designing duct is the fundamentals for a pressure controlled variable air volume (VAV) system. The flow to each zone is controlled at the diffuser outlet which constant pressure draft [9]. The vortex diffuser is generally assumed with high diffusion performance. The flow pattern in the vicinity of outlet region for vortex diffuser and highly turbulent [10]. This paper present a new modal of variable air volume diffuser. One of equipment design for thermal comfort room. The diffuser can mix air supply and air room subject to relation between air temperature and relative velocity for thermal comfort condition. The motor speed control by v/f drive base on fuzzy logic. The diffuser capable of maintaining comfort conditions both a thermal space and reduce main energy. The diffuser save energy by increase air room velocity before decrease temperature air supply. To decrease temperature HVAC air supply system use more power than use in control speed motor diffuser.

Nomenclature

A	=	Surface Area
EMC	=	Energy Management Control
h	=	Convection heat transfer coefficient
HVAC	=	Heating, Ventilation and Air-Conditioning
PI	=	Proportional, Integral
PID	=	Proportional, Integral and Derivative
PMV	=	Predicted Mean Vote
Q	=	Quantity
Ts	=	Surface temperature
$T\infty$	=	Ambient temperature
V	=	Air velocity
VAV	=	Variable Air Volume
ρ	=	Density

II. METHODOLOGY

A. HVAC System

HVAC system show in Fig.1. It consists of the following components: a heat exchange, a circulating air fan, the thermal space, the chiller providing chilled water to the heat exchanger, connecting ductwork, damper, and mixing air components.

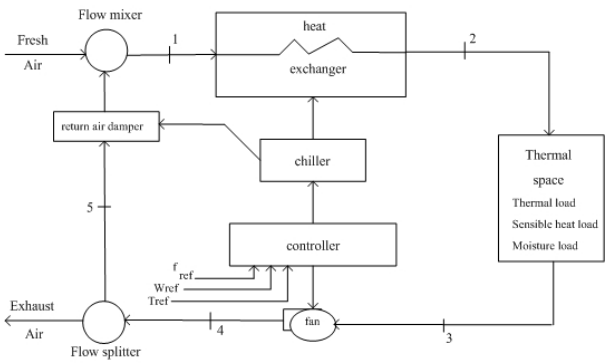

Fig. 1 HVAC system

The basic operation of the system in the cooling mode is as follows:

1. The fresh air is allowed into the system and mixed the recalculated air (number5) at the flow mixed
2. Air mixed at the flow mixer (number1) enters heat exchanger where it gets conditioned. The air entering the heat exchanger is mixed with chilled water from the chilled to get cooled.
3. The air coming out of the heat exchanger is already conditioned to enter the thermal space, and it is called supply air (number2).
4. The supply air enters the thermal space to offset the thermal loads acting upon the system.
5. The air in the thermal space is drawn through a fan (number3), this air gets recalculated and the rest is exhausted from the system.

The controller maintains the heat exchanger temperature, the space temperature the set point. The air flow is to each zone is varied by changing the out lat area of the supply air diffuser, a certain outlet area and static pressure in the branch duct well equal an air flow as shown in Fig.2

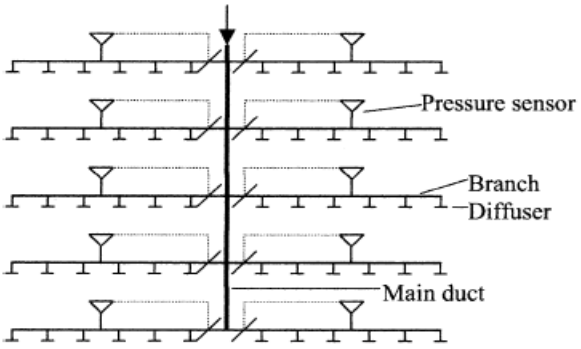

Fig.2 Supply air system with main duct, branches, dampers, pressure sensors

B. Thermal comfort fuzzy system

Fuzzy logic modeling based on the original work of Fanger is used to approximate the human's comfort/discomfort level in a given indoor climate as show in Fig.3. The most common and best understood one is Fanger's 'Predicted Mean Vote' PMV. In 1970, Fanger [4] published a general comfort equation which makes it possible, for any activity level and any clothing insulation, to calculate all combinations of the environmental variables (air temperature, air humidity, mean radiant temperature and relative air velocity) which will create optimal thermal comfort. The PMV index determines whether a given indoor climate is satisfactory or not using a seven-point thermal sensation scale. Fig. 3 summaries the overall process of using the six variables associated with thermal comfort sensation to evaluate the PMV.

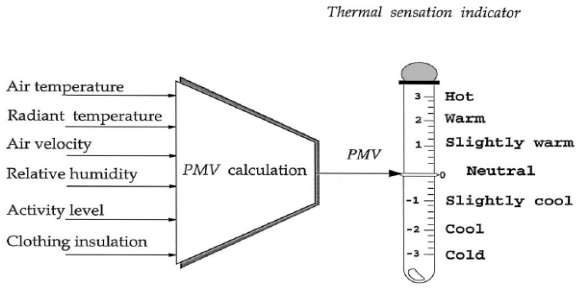

Fig.3 Fanger's PMV and thermal sensation.

On the basis of this analysis, a fuzzy PMV is designed and a general fuzzy rule base is derived to describe the state of human's thermal sensation. For any activity level and any clothing, the fuzzy rule base is able to calculate all combinations of the environmental variables which will create optimal thermal comfort as shown in Fig.4. The new designed thermal sensation index can then be easily used in feedback control.

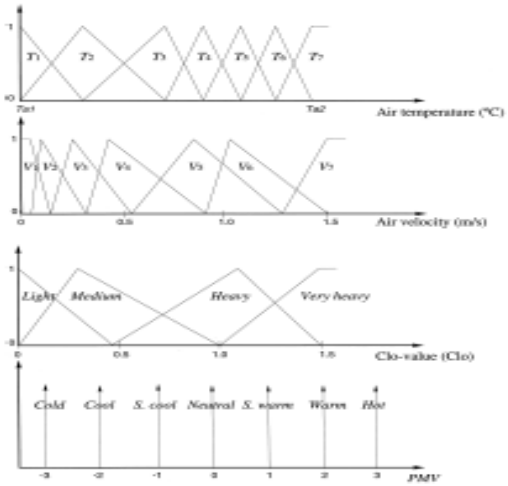

Fig.4 Fuzzy PMV membership functions.

C. Variable air volume diffuser

The variable air volume ceiling diffuser as shown in Fig. 5, has a relatively high entrainment due to the swirl of the exit air,

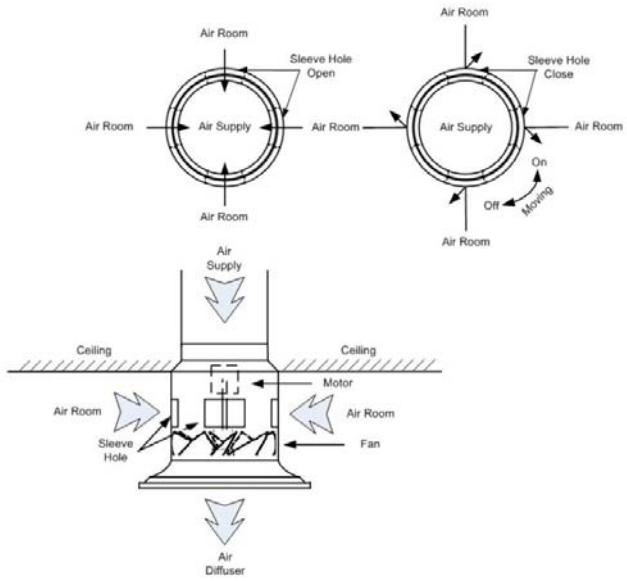

Fig 5. Variable air volume diffuser

which creates a more thorough mixing of supply air and room air than other diffusers. The control of the motor diffuser can be adjusted to the lowest level resulting in a horizontal flow for cooling applications, and to the highest level resulting in a downward flow for heating applications. So the diffuser is a variable outlet load diffuser.

Heat is converted from surface to moving fluid. The temperature gradient is dependent on the rate at which the fluid carries the heat away, a high velocity produces a large temperature gradient, and so on. Thus the temperature gradient at the surface depends on the flow field. To express the overall effect of convection, we use Newton's law of cooling.

$$q = hA\left(T_s - T_\infty\right)$$

The continuity equation below is a statement of conservation of mass. For a system of particles, mass is constant because it can be neither created nor destroyed. In other words, the mass entering the control volume equals mass stored plus mass leaving. For steady flow with no storage of mass.

$$\sum_{in} \rho AV = \sum_{out} \rho AV$$

$$\sum_{in} AV = \sum_{out} AV$$

$$Q_{AirSupply} + 4Q_{AirRoom} = Q_{AirDiffuser}$$

There are fore hole round the diffuser when sleeve move right the hole open and left the hole shut down. The hole round diffuser use for input air round the room when the system increases air quantity.

III. CONTROL SYSTEM

The control system of the variable air volume diffuser is using fuzzy PMV membership functions model The fuzzy PMV model has signal input as clothing set point, room air temperature and air flow rate to start v/f drive for variable speed motor and open or close sleeve hole. shown in Fig,6.

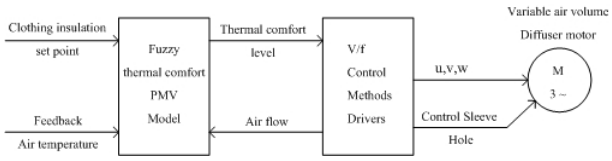

Fig.6 Diffuser motor control loop schematic

In Fig.7 as shown the testing room diagram. It has variable heat load for assume as person activity or sensible heat load.

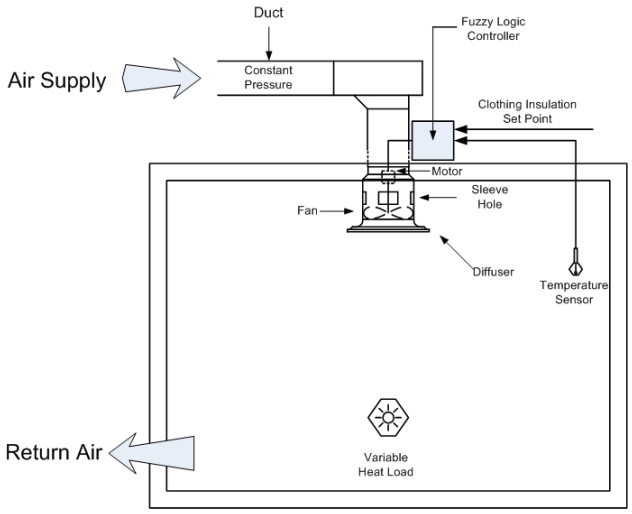

Fig.7 Schematic diagram of the testing room

IV. RESULTS AND CONCLUSION

In this paper, the new modal of variable air volume diffuser for thermal comfort based on fuzzy logic control can help the HVAC systems to maintain the main air supply system. In Fig.8-9 shown that when you have a constant air temperature supply but you want to incrust heat load in the area you can incrust room air velocity. Table 1. shows the testing room thermal comfort result data. The temperature from 22-26°C, load level from 50-70 kcal/m^2hr compare with PMV data.

Load level = 50 kcal/ m^2hr
At 22°C air temperature supply, velocity 0.1m/s
Calculated PMV = -0.33 the thermal sensation is neutral.
At 24°C air temperature supply, velocity 0.2m/s
Calculated PMV = 0.2 the thermal sensation is neutral.
At 26°C air temperature supply, velocity 0.15m/s
Calculated PMV = 0.75 the thermal sensation is slightly warm.

Load level = 60 kcal/ m^2hr
At 22°C air temperature supply, velocity 0.15m/s
Calculated PMV = 0.1 the thermal sensation is neutral.
At 24°C air temperature supply, velocity 1 m/s
Calculated PMV= 0.54 the thermal sensation is slightly warm.
At 26°C air temperature supply, velocity 1.5m/s
Calculated PMV = 0.98 the thermal sensation is warm.

Load level = 70 kcal/ m^2hr
At 22°C air temperature supply, velocity 0.5m/s
Calculated PMV = 0.39 the thermal sensation is neutral.
At 24°C air temperature supply, velocity 1.5 m/s
Calculated PMV= 0.76 the thermal sensation is warm.
At 26°C air temperature supply, velocity 1.5m/s
Calculated PMV = 1.13 the thermal sensation is warm.

Abstract – **In a direct inverse control scheme, a neural network must learn an inverse system of an objective unknown or uncertain plant. The control scheme described here does not require information about the Jacobian of the plant, because the simultaneous pertrubation–stochastic approximation (SPSA) method estimates the gradient using only values of the error defined by the output of the plant and its desired output. This paper aims to assess the potential of the learning rules using the SPSA method for a neuro-controller (NC) of a flexible arm system. The performance of the proposed NC can be improved in terms of preventing weights from shifting, fast convergence to constant values, and suppressing vibration in the flexible arm. Lastly, the proposed control method is compared with the Smith predictor method.**

Keywords – **Stochastic Approximation, Simultaneous Perturbation, Neuro-Controller, Flexible Arm, Learning Rule, Smith Predictor.**

I. Introduction

Over the past several years, neural networks (NNs) have been increasingly applied to the identification and control of nonlinear systems. Since the NNs usually involve a large number of unknown parameters, it is extremely computation-intensive to evaluate the gradient by varying the parameter at a time, as required in conventional finite difference (FD) approximation method[1],[2]. The simultaneous perturbation (SP) approximation method makes use of a very efficient technique based on simultaneous (random) perturbations in all the parameters and requires only two evaluations of the gradient.

However, if we introduce simultaneous perturbation–stochastic approximation (SPSA) learning rules, there is no need to know the sensitivity function of the unknown or uncertain plant. Even if only using the values of an error function, the learning rules can estimate a gradient of the error function with respect to adjustable parameters[3],[4]. Because of this advantage, this paper proposes a NC which uses the SPSA learning rule for a flexible arm system[5]. The NC learns an inverse system of an objective plant and controls the plant at the same time (see Fig.1).

The NN is then trained by the SPSA learning rule in the closed-loop to provide improved training performance over other standard methods, such as the back-propagation (BP) algorithm. Another major motivation for using SPSA instead of the popular BP algorithm is its excellent convergence property[6]. This paper introduces the SPSA method for stochastic optimization of multivariate systems[7], Next, the SPSA method is compared with other methods for reducing the vibration such as the Smith predictor methods, which are known as common and effective dead-time compensators. It guarantees superior control performance for a system with large time delay if an accurate model of the system is available in advance. Many Smith predictors modified with different structures have been proposed. For comparison with our procedure, the Smith predictor presented by Liang[8] is used, because it gives similar performance for suppressing the vibration to the SPSA method.

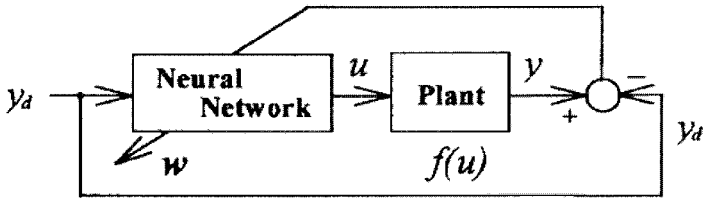

Fig. 1. NC by inverse control scheme: learning rule by SP

II. Stochastic Approximation–Simultaneous Perturbation

One optimization method which has attracted considerable international attention is the simultaneous perturbation–stochastic approximation (SPSA) method. SPSA is especially efficient in high-dimensional problems in terms of providing a good solution for a relatively small number of measurements of the objective function. The essential feature of SPSA, which provides its power and relative ease of use in difficult multivariate optimization problems, is the underlaying gradient approximation which requires only two objective function measurements per iteration regardless of the dimension of the optimization problem. The goal is to minimize a loss function $L(\theta)$, where this is a scalar-valued performance measure and θ is a continuous-valued p-dimensional vector of parameters to be adjusted. The SPSA algorithm works by iterating from an initial guess of the optimal θ, where the iteration process depends on the above-mentioned highly efficient SP approximation to the gradient $g(\theta) = \partial L/\partial\theta$. The optimization problem can be translated into finding the mini-

mum θ^* such that the gradient $g(\theta) = 0$. The general form of SA recursive procedure is given as

$$\hat{\theta}_{k+1} = \hat{\theta}_k - a_k \hat{g}_k(\hat{\theta}_k) \tag{1}$$

where the gain a_k is a positive constant, and $\hat{g}_k(\hat{\theta}_k)$ is the estimate of the gradient $\partial L/\partial\theta = 0$ at the k th iteratition, based on the measurements of the loss function. Under appropriate conditions, the iteration in Eq.(1) converges to θ^* in some stochastic sense[7].

Simultaneous Perturbation (SP): All the elements of $\hat{\theta}_k$ are randomly perturbed together to obtain two measurements of y, but each component of $\hat{g}_k(\hat{\theta}_k)$ is formed from a ratio involving the individual components in the perturbation vector and the difference in the two corresponding measurements. For the two-sided SP, we have

$$\hat{g}_{ki}(\hat{\theta}_k) = \frac{y(\hat{\theta}_k + c_k\Delta_k) - y(\hat{\theta}_k - c_k\Delta_k)}{2c_k\Delta_{ki}} \tag{2}$$

where c_k is a positive scalar and Δ_k is user generated zero-mean random vector satisfying certain regularity conditions, whose i th component is $\Delta_k = [\Delta_{k1}, \Delta_{k2}, \cdots, \Delta_{kp}]^T$ with symmetrically Bernoulli distribuited random variables.

III. Neuro-Conrtoller Via Simultaneous Perturbation

First of all, we define the following perturbation vector c_t which gives small disturbances to all weights:

$$c_t = \left[c_t^1, ..., c_t^n \right]^T \tag{3}$$

where t denotes the number of iterations for updating weights and n denotes the number of weights.

Learning Rule 1: First, we estimate $\partial J/\partial w$. Then, we define the component of the modifying vector of the weight Δw_t as

$$\Delta w_t^i = \frac{J(u(w_t + c_t)) - J(u(w_t))}{c_t^i} \tag{4}$$

Weights of the network are updated in the following manner:

$$w_{t+1} = w_t - \alpha \Delta w_t \tag{5}$$

where α is a positive learning coefficient.

Learning Rule 2: Next, we estimate the first differential coefficient of the unknown plant with respect to the weights of the NN. Then, we define the compobent of the modifying vector of the weight as

$$\Delta w_t^i = e_t \frac{J(u(w_t + c_t)) - J(u(w_t))}{c_t^i} \tag{6}$$

Since the control error e_t can be easily measured, $\partial f/\partial w$ also can be estimated.

IV. Application to Flexible Arm System

In an usual control scheme, we must have an exact model of an objective plant, since controllers are basically designed based on the identified model. We first define the deflection as follows:

$$\mu(x,t) = \sum_{i=1}^{\infty} \phi_i(x) q_i(t) \simeq \sum_{i=1}^{N} \phi_i(x) q_i(t) \tag{7}$$

where ϕ_i is the ith modal function which satisfies boudary conditions described below, and N is the number of vibration modes to be considered in the control, which will be set at 6 in the simulation. The actuator torque $u(t)$ as an input in tuning the arm. In order to derive the state equation from the above equations, we first must determine ϕ_i from the boudary conditions.

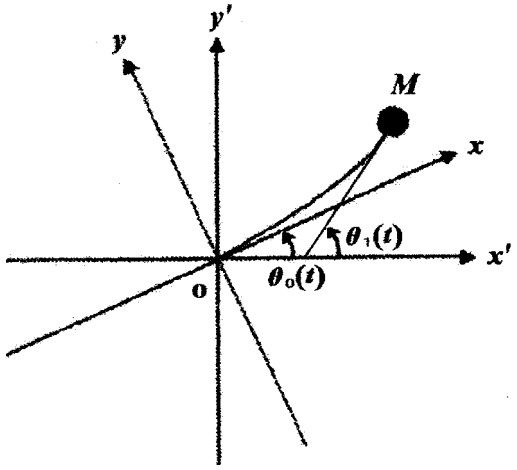

Fig. 2. One-link flexible arm

As well known, the arm is governed by the Euler-Bernoulli equation:

$$EI\frac{\partial^4 \mu(x,t)}{\partial x^4} = -\rho A_b \frac{\partial^2 \mu(x,t)}{\partial t^2} \tag{8}$$

where E is Youg's modulus, I the moment, ρ the density, and A_b the cross section area of the arm. The boundary conditions of Eq.(8) are given by

1) $\mu(0,t) = 0$
2) $\frac{d\mu(0,t)}{dx} = 0$
3) $\frac{d^2\mu(L,t)}{dx^2} = 0$
4) $EI\frac{d^3\mu(L,t)}{dx^3} = -M\frac{d^2\mu(L,t)}{dt^2}$

When taking account into a weight with mass M as shown in Fig. 2. From a certain initial state, we would like to reduce bending at the tip of the flexible arm. For this purpose, we first need a training set for pre-training of the NN. After that, the NN is utilized as a controller of the plant. We next add perturbations at all weights simultaneously. Then, we have a value of the error. By using Eq.(5), we can update all the weights in NC, and repeat this procedure.

Further, six states to control the plant is selected as follows:

$$\bar{x} = \left[\theta_0, \dot{\theta}_0, x_1, \dot{x}_1, \theta_1, \dot{\theta}_1 \right] \tag{9}$$

where θ_0 and $\dot{\theta}_0$ are the angle and angular velocity at the origin, respectively, θ_1 and $\dot{\theta}_1$ are those at the tip, respectively, and x_1 and $\dot{x}_1$ are the x-position and its velocity at the tip, respectively. As seen in Fig. 3, these six states are measurable and neccesary to produce proper command inputs for the NN.

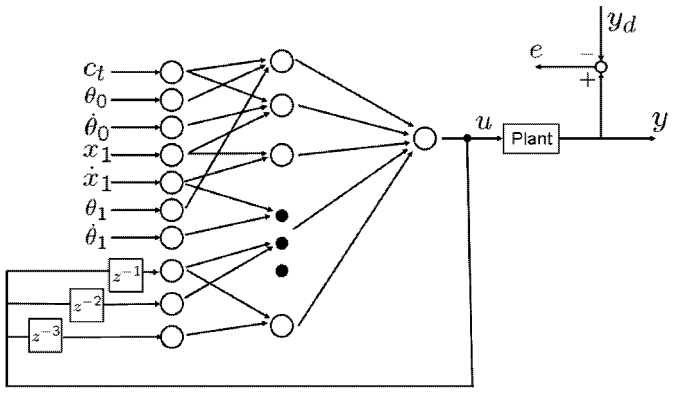

Fig. 3. NC using leaning rules via SPSA

V. Simulation Results

The weights and thresholds of the NNs are randomly initialized $[-1, +1]$. The perturbations used in these simulations are randomly generated in the interval $[-0.01, +0.01]$. The learning coefficient α and the perturbation c are both 0.0002. In this simulation, inputs and outputs of the plant are connected to the time-delay feedforward NN.

If using the learning rule 1 and modifying the weights of every sets of the desired position, we can define the following total error function at the tip position as Eq.(10), and can use the learning rule 1 of Eq.(4) directly:

$$J = \sum_{t=1}^{N_L} (x_{1t} - x_{1dt})^2 + (y_{1t} - y_{1dt})^2 \qquad (10)$$

where (x_1, y_1) and (x_{1dt}, y_{1dt}) denote the measured position and the corresponding desired position at the tip, respectively, and N_L is the total number of learning. That is, the error function is a sum of the squared errors of the desired positions. First, we can measure a series of outputs of the plant for one cycle. We obtain a value of the total error function as a sum of the squared errors at each sampling time. Next, we add the perturbation vector to the weight vector of the NN. Then, the same procedure is repeated. As a result, is obtained a value of the total error function under the perturbation. If using learning rule 2 of Eq.(6), we do not use the total error function like Eq.(10). We have to calculate the follwing modifying quantities of the weights for every sampling time:

$$\Delta w_t^i = (x_{1t} - x_{1dt})\frac{\hat{x}_{1t} - x_{1t}}{c_t^i} + (y_{1t} - y_{1dt})\frac{\hat{y}_{1t} - y_{1t}}{c_t^i} \qquad (11)$$

where ($\hat{x}_1$, $\hat{y}_1$) denotes the position at the tip when adding the perturbation vector to the weights. Once a desired position are applied to the NN, we can measure a position of the arm and calculate the errors (x_{1t} - x_{1dt}) and (y_{1t} - y_{1dt}). In this simulation, we update every sampling time.

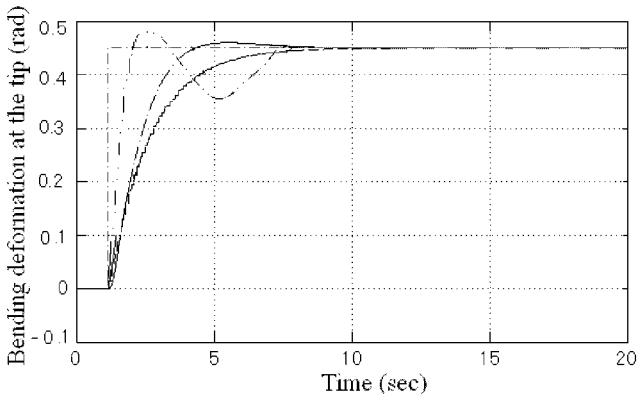

Fig. 4. Bending deformations at tip by SPSA method

Fig. 4 shows typical responses of the system at the tip position to a step-command (dashed-dotted). The dashed-two dotted line shows that using only 100 iterations the response is very poor. Using 25,000 iterations, we found from the dashed-dotted line that the tip moves to the commanded position, and the arm is positioned effectively in about 1.5(sec) from the start. This response is very close to critical damping and there is a very little overshoot. It is possible to increase the rise time at the expense of overshoot by increasing the feedback gains. Using 50,000 iterations, we found from the solid line that the tip position are a little over-damped. The arm is then effectively positioned in about 2.7(sec).

VI. Comparison between SPSA and Smith predictor methods

For comparison of the SPSA with the Smith predictor method, the next simulation is carried out in ordet to reduce the vibration and improve the performance of the system. The Smith predictor method is probabily the most famous method for the control of systems with time delays[8],[9]. Consider a typical feedback control system with time delay θ.

$$\frac{y(s)}{y_d(s)} = \frac{C(s)P_0(s)e^{-\theta s}}{1 + C(s)P_0(s)e^{-\theta s}} \qquad (12)$$

where the system to be controlled is given by $P(s) = P_0(s)e^{-\theta s}$, and the output y is the velocty at the tip and y_d the correponding reference input, which is set at 0. $\hat{P}_0(s)$ and $\hat{P}(s)$ are nominal models of $P_0(s)$ and $P(s)$, respectively. The nominal models can be approximately derived by Eq.(8). Here, only the boundary condition is slightly changed such as

4') $EI\frac{d^3\mu(L,t)}{dx^3} = u(t) = -k_L\frac{d\mu(L,t)}{dt}$

where k_L is a control gain. The boundary controller $C(s)$ combined with $\hat{P}_0(s)$ - $\hat{P}(s)$ is called the Smith predictor, where $\hat{P}_0(s)$ and $\hat{P}(s)$ are nominal models. If assuming the perfect model matching $\hat{P}(s) = P(s)$, we can obtain the

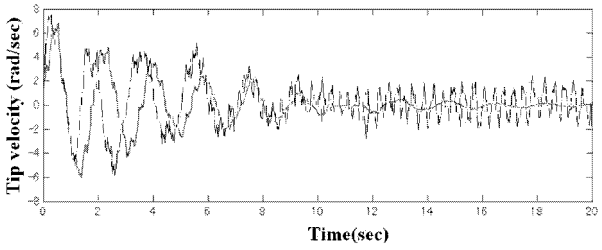

Fig. 5. Tip velocities by SPSA method used 100,000 and 50,000 iterations

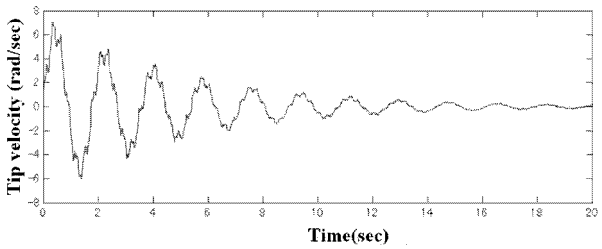

Fig. 6. Tip velocity by Smith predictor method

closed-loop transfer function

$$\frac{y(s)}{y_d(s)} = \frac{C(s)P(s)}{1 + C(s)P_0(s)} \tag{13}$$

Now, it is clear what the underlying idea of the Smith predictor is. In order to attenuate the magnitude of vibration further, we consider to apply the Smith predictor presented by Liang[8]. This version has the best performance among several Smith predictor methods. Therefore, the comparison with SPSA method can give us a better idea about the performance of our method.

The SPSA method is also applied under almost the same conditions as in the previous simulation. The tip velocities of the arm, which is controlled by the SPSA and Smith predictor methods, are shown in Fig. 5 and Fig. 6, respectively. Especially, Fig. 5 includes the two cases of 100,000 (solid) and 50,000 iterations (dashed-dotted) iterations. The latter case cannot suppress vibration even as time goes. However, we can observe that the Smith predictor method and the SPSA mathod with 100,000 iterations gives almost the same response as the Smith method. Therefore, both the methods are very effective in order to attenuate the magnitude of vibration. Generally speaking, the Smith predictor method is easier to be implemented than the SPSA method. However, the SPSA method does not need much infromation on exact model, i.e., the values of physical variables and modal functions.

VII. Conclusions

In this proposal, a direct NC using the SPSA learning rule for an unknown or uncertain plant was introduced and applied to the control of a flexible arm system. The SPSA approach is a very powerful technique which allows an approximation of the gradient and/or the Hessian of a noisy performance criterion, which is computed by effecting simultaneous random perturbations in all the parameters. In the simulation, the deflection was reduced and almost null. In comparison of the performances between iteration numbers of the NN, it was shown that a larger number of iterations reduces the vibration more quickly.

Next, the comparison between the SPSA and Smith predictor methods was shown. The Smith predictor method required less time for suppressing the vibration in the flexible arm than the SPSA method. In the simulation, the magnitudes of both velocity and displacement were very small. The SPSA used 100,000 iterations for obtaining the same suppression as the Smith predictor method. Therefore, the comparison between both methods showed that, while the SPSA method is able to reduce the vibration in this kind of system very well, the Smith predictor method is more effective because the convergence is faster. Nevertheless, the SPSA method is also useful in this kind of unknown or uncertain system.

Although the rigorous proof of the stability of this control scheme is left as a future work, the performance of the SPSA method has been satisfactory in terms of simulations.

***Abstract*-This paper presents an intelligent method for designing proportional-integral-derivative (PID) controllers using the genetic algorithm (GA), one of the most efficient AI search techniques. The goal is considered heuristic approach and more flexible design method. With its robustness and effectiveness, GA can well perform finding optimum parameters of a PID controller in order to minimize some particular objectives. To evaluate its performance, the proposed method is applied to several benchmark systems for PID control presented by Åström, et al. [1]. Based on the result obtained from a series of simulations, the proposed GA-based PID design method is found to yield satisfactory performance for various designing PID controllers.**

I. INTRODUCTION

The proportional-integral-derivative (PID) control schemes in industrial applications were first introduced in 1939 [2]. Due to ease of use and simple realization, PID controllers have been widely used in most of process control systems over decades. To obtain appropriate controller's parameters, one can proceed with available analytical design methods or tuning rules. Mostly the analytical design methods assume known plant models [3],[4],[5], while the tuning rules assume known process responses [6],[7], and known plant models [8]. Every analytical design method and every tuning rule, however, have some particular conditions concerning to the plant models, such as dead time or transport lag, fast and slow poles, real and complex conjugated zeros and poles, as well as unstable poles, and to the process responses, such as oscillation and shapes. These conditions make the design methods and tuning rules non-general. In 2000, Åström, et al. [1] proposed a collection of systems which are suitable for testing PID controllers. These collected systems are considered benchmark problems for evaluating post-proposed PID controller design method.

Over two decades, artificial intelligent (AI) techniques have been employed for the controller design in industrial control applications, for example: designing of an adaptive PID controller by genetic algorithm (GA) [9], self-tuning PID controller by GA [10], and finite-precision PID controller by GA [11]. GA is efficient to find the global minimum of the search space. In this paper, GA is briefly reviewed and then applied to design PID controllers for benchmark systems proposed by Åström, et al. [1]. This paper consists of five sections. The problem formulation of PID design is described in Section 2. Section 3 gives GA algorithm in brief. The GA-based design of the PID controllers is illustrated in Section 4, while Section 5 provides the conclusions.

II. PROBLEM FORMULATION

In conventional control loop represented by the block diagram in Figure 1, the PID controller receives the error signal, $E(s)$, and generates the control signal, $U(s)$, to regulate the output response, $C(s)$, referred to the input, $R(s)$, where $D(s)$ is disturbance signal, $G_p(s)$ and $G_c(s)$ are the plant and the controller transfer functions, respectively.

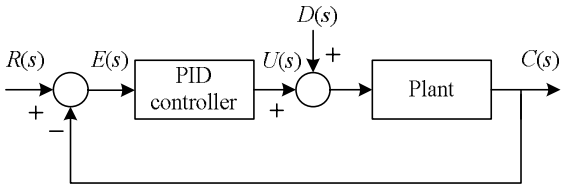

Figure 1. Conventional control loop.

The transfer function of the PID controller is stated in (1), where K_p is proportional gain, K_i is integral gain, and K_d is derivative gain. So, the design problem is simplified to determine the parameters K_p, K_i, and K_d. The closed loop transfer function with PID controller is given in (2).

$$G_c(s) = K_p + \frac{K_i}{s} + K_d s \tag{1}$$

$$\frac{C(s)}{R(s)} = \frac{\left(K_p + \frac{K_i}{s} + K_d s\right) G_p(s)}{1 + \left(K_p + \frac{K_i}{s} + K_d s\right) G_p(s)} \tag{2}$$

$$J = \sum_{t=0}^{T} \left| r(t) - c(t) \right| \tag{3}$$

The use of AI search techniques to design the PID controller can be represented by the block diagram in Figure 2. The cost function, J, sum absolute error (SAE) between $R(s)$ and $C(s)$ as stated in (3), is fed back to the AI tuning block. J is minimized to find the optimum PID controller's parameters that give a satisfactory response. To minimize J, GA method is applied and explained in the next section.

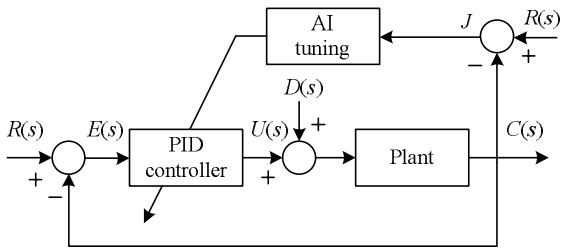

Figure 2. AI-based PID controller design.

III. GENETIC ALGORITHM (GA)

Genetic algorithm (GA) is briefly reviewed in this section. GA is a searching method based on two natural processes, i.e. selection and genetic operation. The search process of GA is similar to the nature evolution of biological creatures in which successive generations of organisms are given birth and raised until they themselves are able to breed. In general, the basic goal of GA is to optimize functions, i.e. fitness and objective functions. GA-based approach differs from other conventional optimization techniques in several ways [12],[13]. Firstly GA works with a coding of the parameter set rather than the parameters themselves. Secondly GA searches from a population of points rather than a single point. Thirdly, GA uses the objective function information, not other auxiliary knowledge. Finally GA uses probabilistic transition rules, not deterministic rules. With these properties, GA is made robust, powerful, and problem-dependent. Algorithms of a simple GA are shown step-by-step as follows.

(1) Random initial populations or chromosomes and set them as a search space.
(2) Evaluate the fitness value of each chromosome via the objective function.
(3) Select some chromosomes giving better fitness value to be parents.
(4) Reproduce new generation (offspring) by genetic operations, i.e. crossover and mutation.
(5) Compute the fitness value of each new chromosome via the objective function.
(6) Replace old chromosomes by new ones and go back to (2).

When the termination criteria are met, GA is stopped. The optimum solution found is the best chromosome in a search space.

IV. GA-BASED DESIGN OF PID CONTROLLER

The GA-based design of the PID controllers is illustrated in this section. Referring to Figure 2, the AI tuning block can be well represented by GA. Then, the parameter tuning process is repeatedly performed in order to minimize J (SAE) stated in (3) until the termination criteria are satisfied. In this work, maximum generation (Max-Gen) of the search process is set as the termination criteria. To evaluate the performance of the proposed design method, the GA-based design of the PID controllers is applied to four benchmark systems suggested by Åström, et al. [1]. Such the systems are difficult to design their PID controllers by conventional design methods or tuning rules.

The desired specification is given in (4), where t_r is rise time, $P.O.$ is percent overshoot, t_s is settling time, E_{ss} is steady state error, $t_{r\text{-}max}$ is maximum rise time allowance, $P.O._{max}$ is maximum percent overshoot allowance, $t_{s\text{-}max}$ is maximum settling time allowance, and $E_{ss\text{-}max}$ is maximum steady state error allowance. They are set as inequality constraints of the optimization. GA is used to obtain K_p, K_i, and K_d of the PID controller. The optimization framework can be defined as (4).

$$\begin{aligned} &\textit{Minimize} && J \\ &\textit{Subject to} && t_r \le t_{r_max},\ P.O. \le P.O._{max}, \\ & && t_s \le t_{s_max},\ E_{ss} \le E_{ss_max} \end{aligned} \tag{4}$$

In GA applied in this work, Max-Gen = 500 is defined as the termination criteria. 40 chromosomes are randomized of which the intervals are heuristically assumed. The chromosomes are selected by the ranking fashion. Crossover and mutation mechanisms are activated at single point with the probability level of 0.8. Replacement could be done on only one chromosome giving better fitness value in each generation.

A. Fourth Order System

The fourth order system as shown in (5) is the first one used to perform the tests. Such the system has four poles whose spacing is determined by parameter α. In this work, α is set as 0.5. The desired specification of this system are given by t_{r_max}=1.0sec, $P.O._{max}$=10.0%, t_{s_max}=2.5sec, and E_{ss_max}=0.00. The parameter ranges to form the search space were given by K_p=K_i=K_d=[0, 10]. After the search process stopped, the PID controller's parameters are successfully obtained. From the search result, the PID controller listed in Table I yields satisfactorily response as shown in Table I. Additionally, the step responses of the fourth order system without and with PID controller are shown in Figure 3, while Figure 4 represents the convergence of J.

$$G_{p1}(s) = \frac{1}{(1+s)(1+\alpha s)(1+\alpha^2 s)(1+\alpha^3 s)} \tag{5}$$

B. Fast and Slow Modes

The system has a fast time constant at T=1sec with a moderate gain and a slow time constant at T=20sec with a large gain as shown in (6). The desired specification of this system is given by t_{r_max}=0.25sec, $P.O._{max}$=10.0%, t_{s_max}=1.5sec, and E_{ss_max}=0.00. The parameter ranges to form the search space were given by K_p=K_i=K_d=[0, 10]. After the search process stopped, the PID controller's parameters are successfully obtained as listed in Table I. The PID controller yields satisfactorily response as also shown in Table I. The step responses of this system without

and with PID controller are shown in Figure 5, and the convergence of J is represented in Figure 6.

$$G_{p2}(s) = \frac{100}{(s+10)^2}\left(\frac{1}{s+1} + \frac{0.5}{s+0.05}\right) \quad (6)$$

C. Oscillatory System

The oscillatory system is expressed in (7), where ω_0 =1 and ζ = 0.1. The desired specification of this system is given by t_{r_max}=2.5sec, $P.O._{max}$=25.0%, t_{s_max}=10.0sec, and E_{ss_max}=0.00. The parameter ranges to form the search space were given by K_p=K_i=K_d=[0, 5]. After the search process stopped, the PID controller's parameters are successfully obtained as listed in Table I. The PID controller yields satisfactorily response as also shown in Table I. The step responses of this system without and with PID controller are shown in Figure 7, and the convergence of J is represented in Figure 8.

$$G_{p3}(s) = \frac{\omega_o^2}{(s+1)(s^2 + 2\zeta\omega_o s + \omega_o^2)} \quad (7)$$

D. Unstable System

The unstable system as stated in (8) is a simple model of an inverted pendulum.The desired specification of this system is given by t_{r_max}=0.1sec, $P.O._{max}$=15.0%, t_{s_max}=0.5sec, and E_{ss_max}=0.00. The parameter ranges to form the search space were given by K_p=[400, 500] and K_i=K_d=[0, 50]. After the search process stopped, the PID controller's parameters are successfully obtained as listed in Table I. The PID controller yields satisfactorily response as also shown in Table I. The step responses of this system without and with PID controller are shown in Figure 9 and, the convergence of J is represented in Figure 10.

$$G_{p4}(s) = \frac{1}{s^2 - 1} \quad (8)$$

V. CONCLUSIONS

The intelligent method for designing PID controllers using GA is proposed in this paper. The proposed method is considered the heuristic approach. It is more flexible than the conventional design methods and tuning rules. The presented method has been evaluated via four benchmark systems. As the results, the appropriated parameters of PID controllers have been successfully obtained, and achieved high satisfactorily responses. The usefulness and flexibility of the proposed intelligent design approach have been confirmed.

***Abstract*—In this paper, we examine a design method for modified PID (Proportional-Integral-Derivative) controllers for stable or minimum-phase time-delay plants. PID controller structure is the most widely used one in industrial applications. Recently the parametrization of all stabilizing PID controller has been considered. However no method has been published to guarantee the stability of PID control system for any stable or minimum-phase time-delay plants and the admissible sets of P-parameter, I-parameter and D-parameter to guarantee the stability of PID control system are independent from each other. In this paper, we propose a design method for modified PID controllers such that the modified PID controller make the feedback control system for any stable or minimum-phase time-delay plants stable and the admissible sets of P-parameter, I-parameter and D-parameter are independent from each other.**

I. Introduction

PID (Proportional-Integral-Derivative) controller is most widely used controller structure in industrial applications [1–3]. Its structural simplicity and sufficient ability of solving many practical control problems have contributed to this wide acceptance. Several papers on tuning methods for PID parameters have been considered [4–14]. However the method in [4–14] do not guarantee the stability of closed-loop system. The reference in [15–18] propose design methods of PID controllers to guarantee the stability of closed-loop system. However, using the method in [15–18], it is difficult to tune PID parameters to meet control specifications. If admissible sets of PID parameters to guarantee the stability of closed-loop system are obtained, we can easily design stabilizing PID controllers to meet control specifications.

The problem to obtain admissible sets of PID parameters to guarantee the stability of closed-loop system is known as a parametrization problem [3], [19], [20]. If there exists a stabilizing PID controller, the parametrization of all stabilizing PID controller is considered in [3], [19], [20]. However the method in [3], [19], [20] remains a difficulty. The admissible sets of P-parameter, I-parameter and D-parameter in [3], [19], [20] are related each other. That is, if P-parameter is changed, then the admissible sets of I-parameter and D-parameter change. From practical point of view, it is desirable that the admissible sets of P-parameter, I-parameter and D-parameter are independent from each other. Yamada and Moki initially tackle this problem and propose a design method for modified PI controllers for any minimum-phase systems such that the admissible sets of P-parameter and I-parameter are independent from each other [21]. Yamada expand the result in [21] and propose a design method for modified PID controllers for minimum-phase plant such that the admissible sets of P-parameter, I-parameter and D-parameter are independent from each other [22]. For stable plants, a design method for modified PID controllers have been considered in [23]. However, no paper gives a design method for modified PID controllers for any stable or minimum-phase time-delay plants such that the stability of control system is guaranteed and the admissible sets of P-parameter, I-parameter, D-parameter, which guarantee the stability of PID control system are independent from each other.

In this paper, we expand the result in [21–23] and propose a design method for modified PID controllers such that modified PID controller makes the closed-loop system stable for any stable or minimum-phase time-delay plants and the admissible sets of P-parameter, I-parameter and D-parameter to guarantee the stability of closed-loop system are independent from each other.

II. Problem formulation

Consider the closed-loop system in Fig. 1. Here, $G(s)e^{-sT}$

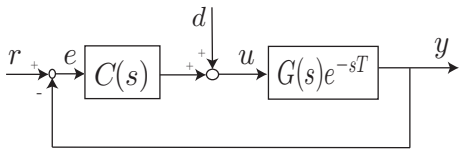

Figure 1. Feedback control system

is the single-input/single-output time-delay plant, $G(s) \in R$ is assumed to be strictly proper and to have no zero on the origin, $T > 0$ is time-delay, $C(s)$ is the controller, $r \in R$ is the reference input, $u \in R$ is the control input, $y \in R$ is the output, $d \in R$ is disturbance and $e \in R$ is the error.

When the controller $C(s)$ has the form written by

$$C(s) = a_P + \frac{a_I}{s} + a_D s, \tag{1}$$

then the controller $C(s)$ is called the PID controller [1], [3], [19], [20], where $a_P \in R$ is the P-parameter, $a_I \in R$ is the I-parameter and $a_D \in R$ is the D-parameter. a_P, a_I and a_D are

settled so that the closed-loop system in Fig. 1 has desirable control characteristics such as steady state characteristic and transient characteristic. For easy explanation, we call $C(s)$ in (1) the conventional PID controller. The transfer function from r to y in Fig. 1 is written by

$$y = \frac{G(s)\left(a_P + \frac{a_I}{s} + a_D s\right)e^{-sT}}{1 + G(s)\left(a_P + \frac{a_I}{s} + a_D s\right)e^{-sT}} r. \tag{2}$$

It is obvious that when a_P, a_I and a_D are settled at random, the stability of the closed-loop system in Fig. 1 does not guaranteed. Using the result in [3], [19], [20], if a stabilizing PID controller $C(s)$ in (1) for $G(s)$ exists, we can design PID controller $C(s)$ in (1) to stabilize the closed-loop system in Fig. 1. That is, the admissible sets of a_P, a_I and a_D to stabilize the closed-loop system in Fig. 1 are obtained in [3], [19], [20]. According to [3], [19], [20], the admissible sets of a_P, a_I and a_D are related each other. That is, if a_P is changed, then the admissible sets of a_I and a_D change. From practical point of view, it is desirable that the admissible sets of a_P, a_I and a_D are independent from each other. Further, generally, the transfer function in (2) has an infinite number of poles. It is difficult to give desirable control characteristics such as input output characteristics and disturbance attenuation characteristics.

The purpose of this paper is to propose a design method for modified PID controllers $C(s)$ in Fig. 1, which have following characteristics.

1) The stability of the closed-loop system in Fig. 1 is guaranteed.
2) The transfer functions from r to y and that from d to y in Fig. 1 have a finite number of poles.
3) The admissible sets of P-parameter a_P, I-parameter a_I and D-parameter a_D to guarantee the stability of closed-loop system in Fig. 1 are independent from each other.
4) The role of P-parameter a_P, I-parameter a_I and D-parameter a_D in the modified PID controller are equivalent to that of the conventional PID controller in (1).

III. The basic idea

In this section, we describe a basic idea to design for modified PID controllers $C(s)$ that have characteristic described in Section II .

In order to design modified PID controllers $C(s)$ that can be applied to any stable or minimum-phase time-delay plants and to make the transfer function from r to y and that from d to y have a finite number of poles, we adopt the parametrization of all stabilizing modified Smith predictors for any stable or minimum-phase time-delay plant in [24]. Using the result in [24], the basic idea to design for modified PID controllers $C(s)$ that have characteristics descibed in Section II . is summarized as follows.

1) When $G(s)$ is stable
According to [24], the parametrization of all stabilizing modified Smith predictor for stable time-delay plants is written by

$$C(s) = \frac{Q(s)}{1 - Q(s)G(s)e^{-sT}}, \tag{3}$$

where $Q(s) \in RH_\infty$ is any function. Using the controller in (3), the transfer function from r to y and that from d to y in Fig. 1 are written by

$$y = Q(s)G(s)e^{-sT}r \tag{4}$$

and

$$y = (1 - Q(s)G(s)e^{-sT})G(s)e^{-sT}d, \tag{5}$$

respectively. From the assumption that $Q(s) \in RH_\infty$, the transfer function in (4) and (5) have a finite number of poles. In addition, it is obvious that the stability of the closed-loop system in Fig. 1 is guaranteed. In order to design the modified PID controllers that have characteristics described in Section II ., the free parameter $Q(s)$ in (3) is settled so that $C(s)$ in (3) has the same characteristics to conventional PID controller $C(s)$ in (1). Therefore, next, we describe the role of conventional PID controller $C(s)$ in (1) in order to clarify the condition that the modified PID controller $C(s)$ must be satisfied. From (1), using $C(s)$, the P-parameter a_P, the I-parameter a_I and the D-parameter a_D are decided by

$$a_P = \lim_{s\to\infty}\left\{-s^2\frac{d}{ds}\left(\frac{1}{s}C(s)\right)\right\}, \tag{6}$$

$$a_I = \lim_{s\to 0}\{sC(s)\} \tag{7}$$

and

$$a_D = \lim_{s\to\infty}\frac{d}{ds}\{C(s)\}, \tag{8}$$

respectively. Therefore, if the controllers $C(s)$ in (3) holds (6), (7) and (8), the role of controller $C(s)$ in (3) is equivalent to that of the conventional PID controller $C(s)$ in (1). That is, we can design stabilizing modified PID controllers such that the role of controllers $C(s)$ in (3) is equivalent to that of the conventional PID controller $C(s)$ in (1).

2) When $G(s)$ is of minimum phase
According to [24], the parametrization of all stabilizing modified Smith predictor for minimum-phase time-delay plants is written by

$$C(s) = \frac{C_f(s)}{1 - C_f(s)G(s)e^{-sT}}, \tag{9}$$

$$C_f(s) = \frac{\bar{G}_u(s)}{G_u(s)}\left(1 + \frac{Q(s)}{G_u(s)}\right), \tag{10}$$

where $Q(s) \in RH_\infty$ is any function, $\bar{G}_u(s) \in \mathcal{U}$ satisfies

$$\bar{G}_u(s_i) = \frac{1}{G_s(s_i)e^{-s_i T}} \quad (i = 1, \ldots, n), \tag{11}$$

n is the number of unstable poles of $G(s)$, $s_i (i = 1, \ldots, n)$ are unstable poles of $G(s)$, $G_s(s)$ is a stable minimum-phase function of $G(s)$, that is, when $G(s)$ is factorized as

$$G(s) = G_u(s)G_s(s), \tag{12}$$

$G_u(s)$ is the unstable biproper minimum-phase function and $G_s(s)$ is the stable minimum-phase function. using the controller in (9), the transfer function from r to y and that from d to y are written by

$$y = \bar{G}_u(s)\left(1 + \frac{Q(s)}{G_u(s)}\right) G_s(s)e^{-sT}r \tag{13}$$

and

$$\begin{aligned} y &= \left\{1 - \bar{G}_u(s)\left(1 + \frac{Q(s)}{G_u(s)}\right)\right. \\ &\quad \left.\cdot G_s(s)e^{-sT}\right\} G(s)e^{-sT}d, \end{aligned} \tag{14}$$

respectively. From $Q(s) \in RH_\infty$, $\bar{G}_u(s) \in \mathcal{U}$, $G_s(s) \in RH_\infty$ and $1/G_u(s) \in RH_\infty$, the transfer function in (13) and (14) have finite number of poles. In addition, it is obvious that the stability of the closed-loop system in Fig. 1 is guaranteed. If the controllers $C(s)$ in (9) holds (6), (7) and (8), the role of controller $C(s)$ in (3) is equivalent to that of the conventional PID controller $C(s)$ in (1). That is, we can design stabilizing modified PID controllers such that the role of controllers $C(s)$ in (9) is equivalent to that of the conventional PID controller $C(s)$ in (1).

IV. Modified PID controller, when $G(s)$ is stable

In this section, we describe a design method for the free parameter $Q(s)$ in (3) to make the controller $C(s)$ in (3) works as a modified PID controller. On account of limited space, we describe a design method of modified PID controller only.

A. Modified PID controller

In this subsection, we mention a design method for modified PID controller $C(s)$ that holds (6), (7) and (8), makes the closed-loop system in Fig. 1 stable and is able to apply to any stable time-delay plant $G(s)e^{-sT}$.

The modified PID controller $C(s)$ satisfying (6), (7) and (8) is written by (3), where

$$Q(s) = \frac{q_0 + q_1 s + q_2 s^2}{\tau_0 + \tau_1 s + \tau_2 s^2} + q_3 s, \tag{15}$$

$$q_0 = \frac{\tau_0}{G(0)}, \tag{16}$$

$$\begin{aligned} q_1 &= \frac{\tau_1}{G(0)} - q_3\tau_0 \\ &\quad - \frac{\tau_0}{G^2(0)}\left\{\frac{1}{a_I} - TG(0) + \frac{d}{ds}\left(G(s)\right)\Big|_{s=0}\right\}, \end{aligned} \tag{17}$$

$$q_2 = \tau_2 a_P \tag{18}$$

and

$$q_3 = a_D, \tag{19}$$

where $\tau_i > 0 \in R (i = 0, 1, 2)$. Since $Q(s)$ in (15) is improper, $Q(s)$ in (15) is not included in RH_∞. In order for $Q(s)$ to be included in RH_∞, (15) is modified as

$$Q(s) = \frac{q_0 + q_1 s + q_2 s^2}{\tau_0 + \tau_1 s + \tau_2 s^2} + \frac{a_D s}{1 + \tau_D s}, \tag{20}$$

where $\tau_D \in R > 0$. From $\tau_D > 0$ in (20), $Q(s)$ in (20) is included in RH_∞. This implies that the controller $C(s)$ in (3) with (20) makes the closed-loop system in Fig. 1 stable for any stable time-delay plant $G(s)e^{-sT}$ independent of a_P, a_I and a_D.

V. Modified PID controller, when $G(s)$ is of minimum-phase

In this section, we describe a design method for the free parameter $Q(s)$ in (10) to make the controller $C(s)$ in (3) works as a modified PID controller. The detail is omitted on account of limited space.

VI. Application for a heat flow experiment

In this section, we show an application for a heat flow experiment to illustrate the effectiveness of the proposed modified PID controller.

The illustrated heat flow experiment is shown in Fig. 2. The heat flow experiment consists of a duct equipped with a

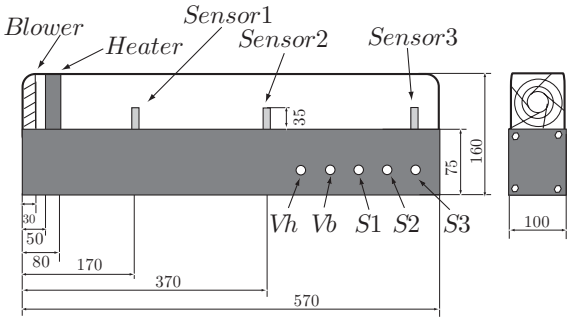

Figure 2. Illustrated heat flow apparatus

heater and a blower at one end and three temperature sensors located along the duct as shown in Fig. 2. V_h and V_b denote the voltage to heater and that to blower, respectively. S_1, S_2 and S_3 are terminals for measurements of temperatures at Sensor 1, Sensor 2 and Sensor 3. We denote T_i a measurements of temperatures at Sensor i.

The problem considered in this section is to design a modified PID controller to make T_3, which is temperature at Sensor 3, $30[\mathrm{deg}]$ steadily. When we settle $V_b = 5[V]$, we find the transfer function from V_h to T_3 which is temperatures at Sensor 3 is written by

$$T_3 = \frac{5.30}{1 + 18.15s}e^{-1.25s}V_h. \tag{21}$$

T_3 and V_h are considered as the output y and the control input u in the control system in Fig. 1, respectively. Then, from (21), $G(s)e^{-sT}$ in Fig. 1 is written by

$$G(s)e^{-sT} = \frac{5.30}{1+18.15s}e^{-1.25s}, \tag{22}$$

where $T = 1.25[\mathrm{sec}]$ and

$$G(s) = \frac{5.30}{1+18.15s}. \tag{23}$$

The reference input r in Fig. 1 is settled by $r(t) = 30[\mathrm{deg}]$.

Since $G(s)$ in (23) is stable, we design a modified PID controllers using the method described in Section IV a_P, a_I and a_D are settled by

$$\begin{cases} a_P &= 4.000 \\ a_I &= 0.140 \\ a_D &= 0.005 \end{cases}. \tag{24}$$

q_0, q_1, q_2 and q_3 are determined by (16), (17), (18) and (19), respectively, where

$$\begin{cases} \tau_0 &= 1 \\ \tau_1 &= 2 \\ \tau_2 &= 1 \end{cases} \tag{25}$$

and τ_D is selected by $\tau_D = 1$. Using above-mentioned parameters, the modified PID controller $C(s)$ is designed by (3) with (20).

Experimental step response of the control system using modified PID controller $C(s)$ is shown in Fig. 3. Figure 3

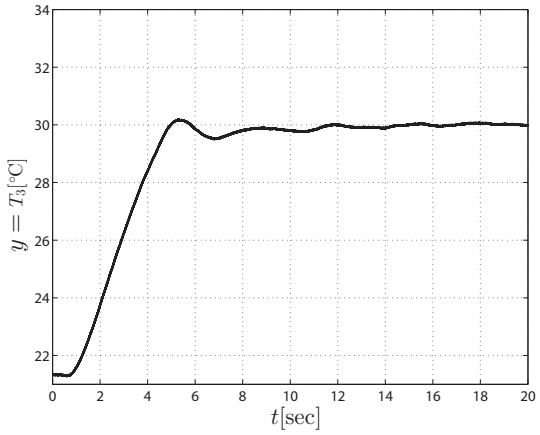

Figure 3. Experimental step response using the modified PID controller

shows that the output $y = T_3$ follows the step reference input $r = 30$ negligible steady state error with high convergence speed comparing to open-loop response.

VII. CONCLUSION

In this paper, we proposed a design method for modified PID controllers such that modified PID controller makes the closed-loop system for any stable or minimum phase time-delay plants asymptotically stable and the admissible sets of P-parameter, I-parameter and D-parameter are independent from each other.

***Abstract*- This paper presents a new technique based on particle swarm optimization (PSO) solving two applications, i.e. identification of a DC motor and tuning PID controller parameters. The identification of a DC motor application, the 2nd order transfer function with time delays is determined by the poles location searching mechanism base on PSO. This application is following: first, time responses of speed are determined by multi-levels step input voltage. Secondly, the noises of time responses are reduced by wavelet soft thresholding. Finally, the noiseless time responses are identified by PSO. The tuning PID controller parameters application, the gains of proportional, integral, and derivative are determined for minimize the integral of time multiplied by absolute error (ITAE) performance criteria by PSO. The simulation results show that the proposed method has effectiveness over Ziegler-Nichols method. This confirms that, the PSO can be efficiently used for system identification and tuning parameters of PID controller.**

Keywords: DC motor, Particle swarm optimization, PID tuning System Identification, Optimization

I. INTRODUCTION

DC motors are widely used in industry for various applications, such as robotics, rolling mills, machine tool, etc. Because of the speed of DC motor is easy to be controlled for the speed-torque curve being almost linear. For the speed control applications, the system identification is a pre-requisite to analysis of a dynamic system and design of an appropriate controller for improving its performance [1,2]. In this paper, a new method based on particle swarm optimization (PSO) to identify more accurate the mathematical model for DC motors is proposed.

During the past decades, the process control techniques in the industry have made great advances. Numerous control methods such as adaptive control, neural control, and fuzzy control have been studied. Among them, the best known is the proportional-integral-derivative (PID) controller, which has been widely used in the industry because of its simple structure and robust performance in a wide range of operating conditions. The Ziegler-Nichols tuning formula is perhaps the best known tuning method [3]. Unfortunately, it has been quite difficult to properly tune the gains of PID controllers because many industrial plants are often burdened with problems such as high order, time delays, and nonlinearities.

To overcome this problem, several heuristic methods have been proposed for tuning parameters of PID controllers. In general, it is often hard to find the optimal or near optimal PID parameters.

Many random search methods, such as simulated annealing (SA), genetic algorithm (GA) [4,5] and tabu search (TS) algorithm and PSO [7], have recently received much interest for achieving high efficiency and searching global optimal solution.

The PSO method, first introduced by Kennedy and Eberhart, is one of the modern heuristic algorithms. It was developed through simulation of a simplified social system, and has been found to be robust in solving continuous nonlinear optimization problems [6]. The PSO technique can generate a high-quality solution within shorter calculation time and stable convergence characteristic than other stochastic methods. Much research is still in progress for proving the potential of the PSO in solving complex problems.

Therefore, this paper, besides demonstrating how to employ the PSO method to identify a DC motor and obtain the optimal PID controller parameters for speed control of DC motor systems.

II. MODELING OF A DC MOTOR AND A PID CONTROLLER

Fig.1 shows a schematic diagram of a dc motor. For constant field, the armature voltage controlled needs to be considered here.

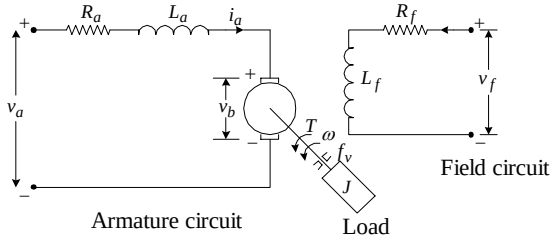

Fig.1. Schematic diagram of a dc motor

A. Mathematical model of a DC motor

Consider the dynamic model of a DC motor given by the following differential equations.

$$T(t) = k_t i_a(t) \quad (1)$$

$$v_b(t) = k_b\omega(t) \quad (2)$$

$$R_a i_a + L_a \frac{di_a(t)}{dt} + k_b\omega(t) = v_a(t) \quad (3)$$

$$T(t) = J\frac{d\omega(t)}{dt} + f_v\omega(t) \quad (4)$$

where, $T(t)$ is motor torque, $i_a(t)$ is armature current, v_b is back emf., $\omega(t)$ is angular velocity, R_a is armature resistance, L_a is armature inductance, $v_a(t)$ is armature voltage, J is moment of inertia, f_v is viscous friction, and k_t, k_b are constants.

Using the Laplace transform, the transfer function from the input voltage, V_a, to the output velocity, W is as follows:

$$G(s) = \frac{W(s)}{V_a(s)} = \frac{k_t}{JL_a s^2 + (JR_a + L_a f)s + R_a f_v + k_t k_b} \quad (5)$$

$$G(s) = \frac{K}{s^2 + as + b} \quad (6)$$

where $K = \frac{k_t}{JL_a}$, $a = \frac{JR_a + L_a f_v}{JL_a}$, and $b = \frac{R_a f_v + k_t k_b}{JL_a}$

Equation (5) is the 2nd order transfer function of a DC motor, If the model is determined using these parameters, it will be complex and will take a long time. Consider equation (5) or (6) again, it consists of two poles and a gain K. The objective of system identification is to determine only the coefficients a, b, and K, which get the time respond equals to the step respond from experiments. This method is an optimization problem, that can be applied to use the PSO

B. PID Controller

The transfer function of a PID controller is

$$u(t) = K_P e(t) + K_I \int_0^t e(t)dt + K_D \frac{de(t)}{dt} \quad (7)$$

where K_P is the proportional gain, K_I is the integral gain, and K_D is the derivative gain.

The variable $e(t)$ represents the tracking error, which is the difference between the desired input value $r(t)$ and the actual output $y(t)$.

The proportional controller K_P will have the effect of reducing the rise time and will reduce, but never eliminate, the steady-state error. An integral control K_I will have the effect of eliminating the steady-state error, but it may make the transient response worse. A derivative control K_D will have the effect of increasing the stability of the system, reducing the overshoot, and improving the transient response.

C. Time delays

Time delays are encounter so frequently in system that they deserve special attention. However, one can be approximated using *Pade' approximation*. In this paper used the 2nd order Pade approximation for approximated the time delays.

$$e^{-Ts} = \frac{1 - Ts/2 + T^2 s^2/12}{1 + Ts/2 + T^2 s^2/12} \quad (8)$$

III. Particle Swarm Optimization

The PSO method is an optimization technique which is motivated by social behaviors of organisms such as fish schooling and bird flocking. PSO provides a population-based search procedure in which individuals called "particles" change their positions (states) with time. In a PSO system, particles fly around in a multidimensional search space. During flight, each particle adjusts its position according to its own experience, and the experience of neighboring particles, making use of the best position encountered by itself and its neighbors. The swarm direction of a particle is defined by the set of particles neighboring the particle and its history experience.

Let x and v denote a particle coordinates (position) and its corresponding flight speed (velocity) in a search space, respectively. Therefore, the i-th particle is represented as $x_i = (x_{i1}, x_{i2}, \mathrm{K}, x_{id})$ in the ***d***-dimensional space. The best previous position of the i-th particle is recorded and represented as $pbest_i = (pbest_{i1}, pbest_{i2}, \mathrm{K}, pbest_{id})$. The index of the best particle among all the particles in the group is represented by the $gbest_d$. The rate of the velocity for particle i is represented as $v_i = (v_{i1}, v_{i2}, \mathrm{K}, v_{id})$. The modified velocity and position of each particle can be calculated using the current velocity and the distance from $pbest_{id}$ to $gbest_{id}$ as shown in the following formulas:

$$v_{id}^{t+1} = w \cdot v_{id}^t + c_1 * rand(\cdot) * \left(pbest_{id} - x_{id}^t\right) + c_2 * rand(\cdot) * \left(gbest_d - x_{id}^t\right) \quad (9)$$

$$x_{id}^{t+1} = x_{id}^t + v_{id}^{t+1},\ i = 1,2,\mathrm{K},n,\ d = 1,2,\mathrm{K},m \quad (10)$$

where n is number of particles in a group; m is number of members in a particle; t is pointer of iterations (generations); w is inertia weight factor; c_1, c_2 are acceleration constants; $rand(\cdot)$ is uniform random value in the range [0,1]; v_i^t is velocity of particle i at iteration t, $V_d^{\min} \le v_{id}^t \le V_d^{\max}$; x_i^t is current position of particle at iteration.

In the above procedures, the parameter $V^{\max}$ determined the resolution, or fitness, with which regions are to be searched between the present position and the target position. In many experiences, $V^{\max}$ was often set at 10–20% of the dynamic range of the variable on each dimension.

The constants c_1 and c_2 represent the weights of the stochastic acceleration terms that pull each particle toward the *pbest* and *gbest* positions. Hence, the acceleration constants c_1 and c_2 were often set to be 2.0 according to past experiences [6]. As originally developed, w often decreases

linearly from about 0.9 to 0.4 during a run. In general, the inertia weight is set according to the following equation:

$$w = w_{\max} - \frac{w_{\max} - w_{\min}}{iter_{\max}} \times iter \qquad (11)$$

where $iter_{\max}$ is the maximum number of iterations and $iter$ is the current number of iterations.

IV. Experiments and Simulation Results

A. Identification DC motor

A 1.1 kW, 220 V, 3000 rpm separately excited DC motor for identification is shown in Fig. 2. Its field current is 0.26 A rated. We applied 40 V to 220 V step input voltage into the DC motor and measured the time response of speed. The test data after reducing noise by wavelet soft thresholding are shown in Fig.3. The aim of identification is to determine the parameters a, b, and K of 2nd order transfer function of the DC motor which get the time response is to match that in the experiment. The performance index is the integral of time multiplied by absolute error (ITAE) between the experiment and the simulation. The ITAE also yields a system with a faster response than other criteria.

$$ITAE = \int_{o}^{t} t\left|f_{ex}(t) - f_{s}(t)\right|dt \qquad (12)$$

where $f_{ex}(t)$ is time response of experiment and $f_s(t)$ is the time response of simulation.

Fig.2 DC motor for identification and speed control

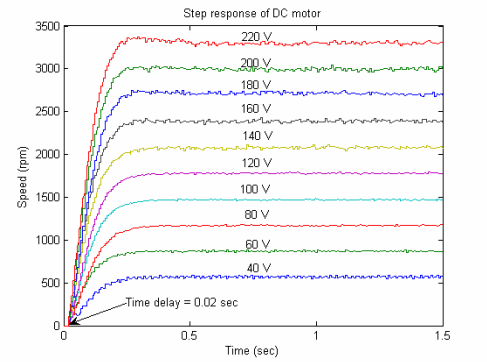

Fig.3 Test data of DC motor

Fig. 4 shows the example for identification in case input voltage is 120 V. After using PSO to identify, the time response of the simulation is nearly matched the time response of the experiment. The error is minimized. For other input voltages,we used the same procedure to identify. The results yield the transfer function for each input voltage as show in Table 1.

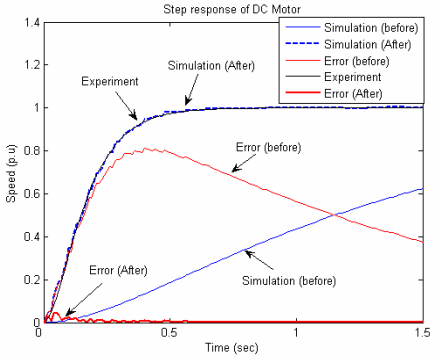

Fig.4 Comparison between experiment and simulation

Table 1 The transfer function of DC motor

Va	G(s)	Va	G(s)
40	$\frac{5632.78}{s^2+43.4s+398.64}$	140	$\frac{6222.45}{s^2+44.3s+433.62}$
60	$\frac{5762.02}{s^2+42.9s+410.4}$	160	$\frac{5860.71}{s^2+40.6s+409.84}$
80	$\frac{5928.01}{s^2+45.3s+416.01}$	180	$\frac{6031.29}{s^2+43.6s+426.24}$
100	$\frac{5826.58}{s^2+44.0s+408.31}$	200	$\frac{6071.60}{s^2+43.9s+420.18}$
120	$\frac{6314.37}{s^2+46.0s+440.64}$	220	$\frac{5855.97}{s^2+44.5s+403.86}$

* Va is input voltage and G(s) represent the transfer function.

The all parameters are represented by interval range.

$$a = [40.6, 46.0],\ b = [398.64, 440.64],\ K = [5632.78, 6314.37]$$

From the experiments, the system have time delays 0.02 sec. The overall transfer function can be compute by averaging the value of all data. Therefore, the overall transfer function with time delays of this DC motor is

$$G(s) = \frac{5950.58}{s^2 + 43.85s + 416.77} . e^{-0.02s} \qquad (13)$$

B. Tuning PID control using PSO

We Used the overall transfer function with time delays of the DC motor is given in equation (13) to design a speed controller based on PID controller using PSO. The objective is finding the parameters of the PID controller to minimize the performance criteria. The performance index used is the integral of time multiplied by absolute error (ITAE). Therefore, the overall transfer function with time delays is

$$G(s) = \frac{2.3802s^2 - 714.0696s + 71406.96}{0.0004s^4 + 0.1375s^3 + 17.4287s^2 + 576.2124s + 5001.24} \quad (14)$$

Table 2 shows the simulation results. In the table, *OS* represents the percent maximum overshoot, t_s stand for the 2 percent settling time, and e_{ss} is the steady state error. Time response is obtained from the process under the control of the PID controller designed using PSO is plotted in Fig.5. The results compare with Ziegler-Nichols method. The controller designed using the proposed method yields better control performance than the Ziegler-Nichols method.

To assess the effectiveness of the optimized PID parameters, the tracking speed input of the whole system, with the standard square wave response as shown in Fig. 6. And then, Fig.7 shows the responses when applied random load.

Table 2 Results obtained by using Ziegler-Nichols and PSO

method	Parameters			Performance		
	k_p	k_i	k_d	t_s	*OS*	e_{ss}
Ziegler-Nichols	0.2536	3.6059	0.0044	0.214	39.34	0
PSO	0.2206	2.1520	0.0063	0.137	12.53	0

*p.u. stand for per unit

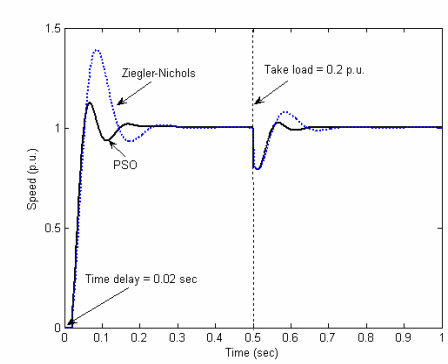

Fig.5 Time response obtained from Ziegler-Nichols and PSO

V. CONCLUSION

The application of PSO in system identification and PID tuning was briefly reviewed in this paper. Therefore, the proposed method has more robust stability and efficiency, and can solve these applications. The experiment confirms the suitability of the proposed method as a high performance control system for the DC motors and tuning PID controller.

***Abstract*- In this paper, a simplified designing method of a PI controller for a higher-order plant by using the concept of plant model reduction and the Coefficient Diagram Method with the less number of stability index γ_i is presented. By ignoring the non-dominant poles of the higher-order plant model, a lower-order plant model is first obtained. Then, the PI controller will be designed for controlling the lower-order plant model by using Coefficient Diagram Method with the appropriate values of stability index in order to achieve the system response without overshoot. Finally, the designed PI controller will be employed to control the original higher-order plant. The proposed controller is implemented to control a two-inertia system. The experimental results show that the PI controller designed from the lower-order plant model is sufficient for controlling the original higher-order plant with acceptable performance.**

I. INTRODUCTION

Since several decades ago, most of industrial processes have employed PID-family controllers due to their simplicity and sufficiency in process control applications. It is reported lately that more than 90% of the industrial controllers used nowadays are PI controllers. However, the parameters of the controller have to be tuned for acceptable responses. The Ziegler-Nichols' tuning formula [1] is the most popular method which is designed to have quarterly decayed overshoot characteristic in the step response but the fine tuning is needed for the practical use to reduce the overshoot in the closed-loop response.

In 1998, a new designing method called Coefficient Diagram Method (CDM) [2] has been proposed. The CDM is an algebraic design algorithm utilizing polynomial form structure. In CDM, the closed-loop characteristic polynomial is designed based on stability index and equivalent time constant, which are used to determine stability and speed of the closed-loop response. Hence, the unknown parameters of the controllers resulting for over-damped response can be obtained accordingly [3-4]. However, it is quite time consuming in designing the parameters of a controller especially for a higher-order plant.

In this paper, the simplified design of a PI controller for higher-order plant using CDM with less number of stability indexes γ_i is presented. By ignoring the non-dominant pole, the higher-order plant model is reduced to be a lower-order plant model. After that, the CDM is used to design the PI controller for controlling the lower-order plant model. Finally, the PI controller designed for the lower-order plant model is employed for controlling the original higher-order plant. In order to check the control capability of this designing method, the simplified PI controller is implemented to control the speed of the two-inertia system.

II. CDM AND PROPOSED CONTROL SYSTEM

The concept of CDM and the rearranged CDM control system structure are described respectively in this section.

A. CDM Concept

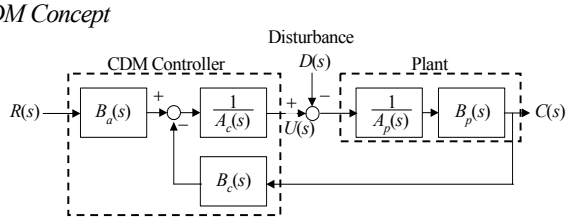

Figure 1. CDM control system structure.

The transfer function of the plant in the polynomial form for each block is

$$A_p(s) = p_k s^k + p_{k-1}s^{k-1} + \ldots + p_0, \tag{1a}$$

$$B_p(s) = q_m s^m + q_{m-1}s^{m-1} + \ldots + q_0, \tag{1b}$$

and the controller polynomials are

$$A_c(s) = l_\lambda s^\lambda + l_{\lambda-1}s^{\lambda-1} + \ldots + l_0, \tag{2a}$$

$$B_c(s) = k_\lambda s^\lambda + k_{\lambda-1}s^{\lambda-1} + \ldots + k_0, \tag{2b}$$

$$B_a(s) = k_0, \tag{2c}$$

where $\lambda < k$ and $m < k$. Hence, the characteristic polynomial of the closed-loop system shown in Fig. 1 can be given as

$$\begin{aligned} P(s) &= A_c(s)A_p(s) + B_c(s)B_p(s) \\ &= \sum_{i=0}^{n} a_i s^i. \end{aligned} \tag{3}$$

Note that it still has unknown controller's parameters to be solved. Based on CDM concept, the performance specification known as stability index γ_i and the equivalent time constant τ are defined by

$$\gamma_i = \frac{a_i^2}{a_{i+1}a_{i-1}}, \tag{4}$$

$$\tau = \frac{a_1}{a_0}, \tag{5}$$

$$\gamma_i^* = \frac{1}{\gamma_{i+1}} + \frac{1}{\gamma_{i-1}} \quad ; \quad \gamma_0, \gamma_n = \infty, \tag{6}$$

where $i = 1,\ldots, n-1$. The equivalent time constant τ is generally selected according to the specified settling time t_s as $t_s = 2.5\tau$ and the standard stability index is recommended to be

$$\gamma_{n-1} = \ldots = \gamma_3 = \gamma_2 = 2, \gamma_1 = 2.5 . \quad (7)$$

From (4) to (6), the coefficient a_i can be written by

$$a_i = a_0 \tau^i \frac{1}{\gamma_{i-1} \cdots \gamma_2^{i-2} \gamma_1^{i-1}} = a_0 \tau^i \prod_{j=1}^{i-1} \frac{1}{\left(\gamma_{i-j}\right)^j} . \quad (8)$$

Consequently, the characteristic polynomial to be employed to design the parameters of a controller is

$$P(s) = a_0 \left[\left\{ \sum_{i=2}^{n} \left(\prod_{j=1}^{i-1} {}^{1}\!/_{\gamma_{i-j}^{j}} \right) (\tau s)^i \right\} + \tau s + 1 \right]. \quad (9)$$

Hence, the parameters of the controller can be obtained by equating the characteristic polynomial in (3) to (9) with the known stability index γ_i and/or the equivalent time constant τ when the mathematical model of the plant is known.

B. Control Systems Structure

For simplicity in design, the original CDM control system structure in Fig. 1 is rearranged to be a rearranged CDM control system structure as shown in Fig. 2.

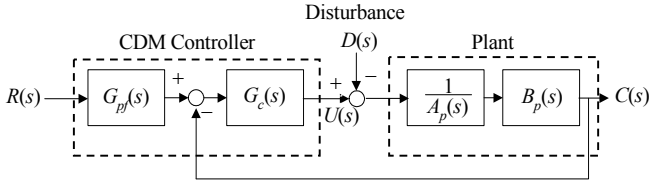

Figure 2. Rearranged CDM control system structure.

The transfer function of controller $G_c(s)$ and the pre-filter $G_{pf}(s)$ of the rearranged control system shown in Fig. 2 are

$$G_c(s) = \frac{B_c(s)}{A_c(s)} \quad (10)$$

and

$$G_{pf}(s) = \frac{B_a(s)}{B_c(s)} . \quad (11)$$

III. Two-Inertia System

The structure of two-inertia system [5] and its block diagram are shown in Fig. 3 and Fig. 4.

Figure 3. Two-inertia system.

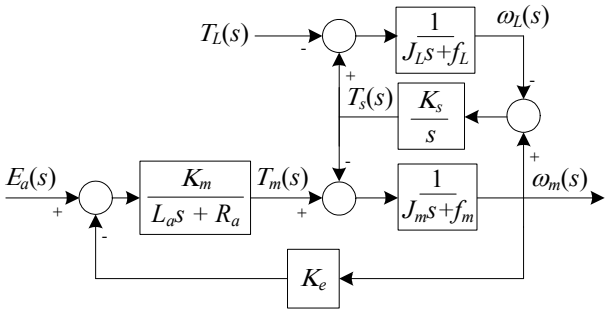

Figure 4. Block diagram of the two-inertia system.

By ignoring the viscous friction of the motor f_m and f_L, the transfer function of the two-inertia system will be

$$G_p(s) = \frac{\omega_m(s)}{E_a(s)} = \frac{a_2 s^2 + a_0}{b_4 s^4 + b_3 s^3 + b_2 s^2 + b_1 s + b_0} \quad (12)$$

where $b_4 = 1$, $b_3 = \frac{R_a}{L_a}$, $b_2 = \frac{K_s L_a (J_m + J_L) + K_m K_e J_L}{J_m J_L L_a}$,

$b_1 = \frac{K_s R_a (J_m + J_L)}{J_m J_L L_a}$, $b_0 = \frac{K_m K_e K_s}{J_m J_L L_a}$, $a_2 = \frac{K_m}{J_m L_a}$, $a_0 = \frac{K_m K_s}{J_m J_L L_a}$

and its parameters are shown in the Table I.

TABLE I
PARAMETER VALUES OF TWO-INERTIA SYSTEM

R_a	Armature resistance	0.25 Ω
L_a	Armature inductance	0.10 *mH*
K_e	Back electromotive force constant	3.85 *v / krpm*
K_m	Motor torque constant	3.2 *N – cm / A*
J_m	Moment of motor inertia	0.8 *kg – cm²*
J_L	Moment of load inertia	0.9 *kg – cm²*
K_s	Torsional stiffness of drive shaft	15 *N – m / rad*

IV. Controller Design

In this section, plant model order reduction, PI controller structure and the controller designing procedure will be described respectively.

A. Plant Model Order Reduction

Consider the *k*-order plant with the transfer function given as

$$G_p(s) = \frac{B_p(s)}{A_p(s)} = \frac{K \prod_{j=1}^{m} (s + z_j)}{\prod_{i=1}^{k} (s + p_i)}; \; k \geq m . \quad (13)$$

Without loss of generality, assuming that the plant contains the non-dominant poles $-p_i$ for $i = 1, 2, \ldots, l$. By ignoring the non-dominant poles, the n-order plant model can then be reduced to a lower-order plant model and its transfer function is

$$\tilde{G}_p(s) = \frac{\tilde{K}\prod_{j=1}^{m}(s+z_j)}{\prod_{i=l+1}^{k}(s+p_i)};\ \tilde{K} = \frac{K}{\prod_{i=1}^{l} p_i};\ k-l \geq m. \quad (14)$$

B. PI Controller Structure

The controller (11) in this paper is the conventional PI controller and its transfer function is

$$G_c(s) = K_p\left(1+\frac{1}{T_i s}\right), \quad (15)$$

where K_p and T_i are the proportional gain and the integral time, respectively. The other form of (15) can also be rewritten as

$$G_c(s) = \frac{B_c(s)}{A_c(s)} = \frac{K_p s + K_i}{s}, \quad (16)$$

where the gain K_p and K_i of (16) can be assigned from the controller design procedure stated in the next sub-section.

C. Controller Design Procedure

The designing steps for the PI controller are as follows:

(1) Find the closed-loop characteristic polynomial of the control system with the lower-order plant model (14) and the PI controller (16).

(2) Choosing the appropriate values of the stability index γ_i and/or the equivalent time constant τ to find the characteristic polynomial such that the over-damped response of the closed-loop system with lower-order plant model including $G_{pf}(s)$ is obtained, where $B_a(s)$ is the coefficient of s^0 of $B_c(s)$.

(3) Find the parameters of the controller by equating the characteristic polynomial obtained in step (2) with the characteristic polynomial obtained in step (1).

(4) Applying the PI controller obtained in step (3) to control the original plant.

V. Experimental Results

The experimental results of the speed control of the two-inertia system using the PI controller obtained from simplified design based on CDM approach will be shown in this section. From the transfer function of the two-inertia system in (12) and the values in Table I, the transfer function from input voltage to the motor speed is given by

$$G_p(s) = \frac{3\times10^4 s^2 + 6.67\times10^7}{s^4 + 2.5\times10^3 s^3 + 1.57\times10^5 s^2 + 8.85\times10^6 s + 2.57\times10^8}.$$

It is the fourth-order system and its open-loop poles are located at s = -39.6, -2436.8, -11.8+j50.2, -11.8-j50.2. The open-loop response of the two-inertia system when applying the input voltage at 5 volts is shown in Fig. 5. It is seen that there is an unsatisfied torsional resonance and must be reduced as much as possible by using a controller.

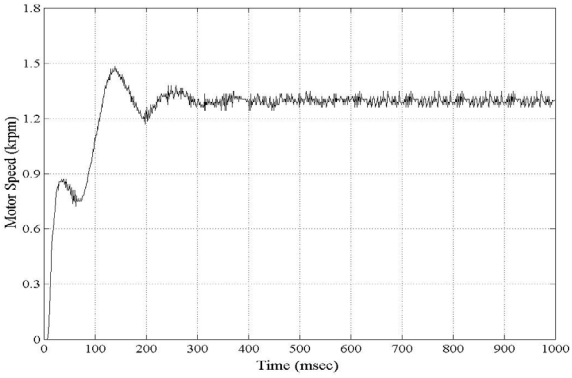

Figure 5. Open-loop step response of two-inertia system.

Since the poles at s = -39.6, -2436.8 are the non-dominant poles, the system is reduced to be a second-order model by ignoring them. Thus, its transfer function can be expressed as

$$\tilde{G}_p(s) = \frac{3\times10^4 s^2 + 6.67\times10^7}{9.65\times10^4 s^2 + 2.28\times10^6 s + 2.57\times10^8}.$$

Based on the controller design procedure stated previously, the parameters K_p and K_i of the PI controller including the equivalent time constant τ of the closed-loop system obtained by using the lower-order plant model with $\gamma_1 = 7$ and $\gamma_2 = 0.5$ are shown in the Table II. Note that the gamma values are chosen to give the positive values of K_p and K_i of the PI controller when the simplified design method is employed. For comparison, the parameters of PI controller and the equivalent time constant τ obtained from the original plant model with $\gamma_1 = 2.5, \gamma_2 = 2, \gamma_3 = 1.34$ and $\gamma_4 = 32.4$ can also be shown in the Table II.

TABLE II
PARAMETERS OF PI CONTROLLERS

Plant Type	K_p	K_i	τ *(msec)*
Original model	0.87	54.08	87
Reduced model	0.41	43.15	88

The PI controller designed from the lower-order plant model is used to control the speed of the two-inertia system at the speed of 1300 rpm. The proposed control system obtained from simplified design method will be compared to the other one using the PI controller obtained by direct design in order to show the effectiveness of the proposed design method. The results will be shown in two aspects. The first aspect is the system performance and the second aspect is the capability of the simplified design PI controller.

A. System Performances

The experimental results in controlling the motor speed of the two-inertia system are shown in Fig. 6. It is seen that the proposed PI controller can control the speed at 1300 rpm without torsional resonance, overshoot and steady-state error. It is also seen that the system response speed quite similar to

the response of the system using PI controller obtained from direct design. This can be seen from the value of equivalent time constant τ obtained from the simplified design shown in the Table II that its value is close to the one obtained from the direct design. The system performances of both control systems are also summarized in Table III.

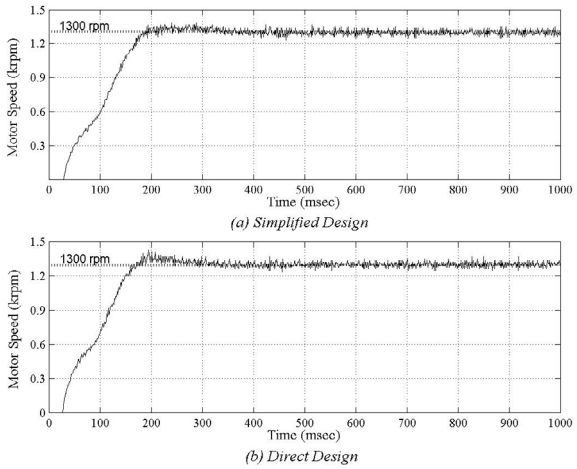

Figure 6. Step responses of control systems at 1300 rpm.

TABLE III
SYSTEM PERFORMANCE AT 1250 RPM.

Design Method	t_r *(msec)*	t_s *(msec)*	P_O *(%)*
Direct	151	292	3.8
Simplified	176	302	2.3

B. Capability of the Simplified Design PI Controller

The capability of the PI controller designed from the lower-order plant model is investigated by retarding the motor reference speed of the control system at 500 msec from 1300 rpm to 800 rpm. Its responses is shown in Fig. 7. From the responses, the motor speed of system using proposed controller can reach to 800 rpm properly and similarly as the control system using the PI controller obtained from direct design.

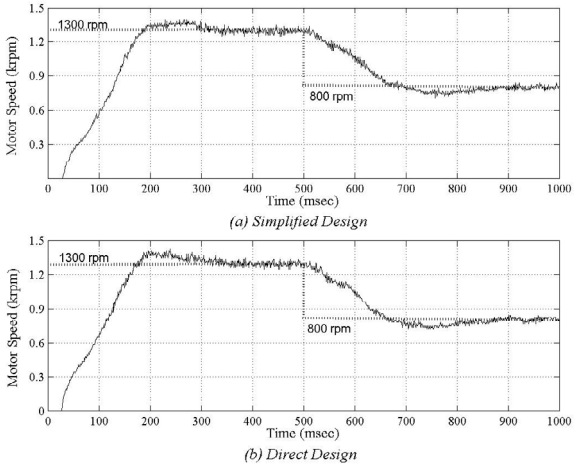

Figure 7. Responses due to speed retard to 800 rpm.

In order to compare the disturbance rejection capability of the simplified design PI controller and the direct design PI controller, the motor reference speed at 1300 rpm and the constant load disturbance entering at 500 msec are considered. It is seen from the Fig. 8 that the proposed control system can reject the effect of the load disturbance and reach to the speed at 1300 rpm without error similarly.

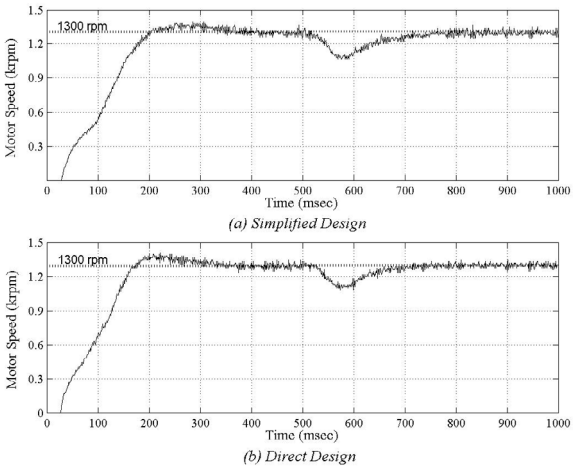

Figure 8. Responses with constant load disturbance.

V. CONCLUSIONS

The simplified design of a PI controller for a higher-order plant by using the CDM concept has been proposed in this paper. The proposed controller is implemented to control the speed of the two-inertia system. Not only the simplicity in designing but the speed of the response can still be improved to meet the desired system performance as well. In addition, the unsatisfied torsional resonance can also be reduced. The effectiveness of this designing method has been confirmed by the experimental results.

***Abstract*-The design of hybrid controller consisting of PD controller and sliding mode controller for inverted pendulum system is proposed in this paper. The PD controller is applied for controlling position of the cart to swing up the pendulum from the natural pendent position to around the upright position. The sliding mode controller is utilized for stabilizing the inverted pendulum in the upright position. Root-locus method is applied to tune the PD controller, while the sliding mode controller is designed based on pole placement. The experimental results of the proposed control system are also shown in this paper.**

I. INTRODUCTION

In control area, the inverted pendulums are one of the most commonly studied systems. Many variations of the inverted pendulum often represent different kinds of the robotic arms [1]. The inverted pendulum to be discussed in this paper is an inverted pendulum on cart as depicted in Fig. 1. This inverted pendulum consists of a cart and a pendulum hinged to the cart via a pivot and only the cart is actuated. Swinging up and stabilizing the inverted pendulum have many advantages in theoretical study such as simple structure, nonlinear and uncertain characteristics. Many control methods have been implemented to control the inverted pendulums, for instance, nonlinear control [2], energy-based method [3] and Qubit neural network [4]. Though using these algorithms gives good performance, they are complicated to design and implement.

In this paper, a controller designed by using hybrid PD controller with sliding mode control algorithm to swing up the pendulum from the natural pendent position to around the upright position and to stabilize inverted pendulum in the upright position is proposed. It composes of two parts. The first part is the PD position control and the second part is the sliding mode control. In the first part, a PD controller is employed for swinging up the pendulum from the natural pendent position to around the upright position. The gains of the PD controller are assigned by root-locus method to obtain fast step response with small overshoot. The PD controller controls the motion of the pendulum by moving the cart back and forth within a limited traveling range of the cart. The cart will be controlled to move to the opposite direction when the angular velocity of the pendulum at the stop point of each travel is zero. The cart movement will be repeated to next assigned cart position until the inverted pendulum swings up around the upright position. When this condition is reached, the second part, which is a sliding mode controller, will be switched to stabilize the inverted pendulum. In this paper, this sliding mode controller is designed based on pole placement method. The effectiveness and reliability of the proposed method in actual experiments will be shown.

II. MATHEMATICAL MODEL

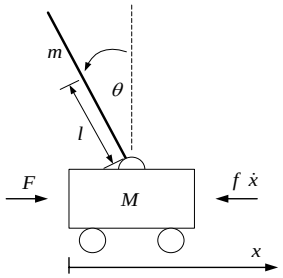

Figure 1. Inverted pendulum on cart.

Fig. 1 shows the structure of the inverted pendulum on cart system where variables θ, x and F denote the pendulum angle (rad), the cart position (m) and the force applied to the cart (N) respectively. The system parameters include the mass of the cart M (kg), the mass of the pendulum m (kg), the distances from the turning center to the center of gravity of the pendulum l (m), and the cart's friction coefficient f (kg/s).

The mathematical model of the inverted pendulum can be computed either by Newton's law or Lagrange's equations with respect to x and θ coordinates. If $x_1 = \theta$, $x_2 = \dot{\theta}$, $x_3 = x$ and $x_4 = \dot{x}$ are selected as state variables and applying force F is denoted by input $u(t)$, the nonlinear state space model of the system can be then obtained as

$$\begin{aligned}
\dot{x}_1 &= x_2 \\
\dot{x}_2 &= \frac{\left(mg \sin x_1 + \dfrac{m \cos x_1 (u - fx_4 - m^2 l x_2^2 \cos x_1 \sin x_1)}{(M+m)} \right)}{\left(\dfrac{4}{3} ml - \dfrac{m^2 l \cos^2 x_1}{(M+m)} \right)} \\
\dot{x}_3 &= x_4 \\
\dot{x}_4 &= \frac{\left(u - fx_1 + \dfrac{3}{4} mg \cos x_1 \sin x_1 - ml x_2^2 \sin x_1 \right)}{(M+m) - \dfrac{3}{4} m \cos^2 x_1}.
\end{aligned} \tag{1}$$

In this case, the input $u(t)$ or the force F is generated by DC motor. The state vector $\mathbf{x}^T(t) = \begin{bmatrix} x_1 & x_2 & x_3 & x_4 \end{bmatrix}^T = \begin{bmatrix} \theta & \dot{\theta} & x & \dot{x} \end{bmatrix}^T$ will be subsequentially used for shortening mathematical notation.

Concerning to the angle of the pendulum, the inverted pendulum system has two distinct equilibrium points. The first one is at the upright position and it is naturally unstable. The other one is at the hanging position and it is stable.

For designing the swinging up PD controller, the model of the inverted pendulum will be linearized at the natural pendent position. Corresponding to this equilibrium point, the control input $u(t)$ and state variables $\mathbf{x}(t)$ are considered at $u_0(t) = 0$ and $\mathbf{x}_0^{\ T}(t) = [\pi \ 0 \ 0 \ 0]^T$. The linear state equations can be obtained as (2)

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{B}u(t). \tag{2}$$

when

$$\mathbf{A} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ \dfrac{-3(M+m)mg}{4ml(M+m)-3m^2l} & 0 & 0 & \dfrac{3mf}{4ml(M+m)-3m^2l} \\ 0 & 0 & 0 & 1 \\ \dfrac{3mg}{4\left((M+m)-\frac{3}{4}m\right)} & 0 & 0 & \dfrac{-f}{(M+m)-\frac{3}{4}m} \end{bmatrix}, \mathbf{B} = \begin{bmatrix} 0 \\ \dfrac{-3m}{4ml(M+m)-3m^2l} \\ 0 \\ \dfrac{1}{(M+m)-\frac{3}{4}m} \end{bmatrix}.$$

As the main interest of this part is to control the position x of the cart, the following output equation can be given in (3) where $\mathbf{C} = [0 \ 0 \ 1 \ 0]$.

$$y(t) = \mathbf{C}\,\mathbf{x}(t) \tag{3}$$

Nevertheless, in order to design the sliding mode controller for stabilizing the inverted pendulum, the model of the inverted pendulum system is also needed to be linearized at the upright position. The linearization is therefore calculated at $u_0(t) = 0$ and $\mathbf{x}_0^{\ T}(t) = [0 \ 0 \ 0 \ 0]^T$. The resulting linear state equations can be similarly obtained as (2) but with

$$\mathbf{A} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ \dfrac{3(M+m)mg}{4ml(M+m)-3m^2l} & 0 & 0 & \dfrac{-3mf}{4ml(M+m)-3m^2l} \\ 0 & 0 & 0 & 1 \\ \dfrac{3mg}{4\left((M+m)-\frac{3}{4}m\right)} & 0 & 0 & \dfrac{-f}{(M+m)-\frac{3}{4}m} \end{bmatrix}, \mathbf{B} = \begin{bmatrix} 0 \\ \dfrac{3m}{4ml(M+m)-3m^2l} \\ 0 \\ \dfrac{1}{(M+m)-\frac{3}{4}m} \end{bmatrix}.$$

III. HYBRID CONTROL SYSTEM STRUCTURE

The overall structure of the proposed control system is shown in Fig. 2. It is composed of a PD controller and a sliding mode controller. The PD controller is employed to control the inverted pendulum around its upright position while the sliding mode controller is used for stabilizing the inverted pendulum in upright position.

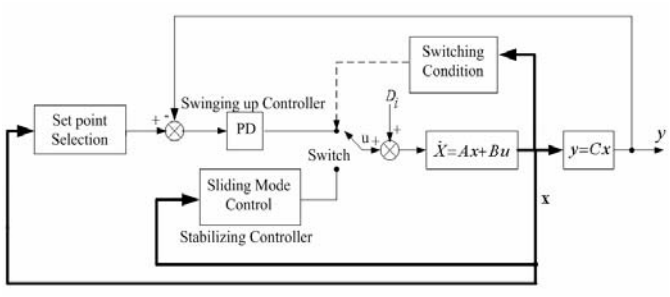

Figure 2. Overall structure of the proposed control system.

A. PD Controller for Position Control

The PD controller is used to control the position of the cart. According to the movement of the cart, the inverted pendulum will be swung up from the natural pendent position to around the upright position. The output command signal $u(t)$ due to the PD controller is given by

$$u(t) = K_p e(t) + K_d \frac{d}{dt} e(t) \tag{4}$$

where K_p is the proportional gain, K_d is the derivative gain and $e(t)$ is the error of the cart position. The PD controller is tuned to achieve fast response without overshoot based on root-locus method. The designed controller will control the cart to move back and forth successively according to the pre-assigned cart position of which the pendulum staying at the natural pendent position is excited. The occurance of back and forth movement of the cart is proceeded when the angular velocity of pendulum is zero until the pendulum can be swung up around the upright position where the sliding mode controller will be switched to stabilize the pendulum.

B. Sliding Mode Controller for Stabilizing

Sliding mode control, often referred as Variable Structure Control, is a high-speed switching feedback control that switches between two values based upon some rule [5], [6]. The control theory uses a high-speed switching law to drive the nonlinear plant's state trajectory onto a specified surface in the state space. This surface is called the "sliding or switching surface". A sliding mode will exist for a system, if in the vicinity of the switching surface the state velocity vector is directed towards the surface. Consider the system

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{B}[u(t) + f(\mathbf{x},t)] \tag{5}$$

where $\mathbf{x}(t)$ is state vector, $u(t)$ is a scalar control and $f(\mathbf{x},t)$ is a nonlinear perturbation with known upper bound $f_o(\mathbf{x},t)$ with assumption that the sliding surface is chosen [7] as

$$s(\mathbf{x},t) = \mathbf{B}^T\mathbf{x}(t) + z(t). \tag{6}$$

when $z(t)$ is governed by an additional first order dynamic subsystem

$$\dot{z}(t) = -\mathbf{B}^T\mathbf{A}\mathbf{x}(t) - (\mathbf{B}^T\mathbf{B})u_a(t),\ z(0) = -\mathbf{B}^T\mathbf{x}(0). \quad (7)$$

Let the control $u(t)$ in (5) be the discontinuous function

$$u(t) = -M(\mathbf{x},t)sign\ s(\mathbf{x},t), \quad (8)$$

where $M(\mathbf{x},t)$ is the magnitude of the control input $u(t)$. The motion projection on the one-dimensional s-space can be computed by (5), (6) and (7) and it is governed by

$$\dot{s}(\mathbf{x},t) = (\mathbf{B}^T\mathbf{B})(u(t) + f(\mathbf{x},t) - u_a(t)). \quad (9)$$

From (8) and (9), the condition for the existence of a sliding mode $(s\dot{s} < 0)$ is corresponding to

$$M(\mathbf{x},t) \geq |u_a(t)| + f(\mathbf{x},t). \quad (10)$$

The sliding mode arises at the initial instant because $s(0) = 0$. The solution to the algebraic equation $\dot{s}(\mathbf{x},t) = 0$ with respect to $u(t)$ should be substituted into (5) to obtain the sliding mode equation in the plane $s(\mathbf{x},t) = 0$ and it is

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{B}u_a(t). \quad (11)$$

Therefore if the linear control $u_a(t) = -\mathbf{K}\mathbf{x}(t)$ is designed in compliance with pole-placement method, the system behavior in the presence of an unknown perturbation $f(\mathbf{x},t)$ is described by the linear time-invariant equation (12) with the assigned poles of the system.

$$\dot{\mathbf{x}}(t) = (\mathbf{A} - \mathbf{B}\mathbf{K})\mathbf{x}(t) \quad (12)$$

If the magnitude of control input take only two values M_0 and $-M_0$, the magnitude of control M_0 should satisfy (10), which means that initial conditions and the perturbation should be bounded.

In summary, the steps for designing the sliding mode controller of the inverted pendulum are as

(1) Choose the desired closed-loop poles of the feedback system (12). The linear control $u_a(t) = -\mathbf{K}\mathbf{x}(t)$ is found accordingly by pole placement method.
(2) The dynamic part of the controller (7) is designed and the equation of the discontinuity plane $s = 0$ is found by (6).
(3) The discontinuous control governed by (6), (8) and (10) is designed.

IV. Experimental results

In this section, the proposed hybrid PD-sliding mode controller for swinging up and stabilizing the inverted pendulum on cart will be implemented. The parameter values of the inverted pendulum system are shown in Table 1.

TABLE I
Parameter Values of Inverted Pendulum

M (kg)	m (kg)	l (m)	f (kg/s)
0.642	0.123	0.25	0.165

The linear models of the inverted pendulum on cart (2) can be obtained where

$$\mathbf{A} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -33.43 & 0 & 0 & 0.74 \\ 0 & 0 & 0 & 1 \\ 1.34 & 0 & 0 & -0.25 \end{bmatrix} \text{ and } \mathbf{B} = \begin{bmatrix} 0 \\ -4.46 \\ 0 \\ 1.49 \end{bmatrix} \quad (13)$$

for equilibrium point at natural pendent position and where

$$\mathbf{A} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 33.43 & 0 & 0 & -0.74 \\ 0 & 0 & 0 & 1 \\ 1.34 & 0 & 0 & -0.25 \end{bmatrix} \text{ and } \mathbf{B} = \begin{bmatrix} 0 \\ 4.46 \\ 0 \\ 1.49 \end{bmatrix} \quad (14)$$

for equilibrium point at the upright position.

The PD position control can now be designed based on the root-locus method to bring the inverted pendulum up around the upright position as fast as possible. In this case, the dominant poles are chosen at $s = -8 \pm j8.39$ which correspond to 0.5 sec for settling time and 5% for percent overshoot respectively. The desired proportional gain K_p and derivative gain K_d are respectively obtained as 97.205 and 12.54. The sequential travelling positions of cart are assigned to be $10, -16, 17, -17$ and 3.8 cm respectively. Zero angular velocity condition occurred at the stop point of the present position will be used as a criterion for moving the cart to the next assigned position.

For sliding mode controller, system matrix $\mathbf{A}$ and input vector $\mathbf{B}$ in (14) are employed. The gain matrix $\mathbf{K}$ in (12) can be found by assigning the values of percent overshoot and the settling time as 15 % and 5 seconds, respectively. Hence, the closed-loop poles of the inverted pendulum system are at $s = -0.8 \pm j1.324$, -10 and -11. This yields $\mathbf{K} =$ [173.001 27.816 -24.609 -21.792]. The discontinuous control is then derived by assigning the values of $f_0(\mathbf{x},t)$ is 2.

For the experiment with simultaneous control of the inverted pendulum from swinging up control to stabilizing control will be investigated. The initial value of the cart position $\mathbf{x}(0)$ is set at zero and the pendulum angle $\theta(0)$ is at natural pendent position. The stabilizing control will be

switched when the pendulum is around the upright position. The switching condition is selected as $|\theta| < 0.04$ rad and $|\dot{\theta}| < 0.1$ rad/s.

The experimental results obtained from a real machine are shown in Fig. 4 (a), (b) and (c). It is seen from Fig. 4 (a) and (b) that the PD controller can swing pendulum up to around the upright position about 4.42 sec, then the system is switched to stabilizing control mode and it can stabilize the pendulum at its upright position and the cart position at zero. The control input signal for swinging up and stabilizing the inverted pendulum is shown in Fig. 4(c).

V. CONCLUSIONS

The hybrid PD controller with sliding mode control algorithm consists of the PD position control for swinging up the pendulum from the natural pendent position to around the upright position and the sliding mode control for stabilizing the inverted pendulum in its upright position has been proposed in this paper. According to the cooperative tasks of PD and sliding mode controller, the experimental results show that the proposed controller can swing the inverted pendulum to the upright position in a short period of time and the controller has good performance in controlling the cart position and pendulum angle at zero line.

***Abstract*- The doubly fed induction generator (DFIG) is one of the most widely used generator in MW-class wind turbines. It can be controlled through rotor slip recovery with machine and line side converters. The machine side converter is of interest in this paper. The active power flow and the reactive power can be controlled independently. A bi-level control objective is presented in this paper. The first level determines the maximum power from the wind. After the maximum active power is determined, the reactive power can be allocated between the stator and rotor to minimize the copper losses. The decoupled control is simulated by the operation of a DFIG in sub- and supper-synchronous speed. The method can reduce the copper losses, thus improving the efficiency of energy production in the wind conversion system.**

Keywords: *doubly fed induction generator, DFIG control, copper loss minimization, wind turbine control, machine side converter.*

I. INTRODUCTION

The doubly fed induction generator (DFIG) is widely used in wind power generation. A DFIG is a wound rotor induction machine with slip rings attached at the rotor fed by power converters. A DFIG can be controlled by a wide range of rotational speeds through sub- and super-synchronous speed operation. It can regulate active and reactive power flow with the help of machine and line side converters. A DFIG has high stability through a fast active power arrangement to the grid and the size of converters can be reduced about 20 to 30 percent of the rating of the DFIG.

The greatest advantage of the DFIG is that it can be controlled from the rotor through slip power while the stator is being connected directly to the grid. The power converters need to be designed for an improvement of total efficiency because of the avoided converter losses. The major part of the active power is fed into the grid through the stator. The machine side converter supplies a small amount to the grid in super-synchronous mode or it is fed the active power from the grid in sub-synchronous mode through the rotor. However, a DFIG requires slip ring systems, which has a problem on contact erosion. This problem can be solved by using new material contact, such as graphite-union, which has very long endurance [1, 2].

This paper presents control strategies of a DFIG used in a wind turbine system to maximize active power and minimize copper losses. The techniques are based on vector control of a machine side converter. A case study is performed to verify the control performance and copper loss minimization for a wide range of wind speeds.

II. MATHEMATICAL AND CONTROL OPERATION OF DFIG

A. *Control Objectives*

There are two main operating regions of wind turbine control: below rated wind speed and above rated wind speed regions. The control objective in the first region is to track the maximum output power at any wind speeds. In the above-rated wind speed, it is necessary to limit the mechanical power generated by the rotor to a specified value, P_n, of the plant to prevent damage on the turbine by pitch control or stall regulation. Figure 1 shows the optimum control trajectory of wind power which is characterized by power and rotational speed with various wind speed. It can be seen that there exists a range of wind speeds ($\omega_{cut-in} - \omega_{rated}$) that should be used for efficient power conversion from the mechanical wind power to the electrical power. Figure 2 shows the corresponding torque trajectory which gives the output power of Fig. 1.

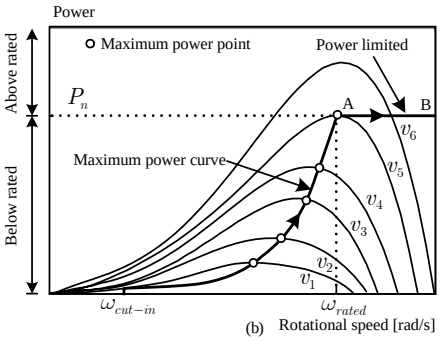

Figure 1. Optimum power trajectory

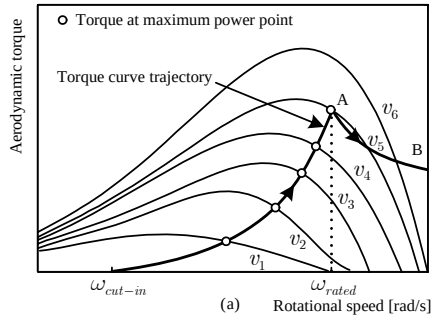

Figure 2. Optimum torque trajectory

Figure 3 shows a schematic diagram of a wind energy conversion system. The stator of the DFIG is directly connected to the grid to supply the active power. In the rotor circuit, there are two voltage-fed PWM converters inserted between the rotor and the grid. The first converter located at line side is used to regulate dc link voltage. There are two modes of operation for this converter. In the first mode called rectifying mode, the DFIG is operated in the sub-synchronous speed to boost voltage. In the second mode called inverting mode, the DFIG is operated in super-synchronous speed. The second converter is located at the machine side connected between the DFIG and the dc link to control the DFIG. This converter supplies and extracts the active power from the rotor when operated in sub- and supper-synchronous speed, respectively.

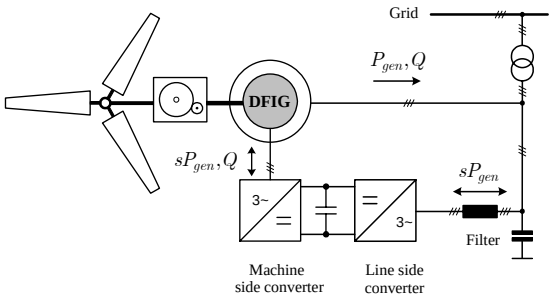

Figure 3. Wind turbine with DFIG vector control system

B. Operating Region

The DFIG generates its output power in sub- and super-synchronous speed with constant voltage and frequency by allowing the machine side converter to supply the rotor frequency at the difference between the rotor and synchronous frequency. When the DFIG is operated at super-synchronous speed (upper part of Fig. 4), the machine side converter supplies the negative sequence to the rotor and therefore the power will flow from both stator and rotor to the grid. When the rotational speed decreases lower than synchronous speed, the machine side converter supplies the reverse sequence and in this case, the power will flow in opposite direction (into the rotor) to prevent the DFIG switching from generator mode to motor-driven mode (lower part of Figure 4). Therefore, the DFIG can generate output power with constant frequency in both speed ranges.

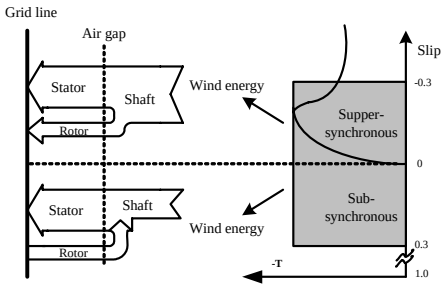

Figure 4. Operating range of DFIG

The optimal operating range of the DFIG should be between $0.7n_S < n < 1.3n_S$ to give the optimal size of converters (30% of the rating). For this reason, converter size is limited and the installed power rating of the wind turbine can be increased only up to 130 % of the rating of the DFIIG. Note that if the operating ranges greater or less than 30 % of synchronous speed, the system requires a larger size of converter that would be uneconomical [3].

C. Vector Control of DFIG

The machine side converter is controlled in a synchronously rotating *d*-, *q*-axis frame, with the *q*-axis oriented along the stator-flux vector position. In this way, a decoupled control between the electrical torque and the rotor excitation current is obtained. The machine side converter provides the actuation, and its controller requires the measurement of the stator and rotor currents, stator voltage and rotor position. Since the stator is connected to the grid, and the influence of the stator resistance is small, the stator magnetizing current i_{ms} can be considered constant. Under stator-flux orientation, the relationship between the torque and the *d*-, *q*- axis voltages, currents and fluxes (all scaled to be numerically equal to the AC per phase values) may be written as [4]:

$$\lambda_S = \lambda_{dS} = L_o i_{mS} = L_S i_{dS} + L_o i_{dR} = \text{constant} \tag{1}$$

$$\lambda_{qS} = L_o i_{qmS} = 0 \tag{2}$$

$$\lambda_{dR} = \frac{L_0^2}{L_S} i_{qmS} + \sigma L_R i_{dR}\,, \quad \lambda_{qR} = \sigma L_R i_{qR} \tag{3}$$

$$v_{dR} = R_R i_{dR} + \sigma L_R \frac{di_{dR}}{dt} - \omega_{slip}\sigma L_R i_{qR} \tag{4}$$

$$v_{qR} = R_R i_{qR} + \sigma L_R \frac{di_{qR}}{dt} + \omega_{slip}(\frac{L_0^2}{L_S} i_{dmS} + \sigma L_R i_{dR}) \tag{5}$$

$$m_M = -3\frac{P}{2} L_m i_{mS} i_{qR} \tag{6}$$

$$\omega_{slip} = \omega_s - \omega_r\,,\ \sigma = 1 - \frac{L_m^2}{L_s L_r} \tag{7}$$

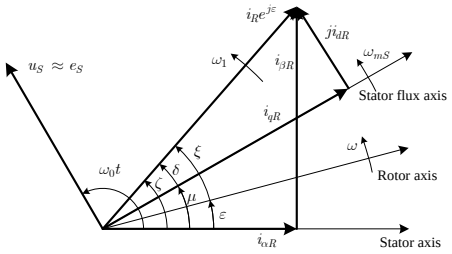

Figure 5. Angular relationships of rotor current vectors in rotor axis, stator flux axis and stator axis

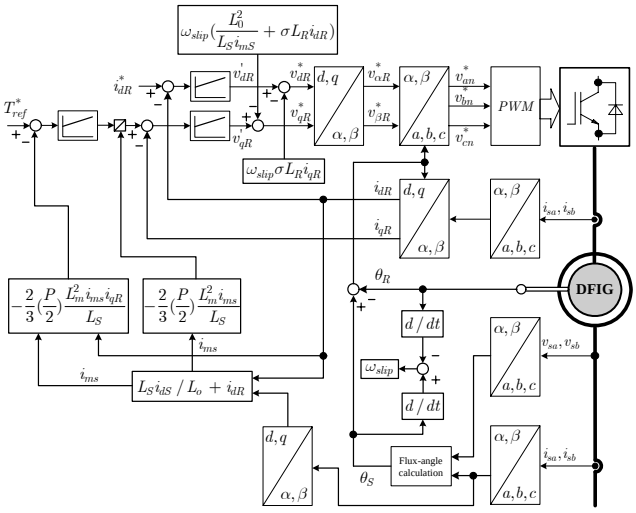

Figure 6. Vector control structure of machine side converter

III. Active and Reactive Power Control with Loss Minimization

A. Active and Reactive Power Control

The stator flux vector is adjusted to be aligned with the *q*-axis. The adjustment of the *d*-axis component of the rotor current controls either the generator torque or the stator side active power of the DFIG. On the other hand, regulating the rotor *d*-axis current component controls directly the stator-side reactive power. Using (1)-(6), the stator active power and reactive power can be obtained as [5-7]

$$P_S = -\frac{3}{2}\frac{L_m}{L_S} v_{qS} i_{qR} \tag{8}$$

$$Q_S = -\frac{3}{2}\frac{L_m}{L_S} v_{qs}(i_{ms} - i_{dR}) \tag{9}$$

where i_{mS} is the magnetizing current

It is noticeable that the stator active power component is proportional to i_{qR} and the stator reactive power component is proportional to i_{dR}. The normal control method is set Q_S equal zero by $i_{dR} = i_{mS}$.

B. Copper Loss Minimization

The output power wind turbine extracted from the wind is shown in (10). The power losses, P_{losses}, are composed of core losses, friction losses and copper losses. The first two losses are constant and therefore only copper losses are focused in this paper. The copper losses, P_{cu}, of DFIG depends on the coil resistances and currents, as described in (11) and (12).

$$P_t = P_S + P_R + P_{losses} \tag{10}$$

$$P_{cu} = P_{cuS} + P_{cuR} \tag{11}$$

where P_{cuS} and P_{cuR} are the stator and rotor copper losses.

$$P_{cu} = \frac{3}{2}(i_{qS}^2 + i_{dS}^2)R_S + \frac{3}{2}(i_{qR}^2 + i_{dR}^2)R_R \tag{12}$$

With $\lambda_S = \lambda_{dS} = L_S i_{dS} + L_o i_{dR}$ and $i_{qS} = -\frac{L_o}{L_S} i_{qR}$, substituting these terms into (12) gives

$$P_{cu} = \frac{3}{2}\left[(-\frac{L_o}{L_S} i_{qR})^2 + (\frac{\lambda_{dS} - L_o i_{dR}}{L_S})^2\right] R_S + \frac{3}{2}(i_{qR}^2 + i_{dR}^2)R_R$$

$$P_{cu} = \frac{3}{2}\left[(-\frac{L_o}{L_S} i_{qR})^2 + \frac{\lambda_{dS}^2}{L_S^2} - 2\frac{\lambda_{dS} L_o i_{dR}}{L_S^2} + \frac{L_o^2 i_{dR}^2}{L_S^2})^2\right] R_S + \frac{3}{2}(i_{qR}^2 + i_{dR}^2)R_R$$

$$P_{cu} = \frac{3}{2}(R_R + \frac{L_o^2}{L_S^2})i_{qR}^2 + \frac{3}{2}\frac{\lambda_{dS}^2}{L_S^2} R_S - 3\frac{L_o}{L_S^2}\lambda_{dS} R_S i_{dR} + \frac{3}{2}(\frac{L_o^2}{L_S^2} R_S + R_R)i_{dR}^2$$

$$P_{cu} = \frac{3}{2}(R_R + \frac{L_o^2}{L_S^2})i_{qR}^2 + \frac{3}{2}\frac{\lambda_{dS}^2}{L_S^2} R_S - 3\frac{L_o}{L_S^2}\lambda_{dS} R_S i_{dR} + \frac{3}{2}(\frac{L_o^2}{L_S^2} R_S + R_R)i_{dR}^2 \tag{13}$$

With constant λ_{dS} and known i_{qR}, the first term of (13) is constant. The copper losses can be minimized by

$$\frac{d}{di_{dR}}[\frac{3}{2}\frac{\lambda_{dS}^2}{L_S^2} R_S - 3\frac{L_o^2}{L_S^2}\lambda_{dS} R_S i_{dR} + \frac{3}{2}(\frac{L_o^2}{L_S^2} R_S + R_R)i_{dR}^2 = 0$$

$$i_{dR} = \frac{\lambda_{dS} R_S L_o}{(R_S L_o^2 + R_R L_S^2)} \tag{14}$$

The value of i_{dR} in (14) is used as the *d*-axis current reference for copper-loss minimization control.

IV. Case Study

The parameters of a DFIG used in this case study is given in the appendix. To verify the control performance of the DFIG and viability of the proposed control scheme, computer simulations are performed using Matlab Simulink.

A. DFIG Operation

The DFIG is initially started with zero stator active power ($i_{qR} = 0$) until t = 250. After that, when the current i_{qR} is stepped up, the DFIG is switched from sub-synchronous speed to super-synchronous speed. Figure 7 a) shows the response for a step change of i_{qR}^* at t = 250 ms with i_{dR}^* constant. Figure 7 b) shows the phase rotor current. Figure 7 c) shows stator voltage and current corresponding to the step current in Figure 7 a). The magnetizing current is initially supplied from both rotor and stator until t = 250 ms. The DFIG generates the active power with a majority part of the magnetizing current from the rotor and some part from the stator to minimize the copper losses. Note that DFIG requires a certain value of reactive power that can be fed from the stator, the rotor or both sides for operation.

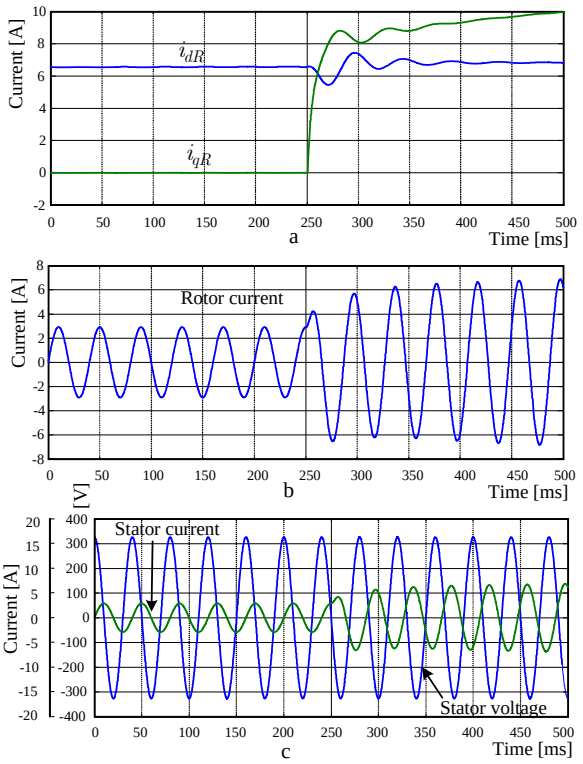

Figure 7. a) *d*- and *q*-axis current, b)rotor current and c)stator current and voltage.

The advantage of the DFIG is a smooth operation through synchronous speed, as can be seen in Fig. 8. The rotor can generate the active power (inverting mode) in the super-synchronous speed. In this case, the DFIG can supply an output power up to 1.3 times of its rating.

B. *Minimization of Copper Loss*

Figure 9 shows the copper losses with various *d*-axis rotor current references and constant torque. It can be seen that there is only one point that yields the minimum copper losses.

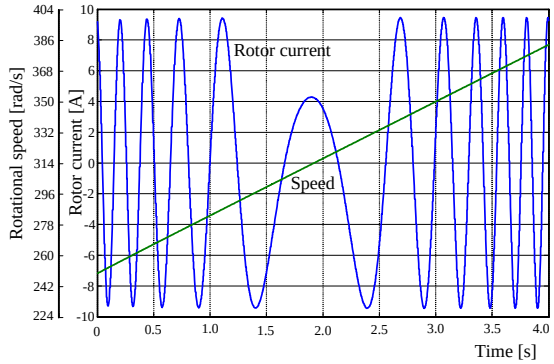

Figure 8. Operation of DFIG through synchronous speed

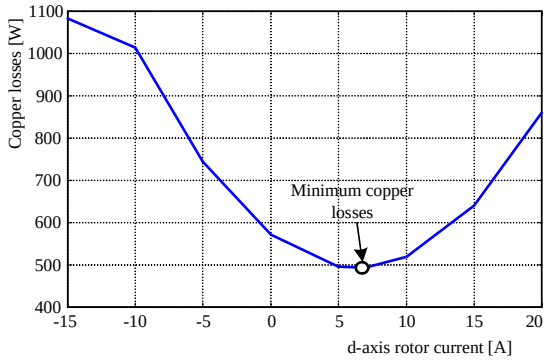

Figure 9. **C**opper losses versus *d*-axis rotor current

C. Efficiency Comparison of Power Losses

Figure 10 compares the efficiency of the copper loss minimization with that of a normal method (i.e., zero stator reactive power). It clearly shows that at low torque (low wind speed), a loss reduction of about 7% can be obtained from the improvement method. For higher torque, the purposed method can decrease a loss by 1-4%.

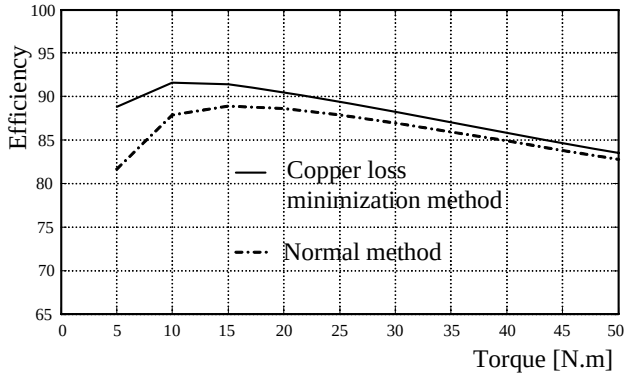

Figure 10. Efficiency with torque variation

V. CONCLUSION

The vector control of machines side converter of DFIG has been described, and the fundamental operational advantages have been verified. The active and reactive power is independently controlled based on *d*- and *q*-axis current, respectively. The main advantages of this control technique are smooth operation through synchronous speed, low distortion current fed to the supply and the ability to control the system power factor. The control objectives are to maximize output power from the wind by *q*-axis rotor current references while minimizing copper losses by *d*-axis rotor current references. The results from a case study show an improvement in the overall efficiency of the DFIG in the wind turbine system, particularly in low torque range (low speed range).

***Abstract*-This paper presents a soft-switching single-phase inverter for small grid-connected photovoltaic system. The proposed inverter is developed from the conventional PWM buck-boost inverter by inserted an auxiliary circuit that is used for achieve the soft-switching conditions without additional current and voltage stresses at switching devices. Theoretical analysis is verified by means of simulation results obtained from a design example rated at 100W. The simulation results show that a smaller switching losses and higher conversion efficiency are obtained by the proposed soft-switching inverter.**

I. INTRODUCTION

Due to the Kyoto agreement on global reduction of greenhouse gas emissions that generated by the burning process from the primary fossil fuels such as coal, oil, natural gas etc.[1] Many renewable energy sources are developed such as solar, wind, biomass and fuel cell. The solar energy is clean and viable source of electricity. It has been used as the main source for electrical loads in rural areas away from the grid or grid-connected in distributed energy production.

In recent years, the conventional buck-boost PWM inverters shown in Fig. 1(a) have been widely used for grid connected PV system [2-3] due to the individual operation and simple control. These systems compose of a PV array, a DC-DC converter and a DC-AC inverter. The DC-DC converter is used to boost the PV voltage to a level higher than the peak of the voltage utility and also responsible for tracking the maximum point of the PV array to fully utilize the PV power. The excessive power from the PV module to the load can be fed to the grid. The balance of power flow is controlled through the inverter. The dc-ac inverter is usually a pulse-width-modulation (PWM) voltage-source inverter, which shapes and inverters the output current. The inverter is also used to act as a high-frequency filter to eliminate the high-frequency component at the inverter output to achieve the low output harmonic distortion and high output power factor.

To minimize the size and weight of overall system, high switching frequency operations are required for inverters. However, high switching causes high switching stresses and switching power losses in the semiconductor devices. In order to solve these problems, resonant converters using zero voltage switching (ZVS) and zero current switching (ZCS) techniques [4] can be used to greatly reduce the switching losses at the expenses of high voltage or current stresses on power switches. For those buck-boost inverters without reactive energy feedback paths, the parasitic reactive energy due to the possible leakage of inductors also imposes transient high voltage, dv/dt or di/dt stresses on switch devices that causes high electromagnetic interference (EMI). Therefore, soft-transition switching techniques such as zero voltage transition (ZVT) and zero current transition (ZCT) [5-6] have been developed to minimize or eliminate both switching losses and stresses, and thus improving converter efficiency.

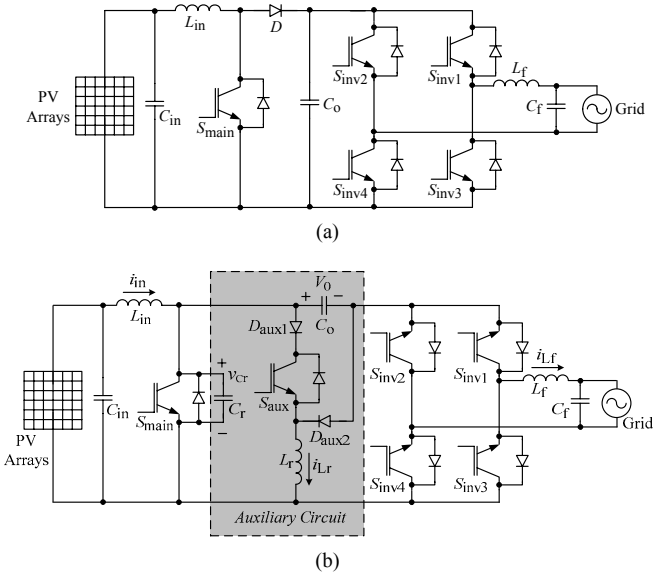

Figure 1. The single-phase inverter for grid-connected PV system
(a) The conventional inverter
(b) The proposed soft-switching inverter

In this paper, a soft-switching single-phase inverter for small grid-connected PV systems shown in figure 1(b) is proposed. This inverter combines the boost PWM dc/dc converter with the buck PWM inverter to a single-stage buck-boost PWM inverter [7]. An auxiliary circuit is used to provide all semiconductor switching devices operate at soft-switching without additional voltage and current stresses.

In the following, the operating principles of the proposed grid-connected PV system will be thoroughly discussed. Simulation results will be given to validate the effectiveness of the fulfilled functions.

II. SOFT-SWITCHING SINGLE-PHASE INVERTER

A. Circuit Description

Fig. 1(b) shows a proposed soft-switching single-phase inverter for small grid-connected PV systems. The circuit is composed of three units. The first unit is a PWM dc-dc boost converter which composed of L_{in}, S_{main} and C_o. The second unit is a PWM dc-ac buck inverter which composed of S_{inv1}, S_{inv2}, S_{inv3} and S_{inv4}. The last section is an auxiliary network that provides the soft-switching on the main switch S_{main}. This unit is composed of auxiliary diode D_{aux1}, D_{aux2}, the resonant inductor L_r, the resonant capacitor C_r and auxiliary switch S_{aux}. In the positive (negative) half-cycle of the output voltage $v_0(t)$, the switch S_{inv4} (S_{inv3}) always on, the switch S_{inv1} (S_{inv2}) and switch S_{inv3} (S_{inv4}) perform the inversion function, while the main switch S_{main} performs the dc-dc boost converter function in PWM continuous conduction mode (CCM).

B. Operation of The Proposed Soft-Switching Inverter

Fig. 2 shows the equivalent circuit of the soft-switching single-phase inverter. The operation modes of the inverter circuit are divided into fourteen operation modes from mode 1 to 14 in accordance with operating timing transitions from t_0 to t_{14}. Fig. 3 shows the relevant voltage and current operating waveforms of the soft-switching single-phase inverter.

To simplify the analysis, it is assumed that proposed inverter is operating in steady-state, the input filter capacitors L_{in} is much greater than the resonant inductor L_r and large enough to assume that the input current I_{lin} is constant, the capacitor C_o is large enough to assume that the voltage V_o is constant and no ripple, the resonant voltage of the resonant capacitor C_r is equaled to V_o and the resonant current of the resonant inductor L_r is equal to zero. The operation principle is described in the following.

1) *Mode* 1 [t_0 - t_1]: Prior to $t=t_0$, the switches S_{inv3} and S_{inv4} are turned on, S_{main} and S_{aux} are turned off. The output loop of the inverter is in a freewheeling state. At this time $t=t_0$, S_{aux} can turn on with ZCS, S_{inv1} and S_{inv3} are turned on and off with ZVS, respectively. The resonant inductor current $i_{Lr}(t)$ increases linearly from zero to I_{in} + I_{Lf} that causes the body diodes of inverter switch S_{inv1}-S_{inv4} turn off at $t=t_1$ with ZCS. The resonant current $i_{Lr}(t)$ and resonant voltage $v_{Cr}(t)$ can be respectively described as follows:

$$v_{Cr}(t) = V_0 \tag{1}$$

$$i_{Lr}(t) = \frac{V_0}{L_r} \cdot t \tag{2}$$

2) *Mode* 2 [t_1 – t_2]: At $t=t_0$ a resonance starts through C_r and L_r. Then $v_{Cr}(t)$ decreases from V_0 to zero in a sinusoidal fashion, $i_{Lr}(t)$ increases in a sinusoidal fashion through C_r and L_r.

$$v_{Cr}(t) = V_0 \cdot \cos \omega_n (t - t_1) \tag{3}$$

$$i_{Lr}(t) = I_{in} + \frac{V_0}{Z_n} \cdot \sin \omega_n (t - t_1) \tag{4}$$

where $\omega_n = 1/\sqrt{L_r \cdot C_r}$ and $Z_n = \sqrt{L_r / C_r}$

3) *Mode* 3 [t_2 – t_3]: During this time, a part of the current $i_{Lr}(t)$ freewheels through D_{aux1}, L_r, S_{aux} and body diode of S_{main}. The switch S_{main} can be turned on with ZVS at this time. S_{aux} is turned off at $t=t_3$.

$$v_{Cr}(t) = 0 \tag{5}$$

$$i_{Lr}(t) = I_{in} + \frac{V_0}{Z_n} \tag{6}$$

4) *Mode* 4 [t_3 – t_4]: The auxiliary switch S_{aux} is already turned off at $t=t_3$ then the auxiliary diode D_{aux2} is turned on. The resonant current $i_{Lr}(t)$ is linearly decreased to zero.

$$v_{Cr}(t) = 0 \tag{7}$$

$$i_{Lr}(t) = -\frac{V_0}{L_r} \cdot t + \left(I_{in} + \frac{V_0}{Z_n} \right) \tag{8}$$

5) *Mode* 5 [t_4 – t_5]: The auxiliary circuit is also used to make the dc-link voltage to zero and keep this status for a short switching transition time whenever the inverter switches need to have their status changed. So the switch S_{main} must be temporally turned off at $t=t_5$ for providing soft commutation at inverter switches.

6) *Mode* 6 [t_5 – t_6]: The switch S_{main} is turned off at $t=t_5$ then the resonant voltage $v_{Cr}(t)$ is linearly increased and the dc-link voltage $v_{pn}(t)$ is linearly decreased, respectively. This mode ends when $v_{Cr}(t)$ reaches V_o and $v_{pn}(t)$ is zero at $t=t_6$.

7) *Mode* 7 [t_6 – t_7]: At this time, all body diodes of the inverter switches can be turned on with ZVS. The inverter switch S_{inv1} and S_{inv3} can be turned off and on with ZVS, respectively.

8) *Mode* 8 [t_7 – t_8]: At $t=t_7$, the switch S_{main} will be turned on again to perform continuously the operation of boost converter, so the switch S_{aux} is turned on at this time for providing the ZVS condition for S_{main}.

After $t=t_8$, the inverter circuit acts continuously the freewheeling state. The operation principles of mode 9 to 13 are the same as the mode 2 to 6. The equivalent circuits of mode 9 to 14 are shown in Fig. 2(i) to Fig. 2(n), respectively. At mode 14 the buck inverter acts continuously the freewheeling state. After mode 14 the operation is returned to the first mode.

C. Soft-Switching Condition and Design Equations

In order to achieve soft commutation at ZVS for the main switch, the following constraints should be satisfied. The on time T_{aux} of the auxiliary switch S_{aux} should be as follows:

$$T_{aux} \geq T_1 + T_2 \tag{9}$$

where $$T_1 \equiv t_1 - t_0 = \frac{L_r \cdot I_{in}}{V_0} \quad (10)$$

$$T_2 \equiv t_2 - t_1 = \frac{\pi}{2} \cdot \sqrt{L_r \cdot C_r} \quad (11)$$

The resonant capacitor and inductor is calculated by

$$C_r = \frac{(a-1) \cdot I_{in,\max} \cdot T_{aux}}{\left[\frac{\pi}{2} + \frac{1}{(a-1)}\right] \cdot V_0} \quad (12)$$

$$L_r = \frac{V_0 \cdot T_{aux}}{\left[(a-1)\frac{\pi}{2} + 1\right] \cdot I_{in,\max}} \quad (13)$$

where a is the constant given by $1 \le a \le 1.5$

III. Simulation Results

A 40kHz, 100W, 220V output inverter is designed and simulated using Orcad PSpice simulation. The simulation waveforms shown in Fig. 4 and 5 confirm the soft-switching operation of the both switches in DC-DC converter and DC-AC inverter. The output voltage and current waveform are shown in Fig. 5

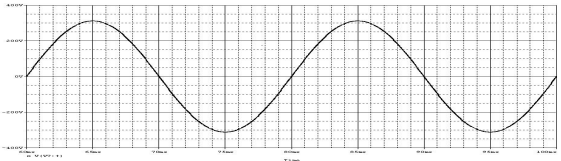
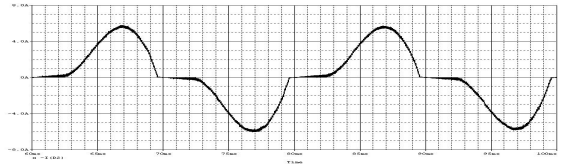
(b) Voltage and current waveforms of inverter switch S_{inv}



(a)



(b)

Figure 5. Simulated output waveform of the proposed inverter
(a) Output voltage (b) Output current

IV. Conclusion

The soft-switching single-phase inverter for small grid-connected PV systems was proposed. The proposed inverter with soft-switching auxiliary circuit was simulated rated at 100W. The simulation results confirmed that the boost switch and inverter switches were operated under soft-switching condition without additional current and voltage stresses.

***Abstract*-This paper proposes the design and implementation of line side converter of doubly fed induction generator. The mathematical models of line side converter, axis transformation, decoupling control and phase locked loop control are derived. A vector control system is implemented on a digital signal controller (DSC) with C language to control a 7.5 kW converter to regulate a 550V DC bus. Experiments are set up to test dynamic performance in rectifying and inverting modes of operation. The experimentation results confirm that the system can regulate the DC bus voltage under step load, can bi-directionally control power flow with a constant DC bus voltage, and reduce the line side current with near-unity power factor and low harmonic.**

Keywords: line side converter, decoupling control, vector control, phase locked loop

I. INTRODUCTION

Wind energy has long been recognized as one of the alternative options for electricity production and is gaining increasing importance throughout the world because it is pollution-free, affordable and sustainable. In general, power from a wind turbine highly depends on wind speed (i.e., power increases rapidly with wind speed). Therefore, locating wind generators in a place where wind speed is strong and reasonably constant is an important factor. In addition to such a constraint, operating a wind power plant requires efficient control techniques to extract power from the turbines as much as possible for any input wind speed. In general, a wind turbine is mechanically designed to produce its rated power at a certain wind speed which is referred as rated wind speed.

There are many types of wind generators such as DC generator, synchronous generator and induction generator but the doubly fed induction generator (DFIG) is widely used because it can deliver the active power in both stator and rotor. In addition, a small size of control converters is needed and the active power and reactive power can be independently controlled [1]. The control of a doubly fed induction generator in a wind conversion system uses a machine side converter and a line side converter [2]. The line side converter has two modes of operation: rectifying mode and inverting mode. In the rectifying mode, when the rotational speed of the DFIG is lower than synchronous speed, the rotor consumes the active power from the dc bus voltage, causing a decrease in the dc bus voltage. The line side converter charges the dc bus capacitor to regulate the dc bus voltage. In the inverting mode, when the rotational speed of the DFIG is higher than synchronous speed. The rotor delivers the active power to the dc bus voltage, causing an increase in the dc bus voltage. The line side converter discharges the dc bus capacitor to the grid to regulate the dc bus voltage.

The conversion from single phase and three-phase AC to DC voltage normally uses diode rectifiers, which cause non-sinusoidal line side current. As a result, the line side current contains many harmonic components and causes the difficulty in power factor correction by capacitor banks. For this reason, a new technique is developed to solve the above problem.

This paper proposes the design and construction of a three phase 7.5 kW line side converter. The mathematical models of line side converter, voltage decoupling control, phase locked loop (PLL) and the control block diagram are presented. The converter uses the decoupling control to regulate the DC bus voltage and drive the power converter by space vector PWM. The controller is implemented on a developed DSC board and tested with load to verify control performance.

II. MATHEMATICAL MODEL OF LINE SIDE CONVERTER

Figure 1 shows a three phase line side converter that converts AC voltage to DC voltage by a space vector PWM converter. The per phase voltage equation can be written as in (1)-(3).

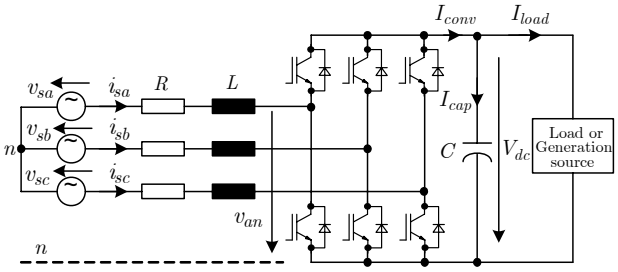

Figure 1. Line side converter

$$v_{sa} = Ri_{sa} + L\frac{di_{sa}}{dt} + v_{an} \quad (1)$$

$$v_{sb} = Ri_{sb} + L\frac{di_{sb}}{dt} + v_{bn} \quad (2)$$

$$v_{sc} = Ri_{sc} + L\frac{di_{sc}}{dt} + v_{cn} \quad (3)$$

Transforming (1)-(3) in three phases in stationary reference frame to two phase synchronous reference frame (*d*-, *q*-axis) gives

$$v_{sd} = (Ls + R)i_{sd} - \omega L i_{sq} + v_{dn} \quad (4)$$

$$v_{sq} = (Ls + R)i_{sq} + \omega L i_{sd} + v_{qn} \quad (5)$$

For the balance three phase,

$$v_{sd} = V_m \quad (6)$$

$$v_{sq} = 0 \quad (7)$$

The converter power, P_{conv}, and current, i_{conv}, can be calculated by (8) and (9) [3].

$$P_{conv} = \frac{3}{2}\left(v_{sd}i_{sd} + v_{sq}i_{sq}\right) \quad (8)$$

$$I_{conv} = \frac{P_{conv}}{V_{dc}^*} = \frac{3}{2}\frac{\left(v_{sd}i_{sd} + v_{sq}i_{sq}\right)}{V_{dc}^*} \quad (9)$$

The capacitor current, I_{cap}, and DC bus voltage, V_{dc}, can be calculated by (10) and (11).

$$I_{cap} = I_{conv} - I_{load} \quad (10)$$

$$V_{dc} = \frac{1}{Cs}\int I_{cap}dt \quad (11)$$

With the transformation of (4)-(11) into s-domain, a block diagram in *d*-, *q*-axis reference frame can be constructed as shown in Fig. 2. It is clear that there is the voltage cross coupling between v_{dn} and v_{qn}. To have independent control of V_{dc}, the coupling voltage should be compensated by a controller [4-5].

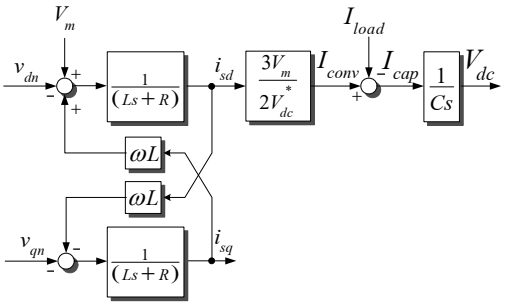

Figure 2. block diagram of line side converter in *d*-, *q*-axis reference frame

III. Control of Line Side Converter

The main control objective is to regulate the DC bus voltage without the voltage cross coupling. To achieve this objective, it is necessary to compensate the coupling components $\omega L i_{sq}$ and $\omega L i_{sd}$ with a PI controller. The control equations are as follows.

$$v_{dn}^* = (K_{pi} + \frac{K_{ii}}{s})(i_{sd}^* - i_{sd}) + \omega L i_{sq} + V_m \quad (11)$$

$$v_{qn}^* = (K_{pi} + \frac{K_{ii}}{s})(i_{sq}^* - i_{sq}) - \omega L i_{sd} \quad (12)$$

If the voltage couplings are compensated, the bus voltage depends only on the current i_{sd}. The PI controller is then used to control the bus voltage by the current i_{sd}. The control equation is shown in (13).

$$i_{sd}^* = (K_{pi} + \frac{K_{ii}}{s})(V_{dc}^* - V_{dc}) \quad (13)$$

With (11)-(13), the line side converter control with a voltage decoupling block diagram can be constructed as in Fig. 3. In the block diagram, the voltage cross coupling is compensated by feeding i_{sd} and i_{sq} with gain ωL. After the voltage is decoupled, the DC bus voltage is controlled by two loops: current and voltage loops. The current i_{sq} does not affect the bus voltage and therefore it is not used. The value of i_{sq} is set to zero.

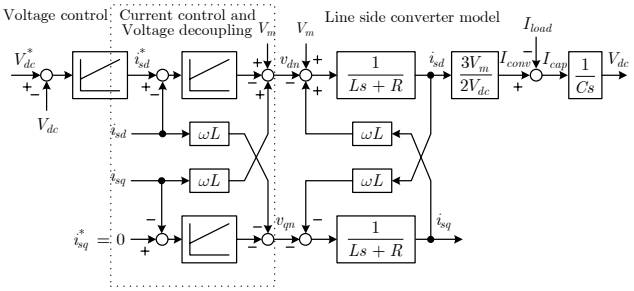

Figure 3. Line side converter with voltage decoupling control

The controller of the line side converter is controlled in *d*-, *q*-axis reference frame. The transformation between three phases and *d*-, *q*-axis requires an angle of phase voltage. A phase locked loop (PLL) to calculate the angle of phase voltage, θ^*, is shown in Fig. 4 [6]. The PLL is composed of voltage transformation, sine and cosine calculation and PI controller. The parameter θ^* in the transformation is obtained by integrating frequency command ω^*. If the frequency is identical to the grid frequency, the voltages v_{sd} and v_{sq} become DC values, depending on the angle θ^*. A PI regulator is used to obtain that value of ω^*, which drives the feedback voltage v_{sq} to the command value v_{sq}^*. The magnitude of the controlled quantity v_{sq} determines the phase difference between the utility voltages and sin(θ^*) or cos(θ^*). This system sets $v_{sq}^* = 0$.

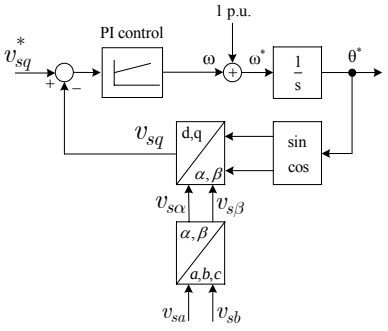

Figure 4. Phase locked loop

IV. Control Block Diagram

The overall control block diagram in Fig. 5 has two main parts. The first part is a power unit consisting of three single phase inductors, a power converter, DC-link capacitors and loads (right hand side). The second part is a control unit consisting of phase lock loop (PLL), axis transformation

(three phase to *d*-, *q*-axis), three PI controllers, axis transformation from *d*-, *q*-axis to a three phase and space vector PWM (left hand side).

To be operated in the rectifying mode, the converter obtains the power from the grid via the three phase inductor used to boost the voltage to the DC bus voltage. The DC output is connected with filter capacitor and loads. The power unit has three current sensors (two for line side and one for DC bus current) and three voltage sensors (two for line side and one for DC bus voltage). When the converter is operated in the inverting mode, the active power in the capacitor is injected via the converter to the grid to regulate the DC bus voltage or vice versa.

The digital signal controller controls the system with two references. One is i_{sq}^* for reactive power control (zero reactive power) and the other is V_{dc}^* for DC bus voltage control (550V). Both references are the inputs of PI controllers. The output of the controller will be changed to *d*-, *q*-axis voltage which is then transformed to three phase voltage. This voltage is converted to drive signal by the SVPWM to control the converter.

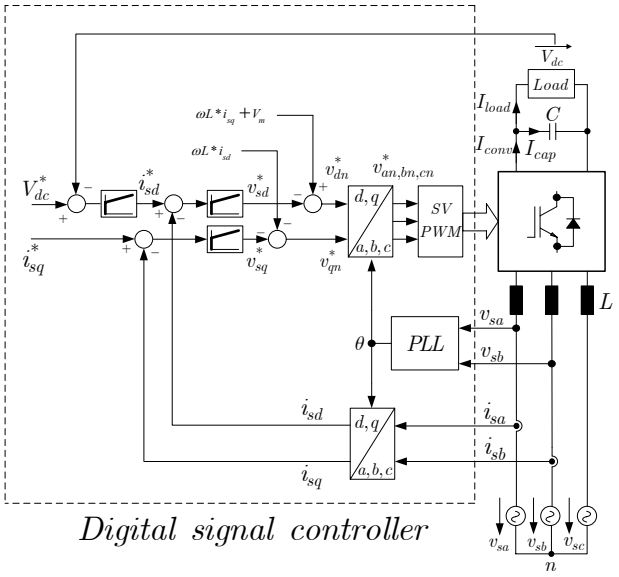

Figure 5. Control block diagram

V. CASE STUDY

A. Experimental Systems

The test system is shown in Fig. 6. The upper right corner of the figure is composed of a three phase 7.5 kW converter, DC link capacitors (925 μF), three single phase inductors (4.5mH), three phase variable voltage transformer, loads, voltage and current sensors. The lower part is composed of a data acquisition system connected to a DSC board, an oscilloscope and a personal computer. The controller board uses a high performance 16 bits dsPIC30f6010 combining the advantage of a high performance 16-bit microcontroller (MCU) and a high computation speed digital signal processors (DSP). The upper left corner is a variable DC voltage supply for tests in the inverting mode. This part can increase the DC voltage higher than the bus voltage to supply the active power in inverting operation.

This system is designed to regulate the DC bus voltage at 550 V and unity power factor with bi-directional power flow. The controller is implemented in the DSC and linked with a personal computer via RS232 port for transferring wind speed data to the DSC board and the other for sending parameters (e.g., $v_{sa}, i_{sb}, i_{sd}, i_{sq}$) to the computer for control verification.

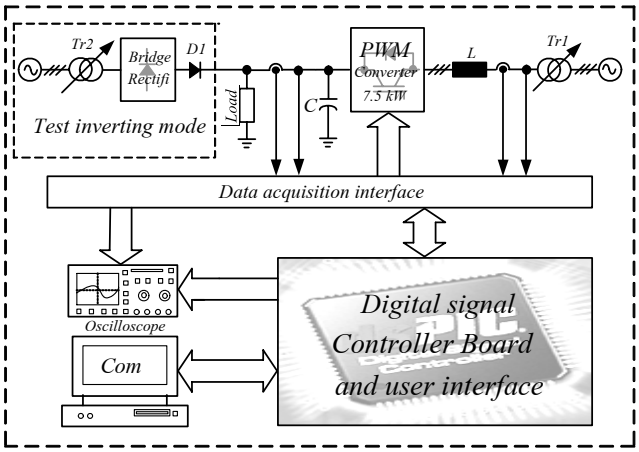

Figure 6. The test system

B. Dynamic Response

Figure 7 shows the DC bus voltage of the line side converter regulated at 550V, $t = 0.2$ seconds (point A). It can be seen that step resistance load causes a reduction in the DC bus voltage. The PI controller then commands to increase current i_{sd} (shown in Figure 8) to regulate the DC bus voltage. It takes 250 milliseconds to reach steady state with an undershoot voltage of 16.36%. At $t = 1.1$ second (point B), the resistance load is removed causing an increase in the DC bus voltage. The PI controller then commands to reduce current i_{sd} (as shown in Figure 8) to regulate the DC bus voltage. It takes 500 milliseconds to reach steady state with an overshoot voltage of 25.24%.

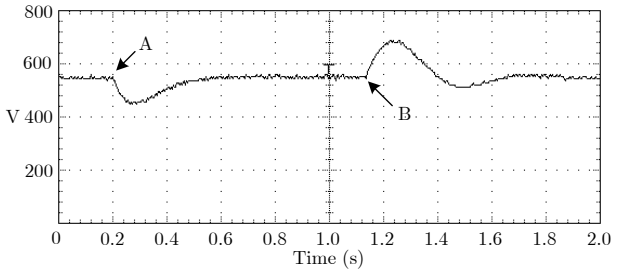

Figure 7. bus voltage with rectifying and inverting mode

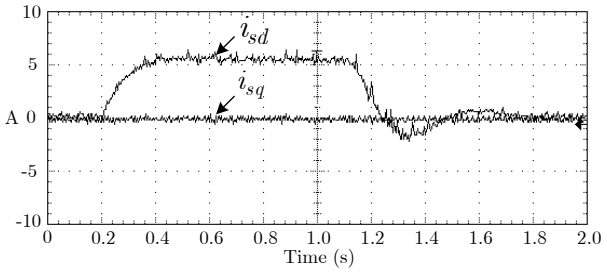

Figure 8. *d*, *q*-axis line current (i_{sd} , i_{sq})

Figure 9 shows the phase voltage v_{sa} and current i_{sa} of the supply side converter when it transits from the rectifying mode to the inverting mode. In the initial state, the system supplies load current and operates in the rectifying mode. After that, the load is suddenly reduced at $t = 10$ seconds, causing the DC bus voltage to increase, and the phase current to reduce to zero and flow to reverse direction. The operating mode is switched to inverting mode with 180° phase shift respect to the phase voltage with a transition time about 120 milliseconds.

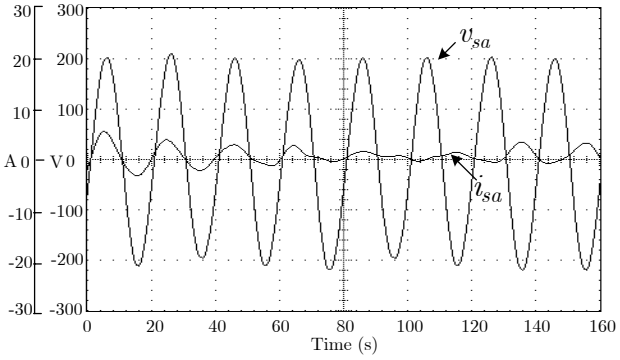

Figure 9. Line voltage, v_{sa} and current, i_{sa}

C. Rectifying and Inverting Mode Operation

Figure 10 shows the phase voltage v_{sa} and current i_{sa} of the supply side in the rectifying mode operation. It is clearly seen that the phase current has a low total harmonic distortion. The phase voltage and current are in phase, and by this mean this converter consumes the only active power from grid. Note that the actual power factor from a measurement is 0.98.

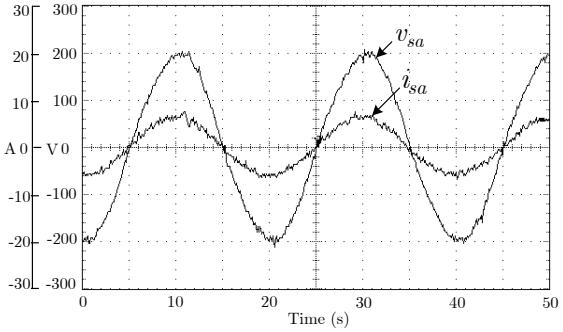

Figure 10. Line voltage, v_{sa} and current, i_{sa} in rectifying mode

Figure 11 shows the phase voltage v_{sa} and current i_{sa} of the supply side in the inverting mode operation. It is clearly seen that phase current has a low total harmonic distortion. The phase voltage and current are 180° out of phase, indicating this converter generates only active power to the grid.

VI. CONCLUSION

The detailed study and implementation of a 7.5 kW, three phase vector control PWM line side converter is presented. The algorithms are implemented on a developed low cost and high performance DSC board. This board also prepares computer interface for data acquisition system. The experimentation results confirm the following advantages of the implemented system. First, the DC bus voltage can be regulated in both rectifying and inverting modes. Second, the system can bi-directional control active power flow with unity power factor. Third, the controller can regulate the DC bus voltage under step load. Finally, this converter is suitable for front end of a doubly fed induction generator in wind turbine systems, power factor correction of the high power inverter and for electronic loads. However, the disadvantages of this system are high overshoot and undershoot voltage, and long setting time. Future work is the improvement of these problems.

Thermal Conductivity Tester

Santi Wangnipparnto and Tianchai suksri
Faculty of Engineering, Pathumwan Institute of Technology,
833 Ram 1 rd, Pathumwan, Bangkok, 10330, Thailand.

Abstract- This research has been designed and built the prototype of thermal conductivity tester for appropriate using in Thailand. Temperature ranges 40-60 ^{o}C are controlled by fuzzy logic controller. The four types of material, flat cement asbestos, black glazed mirror, clear mirror, and normal gypsum board are prepared and tested in standard size 100 mm wide, 100 mm long and thickness less than 10 mm. The controller is built by the personal computer, Interface card, and Visual Basic 6.0 program. All equipments are tested in the room where has the temperature range 23-25^{o}C. From the experimental shown that the fuzzy logic controller can be keep the temperature at the set point and has steady state error less than ± 0.5^{o}C. The thermal conductivity (k) value of four materials has the average margin error less than 15.3 % .

I. Introduction

Nowaday everyone interesting the saving energy and the environment in the home, building, and industry. Thermal insulation is the method of preventing heat from escaping a container or from entering the container. In other words, thermal insulation can keep an enclosed area such as a building warm, or it can keep the inside of a container cold. In any location where the effort is to minimize the transfer of heat from one area to another. So the thermal conductivity tester is importance to measuring thermal conductivity (k) of the thermal insulator materials and calculating the heat gain in order to prevent its by adding thickness of insulator or design the new composite insulator materials. For this research is designed and built the prototype of thermal cconductivity tester for using in Thailand.

II. Theory

Thermal conductivity

Thermal conductivity is a property of materials that expresses the heat flux (W/m^2) that will flow through the material if a certain temperature gradient DT (K/m) exists over the material as shows in Fig. 1.

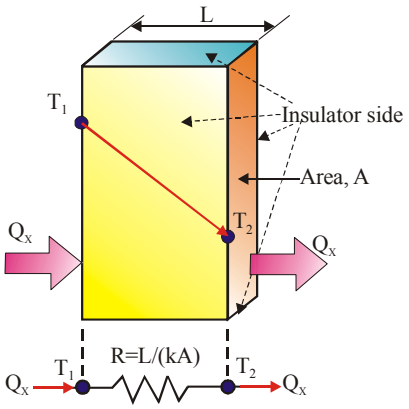

Figure 1. Conduction heat transfer equivalent.

Thermal conductivity is defined as:

$$k = \frac{Q/A}{\Delta T/\Delta L} \qquad (1)$$

where Q is the amount of heat passing through a cross section, A, and causing a temperature difference, ΔT, over a distance of ΔL. Q / A is the heat flux which is causing the thermal gradient, $\Delta T / \Delta L$. The measurement of thermal conductivity, therefore, always involves the measurement of the heat flux and temperature difference. The difficulty of the measurement is always associated with the heat flux measurement. Where the measurement of the heat flux is done directly (for example, by measuring the electrical power going into the heater), the measurement is called absolute.

Fuzzy logic controller

The conventional proportional-integral-derivative(PID) is commonly utilized in controlling the temperature, but the parameters of those controllers must be turned by tuning method[1,2]. On the other hand, the fuzzy logic controller is popularly implemented in many practical industrial automation applications. In this paper, we implement its by control the temperature in the one side of the hot flat plate as show in Fig. 2.

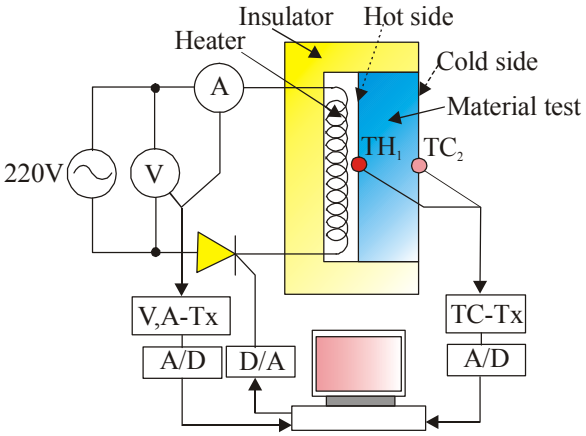

Figure 2. Schematic of thermal conductivity tester.

The input of fuzzy logic controller is the temperature error(e) between the set point and the process or hot plate side variable. The fuzzy logic controller consists of fuzzification, control rule and defuzzification stages as shown in Fig. 3.

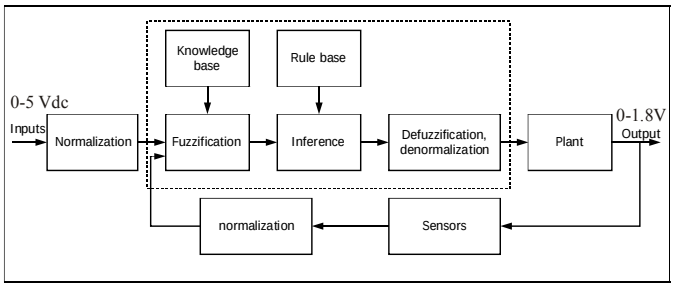

Figure 3. Block diagram of fuzzy logic controller.

Membership function editor is used for expressing input and output variables. The number of membership functions for each input variable is designated in five ranges and the names of its are positive big /positive small/zero/negative small/ negative big. The form of all input and output membership functions are selected to be triangle-shaped functions for simplicity. In fuzzification stages, the input variables, the temperature is converted into fuzzy variables using the membership function as shown in Fig. 4. The linguistic rules of e and ce of temperature are shown in Table 1.

Control rules for input and output variables

ce \ e	NB	NS	ZE	PS	PB
NB	T_1	T_1	T_1	T_1	T_1
NS	T_1	T_1	T_2	T_2	T_2
ZE	T_2	T_2	T_3	T_4	T_4
PS	T_4	T_4	T_4	T_5	T_5
PB	T_5	T_5	T_5	T_5	T_5

The defuzzificating operation, in this paper, uses the centroid defuzzification method because of its implementation simplicity.

III. Experimental Setup

The simplified of the thermal conductivity tester can be divided in two parts. The hardware consists of the testing box, personal computer and interface card as shown in Fig. 5. The software consists of the program control and front view of data that built its by Visual Basic 6.0 as shown in Fig. 6.

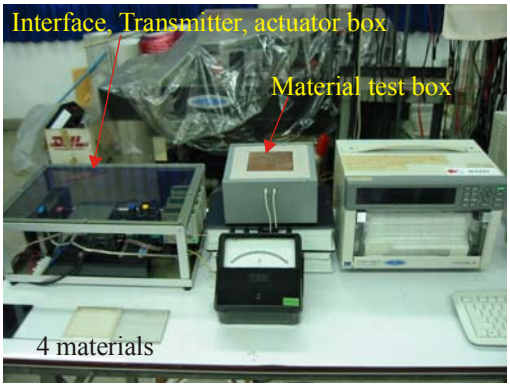

Figure 5. The experimental setup.

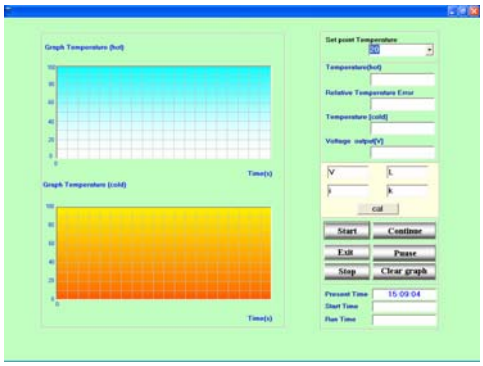

Figure 6 Front view of the thermal conductivity tester.

IV. EXPERIMENTAL RESULTS

The experimental results in this paper can be divided in two parts, the first shows performance of the fuzzy logic controller, the second finds thermal conductivity of four materials which compairing the standard value.

Temperature control by fuzzy logic controller

The hot plate side temperature of material test box is controlled by fuzzy logic controller. The responses time and steady state error of the temperature control when changing the step set point from 30–40°C and 30-60°C are shown in Fig.7 and Fig.8 respectively. From Fig.7 and Fig.8 show that steady state error less than ± 0.5°C and the response time less than 3 minutes.

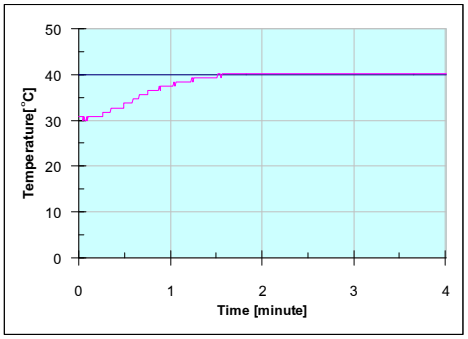

Figure 7. Changing the step set point from 30–40°C.

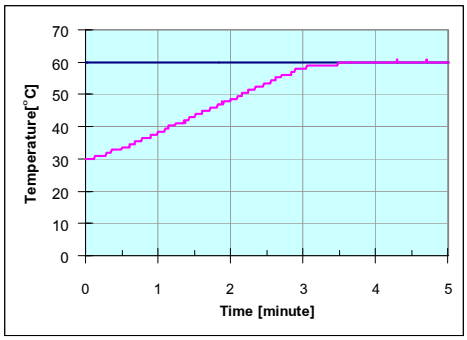

Figure 8. Changing the step set point from 30–60°C.

Thermal conductivity of materials

The four types of material, flat cement asbestos, black glazed mirror, clear mirror, and normal gypsum board are determinded the thermal conductivity by prepairing its in standard size 100 mm wide, 100 mm long and thickness less than 10 mm. Figure 9 shows the thermal conductivity of four materials which compaired the standard value and found that the maximum error occurred at flat cement asbestos about 15.31%.

b.)

Figure 9 The thermal conductivity of materials

V. CONCLUSION

The thermal conductivity tester which controlling the hot plate temperature by the fuzzy logic controller has been proposed. It has been shown that the steady state error of the

temperature control less than ± 0.5^{o}C and the response ttime less than 3 minutes.

A good agreement between the thermal conductivity value of all materials that testing by the thermal conductivity tester and the standard value, the flat cement asbestos has the maximum error about 15.31% from the standard value.

An Enhanced Adaptive Voltage Control in Gas Tungsten Arc Welding

Poolsak Koseepaporn

Department of Teacher Training in Electrical Engineering
Faculty of Technical Education
King Mongkut's Institute of Technology North Bangkok

***Abstract*-An improvement of the adaptation law of model-based adaptive control scheme is presented in this work. The proposed adaptation modification is designed for an adaptive voltage control in gas tungsten arc welding process. This method can overcome the limitation of persistent excitation of the conventional adaptation; the estimated of unknown parameters would converge to the correct values if the system is persistently excited. For the proposed approach, the true values of unknown parameters are mathematically obtained. As the results, the estimated unknown parameters can be forced to converge to the true values with and without persistent excitation. Therefore, the dynamic performance of the system is improved. The simulation results of the proposed method applied to gas tungsten arc welding process with argon shielding gas model show that the parameter adaptation is improved.**

I. INTRODUCTION

Automatic welding control is widely used for several decades. Servo drive is usually applied to control welding torch moving upward and downward in order to maintain distance from the workpiece which is commonly applied in piping welding based on Gas Tungsten Arc Welding (GTAW). One type of this kind of welding is so called "Automatic Voltage Control (AVC)". As shown in Fig. 1, AVC employs arc voltage, measured from electrode, to maintain arc length at a certain operating electric current. Although AVC is typically working well for automatic welding control, it has some limitation when the system gain has been changed due to welding parameters. It is because system gain varies with the arc length, arc voltage, and arc current as described by Bjorgvinson [1]. In addition, the welding current has to be ramped up and ramped down in order to prevent cracking at the starting and ending point of weld. Therefore, AVC that is designed for constant operating point can not cope with entire welding, especially for those ramped up and ramped down period. Consequently, oscillatory of welding torch will cause some damage at workpiece.

To solve this problem, gain scheduling method [2] has been proposed. However, this technique has a limitation of control method. All of possible welding parameters must be preprogrammed which is time consuming and also requires huge memory to store welding database. Later, an adaptive control method [3] is introduced to eliminate the previous limitation. The designed model-based adaptive controller is able to track the change in welding system gain due to the change in welding current while a fuzzy logic controller is used as a supervisor to monitor and to maintain the arc length stay in safe zone. Although this type of controller can successfully control the welding system, it cannot guarantee that the estimated parameters will converge to the actual unknown values. This is usually occurred if the system is not persistently excited. The reason behind this problem may come from one of these reasons. First, the adaptation gain is not appropriately selected to force the convergence of the estimated parameters to be fast enough within excitation period. Second, the excitation period is too short due to the small change in motion command. For these reasons, the dynamic behavior may not perform well and it requires several tests in order to get the desired dynamic behavior.

This paper presents an improvement of adaptation scheme for overcoming the limitation of persistence excitation. The controller and system equation are used to extract the unknown parameters which will be used to force the adaptive controller to adapt the system parameters to the correct values with and without excitation.

II. ADAPTIVE CONTROLLER DESIGN

To control the position of the welding torch, dc servo motor is widely used. As depicted in Fig. 2, the transfer function of servo motor expresses the relationship between the input motor voltage, $V_m(s)$, and the output arc length, $L_a(s)$. This transfer function is given by

$$G_s(s) = \frac{L_a(s)}{V_m(s)} = \frac{k_s}{s(s+a_s)}, \tag{1}$$

where k_s and a_s are servo gain and servo time constant, respectively. By using the relationship between the arc length and the arc voltage which is $L_a k_a = V_a$, equation (1) can be rewritten in time-domain equation as $\ddot{v}_a + a_s \dot{v}_a = k_s k_a v_m$. By letting $c_1 = (a_s / k_s k_a)$ and $c_2 = (1/k_s k_a)$, this time-domain equation is then

$$c_2 \ddot{v}_a + c_1 \dot{v}_a = v_m. \tag{2}$$

Note that k_a in c_1 and c_2 is a nonlinear function of welding current and arc length. It is, therefore, chosen to be unknown

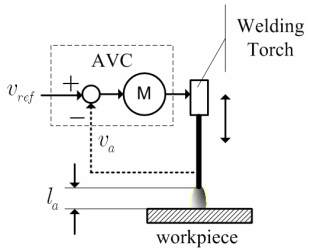

Figure 1. AVC in GTAW system.

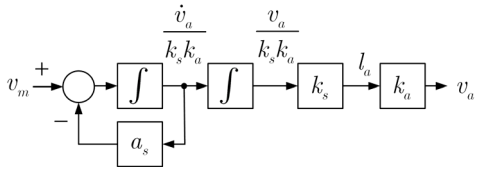

Figure 2. Block diagram of open-loop AVC.

parameters for adaptive system. Let replace the input of motor with a function of proportional-plus-derivative control law as given by

$$v_m = \hat{c}_2 v_m' + \hat{c}_1 \dot{v}_a \,, \tag{3}$$

where $\hat{c}_1$ and $\hat{c}_2$ are the estimated parameters of c_1 and c_2, respectively. In addition, v_m' is chosen as

$$v_m' = \ddot{v}_{ref} + k_v \dot{e} + k_p e \,, \tag{4}$$

where $e = v_{ref} - v_a$ is the error between voltage reference and the measured arc voltage. And k_v and k_p are the derivative and proportional error gain, respectively. By putting (4) into (3) and equating to (2), which is

$$c_2 \ddot{v}_a + c_1 \dot{v}_a = \hat{c}_2 [\ddot{v}_{ref} + k_v \dot{e} + k_p e] + \hat{c}_1 \dot{v}_a \,. \tag{5}$$

By rearranging (5) to be

$$c_2 \ddot{v}_a + (c_1 - \hat{c}_1)\dot{v}_a = \hat{c}_2 \ddot{v}_{ref} + \hat{c}_2 [k_v \dot{e} + k_p e] \,, \tag{6}$$

and subtracting both side by $\hat{c}_2 \ddot{v}_a$, it results in

$$\hat{c}_2 [\ddot{e} + k_v \dot{e} + k_p e] = \tilde{c}_2 \ddot{v}_a + \tilde{c}_2 \dot{v}_a \,, \tag{7}$$

where $\ddot{e} = \ddot{v}_{ref} - \ddot{v}_a$, $\tilde{c}_2 = c_2 - \hat{c}_2$, and $\tilde{c}_1 = c_1 - \hat{c}_1$.
The desired error equation, therefore, is

$$[\ddot{e} + k_v \dot{e} + k_p e] = \hat{c}_2^{-1} [\tilde{c}_2 \ddot{v}_a + \tilde{c}_2 \dot{v}_a] \,. \tag{8}$$

The result shown in (8) implies that if the estimated parameters ($\hat{c}_1$ and $\hat{c}_2$) are perfectly matched to the unknown parameters (c_1 and c_2), the error dynamic will, therefore, converge to zero. Furthermore, the error dynamic will behave upon the chosen k_v and k_p, the derivative and proportional error gain, respectively. Note that the proportional error gain is selected based on the closed-loop stiffness where the derivative gain in chosen upon the desired damping factor.

To derive the parameter estimation equation, the unknown parameters must be extracted from the error equation as

$$\ddot{e} + k_v \dot{e} + k_p e = \hat{c}_2^{-1} \mathbf{W}(\dot{v}_a, \ddot{v}_a)\Phi \,, \tag{9}$$

where

$$\Phi = \begin{bmatrix} c_2 - \hat{c}_2 \\ c_1 - \hat{c}_1 \end{bmatrix} = \begin{bmatrix} \tilde{c}_2 \\ \tilde{c}_1 \end{bmatrix} \text{ and } \mathbf{W}(\dot{v}_a, \ddot{v}_a) = \begin{bmatrix} \ddot{v}_a & \dot{v}_a \end{bmatrix}.$$

Let introduce a filtered servo error signal as

$$\mathbf{E}_1(s) = (s + \psi)\mathbf{E}(s) \,, \tag{10}$$

and substitute to (9) in Laplace transform, then yields

$$\begin{aligned} \mathbf{E}_1(s) &= \frac{s + \psi}{s^2 + k_v s + k_p} \hat{c}_2^{-1} \mathbf{W}\Phi \\ &= \mathbf{H}(s)\hat{c}_2^{-1}\mathbf{W}\Phi \end{aligned} \,, \tag{11}$$

which is corresponding to

$$\begin{aligned} \dot{\mathbf{x}} &= \mathbf{A}\mathbf{x} + \mathbf{B}(\hat{c}_2^{-1}\mathbf{W}\Phi) \\ \mathbf{y} &= \mathbf{C}\mathbf{x} \end{aligned} \,, \tag{12}$$

where $\mathbf{x} = \begin{bmatrix} e & \dot{e} \end{bmatrix}^T$. From the state equation in (12), there exists two positive-definite matrices $\mathbf{P} > \mathbf{0}$ and $\mathbf{Q} > \mathbf{0}$ such that

$$\begin{aligned} \mathbf{A}^T\mathbf{P} + \mathbf{P}\mathbf{A} &= -\mathbf{Q} \\ \mathbf{P}\mathbf{B} &= \mathbf{C}^T \end{aligned} \,. \tag{13}$$

The stability of this system can be obtained by choosing candidate Lyapunov function [4] as

$$\mathbf{V}(\mathbf{x}, \Phi) = \mathbf{x}^T\mathbf{P}\mathbf{x} + \Phi^T\Gamma^{-1}\Phi \,, \tag{14}$$

where $\Gamma = diag(\gamma_1, \gamma_2)$ and γ_i is nonnegative adaptation gain. Hence, the derivative of (14) is

$$\dot{\mathbf{V}}(\mathbf{x}, \Phi) = -\mathbf{x}^T\mathbf{Q}\mathbf{x} + 2\Phi^T(\mathbf{W}^T\hat{c}_2^{-1}e_1 + \Gamma^{-1}\dot{\Phi}). \tag{15}$$

To guarantee the stability of the system, $\dot{\Phi}$ is chosen to be

$$\dot{\Phi} = -\Gamma\mathbf{W}^T\hat{c}_2^{-1}e_1 \,, \tag{16}$$

which gives $\dot{\mathbf{V}}(\mathbf{x}, \Phi) = -\mathbf{x}^T\mathbf{Q}\mathbf{x}$. As can be seen, (16) is therefore the adaptation law for model-based adaptive control.

III. Adaptation Law Modification

From the arc model as shown in Fig. 2, the state after the first integrator gives

$$\frac{1}{k_s k_a}\dot{v}_a = \int v_m dt - \frac{a_s}{k_s k_a} v_a . \tag{17}$$

By rearranging (17) to be

$$\frac{a_s}{k_s k_a} v_a = \int v_m dt - \frac{1}{k_s k_a}\dot{v}_a . \tag{18}$$

Assuming that k_a is constant, the arc length and arc voltage relationship then is $k_a \dot{l}_a \triangleq \dot{v}_a$. Replacing this part to (18), one of unknown parameters can then be written as

$$c_1 = \frac{1}{v_a}\left[\int v_m dt - \frac{1}{k_s}\dot{l}_a\right]. \tag{19}$$

Note that the servo gain (k_s) is assumed to be known which can be obtained at steady state condition. By integrating (2), another unknown parameter can be determined by

$$c_2 = \frac{1}{v_a}\left[\iint v_m dt dt - \int c_1 v_a dt\right]. \tag{20}$$

Based on the adaptation derived from (16), the estimated parameters which are obtained by integration thus are

$$\begin{bmatrix}\hat{c}_1\\ \hat{c}_2\end{bmatrix} = \int \left(\Gamma \mathbf{W}^T \hat{c}_2^{-1} e_1\right) dt . \tag{21}$$

By applying the results from (19) and (20), (21) can be modified such that the estimated parameters converge to the correct values as

$$\begin{bmatrix}\hat{c}_1\\ \hat{c}_2\end{bmatrix} = \int \left(\Gamma \mathbf{W}^T \hat{c}_2^{-1} e_1\right) dt + \int \Phi e^{-\eta|v'_m|} dt , \tag{22}$$

where η is a nonnegative number for adjusting convergence rate. As shown in Fig. 3, the result of the proposed adaptation law can be illustrated in block diagram modified from the conventional adaptive method.

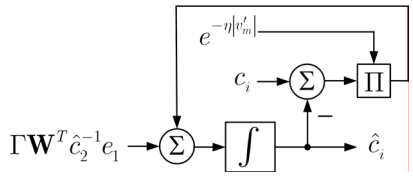

Figure 3. Block diagram of proposed adaptation law.

IV. Simulation Results

This section illustrates the evaluation of the proposed method in the GTAW process. Based on the arc model described in [1], the argon type of shielding gas gives the relation between arc voltage and arc length so called arc sensitivity which as

$$k_v = \frac{dv_a}{dl_a} = \left[0.446 + 0.0029 i_a + e^{-0.073 i_a}\right]. \tag{23}$$

To verify the proposed method, two simulations are introduced. The first simulation demonstrates the dynamic behavior of the system for input step function. The second simulation shows tracking performance when the closed-loop parameters are changed according to the change in arc current set point. The comparison between conventional and the proposed method are provided in both simulations.

Throughout the first simulation, following parameters are set; $k_p = 30$, $k_v = 5$, $a_s = 10$, $k_s = 9$, $\psi = 1.4$, and $\Gamma = diag(0.01, 0.0001)$. In addition, arc current set point is chosen at 100 A, where the reference voltage is a step function from 8 V to 15 V at 5 seconds of time. Result from the first simulation shows that the estimated parameters of the conventional adaptive system could not converge to correct values where the proposed method is able to improve the convergence of the estimated parameters to the actual values as shown in Fig. 4 and 5. As the results, the arc voltage of the proposed method has an improved response compared to the conventional method as illustrated in Fig. 6.

The second simulation demonstrates the behavior of the adaptive systems when the system parameters are changed according to the change of arc current set point varied from 100 A to 5 A as illustrated in Fig. 7. By applying the same set of controller parameters employed in the first simulation, the estimated parameters of the conventional adaptive system cannot be updated to the correct values. In contrast, the estimated parameters of the proposed method can converge to the actual values as shown in Fig. 8. Consequently, the response of the proposed method has a smaller perturbation causing by input current set point as shown in Fig. 9.

V. Conclusions

The higher efficient adaptation law is presented for overcoming the problem of persistence excitation which improves overall dynamic performance of a special type of adaptive system. The unknown welding system parameters can be obtained mathematically resulting in the convergence of the estimated parameters to the true values. For this reason, the proposed adaptive method for GTAW can track the change of system parameters due to the change in arc current set point which is generally to prevent cracking at the starting and ending point of weld. As the results, the dynamic performance of the adaptive system is improved with less effort in finding control parameters.

Robust $\mathcal{H}_\infty$ Fuzzy Control Design for Nonlinear Two-Time Scale System with Markovian Jumps based on LMI Approach

Wudhichai Assawinchaichote* and Sing Kiong Nguang

***Abstract*— This paper examines the problem of designing a robust $\mathcal{H}_\infty$ state-feedback controller for a class of nonlinear two-time scale systems with Markovian Jumps described by a Takagi-Sugeno (TS) fuzzy model. Based on a linear matrix inequality (LMI) approach, LMI-based sufficient conditions for the uncertain Markovian jump nonlinear two-time scale systems to have an $\mathcal{H}_\infty$ performance are derived. The proposed approach does not involve the separation of states into slow and fast ones and it can be applied not only to standard, but also to nonstandard nonlinear two-time scale systems. A numerical example is provided to illustrate the design developed in this paper.**

I. INTRODUCTION

Markovian jump systems, sometimes called hybrid systems with a state vector, consists of two components; i.e., the state (differential equation) and the mode (Markov process). The Markovian jump system changes abruptly from one mode to another mode caused by some phenomenon such as environmental disturbances, changing subsystem interconnections and fast variations in the operating point of the system plant, etc. The switching between modes is governed by a Markov process with the discrete and finite state space. Over the past few decades, the Markovian jump systems have been extensively studied by many researchers; see [1]-[12]. This is due to the fact that jumping systems have been a subject of the great practical importance.

For the past three decades, singularly perturbed systems have been intensively studied by many researchers; see [12]-[17]. Singularly perturbed systems also known as multiple (two) time-scale dynamic systems normally occur due to the presence of small "parasitic" parameters, typically small time constants, masses, etc. In state space, such systems are commonly modelled using the mathematical framework of singular perturbations, with a small parameter, say ε, determining the degree of separation between the "slow" and "fast" modes of the system. However, it is necessary to note that it is possible to solve the singularly perturbed systems without separating between slow and fast mode subsystems. But the requirement is that the "parasitic" parameters must be large enough. In the case of having very small "parasitic" parameters which normally occur in the description of various physical phenomena, a popular approach adopted to handle these systems is based on the so-called reduction technique. According to this technique the fast variables are replaced by their steady states obtained with "frozen" slow variables and controls, and the slow dynamics is approximated by the corresponding reduced order system. This time-scale is asymptotic, that is, exact in the limit, as the ratio of the speeds of the slow versus the fast dynamics tends to zero.

In the last few years, the research on singularly perturbed systems in the $\mathcal{H}_\infty$ sense has been highly recognized in control area due to the great practical importance. $\mathcal{H}_\infty$-optimal control of singularly perturbed linear systems under either perfect state measurements or imperfect state measurements has been investigated via differential game theoretics approach. Although many researchers have studied the $\mathcal{H}_\infty$ control design of linear singularly perturbed systems for many years, the $\mathcal{H}_\infty$ control design of nonlinear singularly perturbed systems remains as an open research area. This is due to, in general, nonlinear singularly perturbed systems can not be decomposed into slow and fast subsystems.

Recently, a great amount of effort has been made on the design of fuzzy $\mathcal{H}_\infty$ for a class of nonlinear systems which can be represented by a Takagi-Sugeno (TS) fuzzy model; see [18]-[21]. Recent studies [18]-[22] show that a fuzzy model can be used to approximate global behaviors of a highly complex nonlinear system. In this fuzzy model, local dynamics in different state space regions are represented by local linear systems. The overall model of the system is obtained by "blending" of these linear models through nonlinear fuzzy membership functions. Unlike conventional modelling which uses a single model to describe the global behavior of a system, fuzzy modelling is essentially a multi-model approach in which simple sub-models (linear models) are combined to describe the global behavior of the system. Employing the existing fuzzy results [18]-[22] on the singularly perturbed system, one ends up with a family of ill-conditioned linear matrix inequalities resulting from the interaction of slow and fast dynamic modes. In general, ill-conditioned linear matrix inequalities are very difficult to solve.

What we intend to do in this paper is to design a robust $\mathcal{H}_\infty$ fuzzy state-feedback controller for a class of uncertain nonlinear two time-scale dynamic systems with Markovian jumps. First, we approximate this class of uncertain nonlinear two time-scale dynamic systems with Markovian jumps by a Takagi-Sugeno fuzzy model with Markovian jumps. Then based on an LMI approach, we develop a technique for designing a robust $\mathcal{H}_\infty$ fuzzy state-

feedback controller such that the $\mathcal{L}_2$-gain of the mapping from the exogenous input noise to the regulated output is less than a prescribed value. To alleviate the ill-conditioned linear matrix inequalities resulting from the interaction of slow and fast dynamic modes, these ill-conditioned LMIs are decomposed into ε-independent LMIs and ε-dependent LMIs. The ε-independent LMIs are not ill-conditioned and the ε-dependent LMIs tend to zero when ε approaches to zero. If ε is sufficiently small, the original ill-conditioned LMIs are solvable if and only if the ε-independent LMIs are solvable. The proposed approach does not involve the separation of states into slow and fast ones, and it can be applied not only to standard, but also to nonstandard two time-scale dynamic systems.

This paper is organized as follows. In Section II, system descriptions and definition are presented. In Section III, based on an LMI approach, we develop a technique for designing a robust $\mathcal{H}_\infty$ fuzzy state-feedback controller such that the $\mathcal{L}_2$-gain of the mapping from the exogenous input noise to the regulated output is less than a prescribed value for the system described in Section II. The validity of this approach is demonstrated by an example from a literature in Section IV. Finally, conclusions are given in Section V.

II. System Descriptions and Definitions

The class of nonlinear uncertain two-time scale systems with Markovian jumps under consideration is described by the following TS fuzzy model with Markovian jumps:

$$\begin{aligned} E_\varepsilon \dot{x}(t) &= \sum_{i=1}^{r} \mu_i(\nu(t))\Big[[A_i(\eta(t)) + \Delta A_i(\eta(t))]x(t) \\ &\quad +[B_{1_i}(\eta(t)) + \Delta B_{1_i}(\eta(t))]w(t) \\ &\quad +[B_{2_i}(\eta(t)) + \Delta B_{2_i}(\eta(t))]u(t)\Big], \;\; x(0) = 0, \\ z(t) &= \sum_{i=1}^{r} \mu_i(\nu(t))\Big[[C_{1_i}(\eta(t)) + \Delta C_{1_i}(\eta(t))]x(t) \\ &\quad +[D_{12_i}(\eta(t)) + \Delta D_{12_i}(\eta(t))]u(t)\Big] \end{aligned} \tag{1}$$

where $E_\varepsilon = \begin{bmatrix} I & 0 \\ 0 & \varepsilon I \end{bmatrix}$, $\varepsilon > 0$ is the singular perturbation parameter, $\nu(t) = [\nu_1(t) \; \cdots \; \nu_\vartheta(t)]$ is the premise variable that may depend on states in many cases, $\mu_i(\nu(t))$ denote the normalized time-varying fuzzy weighting functions for each rule, ϑ is the number of fuzzy sets, $x(t) \in \Re^n$ is the state vector, $u(t) \in \Re^m$ is the input, $w(t) \in \Re^p$ is the disturbance which belongs to $\mathcal{L}_2[0,\infty)$, $z(t) \in \Re^s$ is the controlled output, the matrix functions $A_i(\eta(t))$, $B_{1_i}(\eta(t))$, $B_{2_i}(\eta(t))$, $C_{1_i}(\eta(t))$, $D_{12_i}(\eta(t))$, $\Delta A_i(\eta(t))$, $\Delta B_{1_i}(\eta(t))$, $\Delta B_{2_i}(\eta(t))$, $\Delta C_{1_i}(\eta(t))$ and $\Delta D_{12_i}(\eta(t))$ are of appropriate dimensions. $\{\eta(t))\}$ is a continuous-time discrete-state Markov process taking values in a finite set $\mathcal{S} = \{1, 2, \cdots, s\}$ with transition probability matrix $Pr \triangleq \{P_{\imath k}(t)\}$ given by

$$\begin{aligned} P_{\imath k}(t) &= Pr(\eta(t+\Delta) = k | \eta(t) = \imath) \\ &= \begin{cases} \lambda_{\imath k}\Delta + O(\Delta) & \text{if } \imath \neq k \\ 1 + \lambda_{\imath\imath}\Delta + O(\Delta) & \text{if } \imath = k \end{cases} \end{aligned} \tag{2}$$

where $\Delta > 0$, and $\lim_{\Delta \longrightarrow 0} \frac{O(\Delta)}{\Delta} = 0$. Here $\lambda_{\imath k} \geq 0$ is the transition rate from mode $\imath$ (system operating mode) to mode k ($\imath \neq k$), and

$$\lambda_{\imath\imath} = -\sum_{k=1, k\neq\imath}^{s} \lambda_{\imath k}. \tag{3}$$

For the convenience of notations, we let $\mu_i \triangleq \mu_i(\nu(t))$, $\eta = \eta(t)$, and any matrix $M(\mu, \imath) \triangleq M(\mu, \eta = \imath)$. The matrix functions $\Delta A_i(\eta)$, $\Delta B_{1_i}(\eta)$, $\Delta B_{2_i}(\eta)$, $\Delta C_{1_i}(\eta)$ and $\Delta D_{12_i}(\eta)$ represent the time-varying uncertainties in the system and satisfy the following assumption.

Assumption 1:

$$\begin{aligned} \Delta A_i(\eta) &= F(x(t), \eta, t)H_{1_i}(\eta), \\ \Delta B_{1_i}(\eta) &= F(x(t), \eta, t)H_{2_i}(\eta), \\ \Delta B_{2_i}(\eta) &= F(x(t), \eta, t)H_{3_i}(\eta), \\ \Delta C_{1_i}(\eta) &= F(x(t), \eta, t)H_{4_i}(\eta), \\ \text{and } \; \Delta D_{12_i}(\eta) &= F(x(t), \eta, t)H_{5_i}(\eta), \end{aligned}$$

where $H_{j_i}(\eta), \; j = 1, 2, \cdots, 5$ are known matrices which characterize the structure of the uncertainties. Furthermore, there exists a positive function $\rho(\eta)$ such that the following inequality holds:

$$\|F(x(t), \eta, t)\| \leq \rho(\eta). \tag{4}$$

We recall the following definition.

Definition 1: Suppose γ is a given positive number. A system of the form (1) is said to have the $\mathcal{L}_2$-gain less than or equal to γ if

$$\mathbf{E}\left[\int_0^{T_f} \{z^T(t)z(t) - \gamma^2 w^T(t)w(t)\}\, dt\right] \leq 0, \; x(0) = 0 \tag{5}$$

where $\mathbf{E}[\cdot]$ stands for the mathematical expectation, for all T_f and all $w(t) \in \mathcal{L}_2[0, T_f]$.

Note that for the symmetric block matrices, we use $(*)$ as an ellipsis for terms that are induced by symmetry.

III. Robust $\mathcal{H}_\infty$ Fuzzy State-Feedback Control Design

This section provides the LMI-based solutions to the problem of designing a robust $\mathcal{H}_\infty$ fuzzy state-feedback controller that guarantees the $\mathcal{L}_2$-gain of the mapping from the exogenous input noise to the regulated output to be less than some prescribed value.

First, we consider the following $\mathcal{H}_\infty$ fuzzy state-feedback which is inferred as the weighted average of the local models of the form:

$$u(t) = \sum_{j=1}^{r} \mu_j K_j(\imath)x(t). \tag{6}$$

Then, we describe the problem under our study as follows.

Problem Formulation: Given a prescribed $\mathcal{H}_\infty$ performance $\gamma > 0$, design a robust $\mathcal{H}_\infty$ fuzzy state-feedback controller of the form (6) such that the inequality (5) holds.

Before presenting our first main result, we recall the following lemma.

Lemma 1: Consider the system (1). Given a prescribed $\mathcal{H}_\infty$ performance $\gamma > 0$, for $\imath = 1, 2, \cdots, s$, if there exist matrices $P_\varepsilon(\imath) = P_\varepsilon^T(\imath)$, positive constants $\delta(\imath)$ and matrices $Y_j(\imath)$, $j = 1, 2, \cdots, r$ such that the following ε-dependent linear matrix inequalities hold:

$$P_\varepsilon(\imath) > 0 \tag{7}$$
$$\Psi_{ii}(\imath, \varepsilon) < 0, \quad i = 1, 2, \cdots, r \tag{8}$$
$$\Psi_{ij}(\imath, \varepsilon) + \Psi_{ji}(\imath, \varepsilon) < 0, \quad i < j \leq r \tag{9}$$

where

$$\Psi_{ij}(\imath, \varepsilon) = \begin{pmatrix} \Phi_{ij}(\imath, \varepsilon) & (*)^T & (*)^T & (*)^T \\ \mathcal{R}(\imath)\tilde{B}_{1_i}^T(\imath) & -\gamma\mathcal{R}(\imath) & (*)^T & (*)^T \\ \Upsilon_{ij}(\imath, \varepsilon) & 0 & -\gamma\mathcal{R}(\imath) & (*)^T \\ \mathcal{Z}^T(\imath, \varepsilon) & 0 & 0 & -\mathcal{P}(\imath, \varepsilon) \end{pmatrix} \tag{10}$$

$$\begin{aligned} \Phi_{ij}(\imath, \varepsilon) =& A_i(\imath)E_\varepsilon^{-1}P_\varepsilon(\imath) + E_\varepsilon^{-1}P_\varepsilon(\imath)A_i^T(\imath) \\ &+ B_{2_i}(\imath)Y_j(\imath) + Y_j^T(\imath)B_{2_i}^T(\imath) \\ &+ \lambda_{\imath\imath}E_\varepsilon^{-1}P_\varepsilon(\imath), \end{aligned} \tag{11}$$

$$\Upsilon_{ij}(\imath, \varepsilon) = \tilde{C}_{1_i}(\imath)E_\varepsilon^{-1}P_\varepsilon(\imath) + \tilde{D}_{12_i}(\imath)Y_j(\imath), \tag{12}$$

$$\mathcal{R}(\imath) = \text{diag}\left\{\delta(\imath)I, I, \delta(\imath)I, I\right\}, \tag{13}$$

$$\begin{aligned} \mathcal{Z}(\imath, \varepsilon) =& \Big(\sqrt{\lambda_{\imath 1}}E_\varepsilon^{-1}P_\varepsilon(\imath) \ \cdots \ \sqrt{\lambda_{\imath(\imath-1)}}E_\varepsilon^{-1}P_\varepsilon(\imath) \\ & \sqrt{\lambda_{\imath(\imath+1)}}E_\varepsilon^{-1}P_\varepsilon(\imath) \ \cdots \ \sqrt{\lambda_{\imath s}}E_\varepsilon^{-1}P_\varepsilon(\imath)\Big), \end{aligned} \tag{14}$$

$$\begin{aligned} \mathcal{P}(\imath, \varepsilon) =& \ diag\Big\{E_\varepsilon^{-1}P_\varepsilon(1), \cdots, E_\varepsilon^{-1}P_\varepsilon(\imath-1), \\ & E_\varepsilon^{-1}P_\varepsilon(\imath+1), \cdots, E_\varepsilon^{-1}P_\varepsilon(s)\Big\}, \end{aligned} \tag{15}$$

with

$$\begin{aligned} \tilde{B}_{1_i}(\imath) =& \begin{bmatrix} I & I & I & B_{1_i}(\imath) \end{bmatrix} \\ \tilde{C}_{1_i}(\imath) =& \Big[\gamma\rho(\imath)H_{1_i}^T(\imath) \ \sqrt{2}\aleph(\imath)\rho(\imath)H_{4_i}^T(\imath) \\ & 0 \ \sqrt{2}\aleph(\imath)C_{1_i}^T(\imath)\Big]^T \\ \tilde{D}_{12_i}(\imath) =& \Big[0 \ \sqrt{2}\aleph(\imath)\rho(\imath)H_{5_i}^T(\imath) \\ & \gamma\rho(\imath)H_{3_i}^T(\imath) \ \sqrt{2}\aleph(\imath)D_{12_i}^T(\imath)\Big]^T \\ \aleph(\imath) =& \left(I + \rho^2(\imath)\sum_{i=1}^{r}\sum_{j=1}^{r}\left[\|H_{2_i}^T(\imath)H_{2_j}(\imath)\|\right]\right)^{\frac{1}{2}} \end{aligned}$$

then the inequality (5) holds. Furthermore, a suitable choice of the fuzzy controller is

$$u(t) = \sum_{j=1}^{r}\mu_j K_{\varepsilon_j}(\imath)x(t) \tag{16}$$

where

$$K_{\varepsilon_j}(\imath) = Y_j(\imath)(P_\varepsilon(\imath))^{-1}E_\varepsilon. \tag{17}$$

Proof: The desired result can be carried out by a similar technique used in [23], [24], and [25]. The detail of the proof is omitted for brevity. ■

Remark 1: The linear matrix inequalities given in Lemma 1 becomes ill-conditioned when ε is sufficiently small, which is always the case for the singularly perturbed system. In general, these ill-conditioned linear matrix inequalities are very difficult to solve. Thus, to alleviate these ill-conditioned linear matrix inequalities, we have the following theorem which does not depend on ε. □

Now we are in the position to present our first result.

Theorem 1: Consider the system (1). Given a prescribed $\mathcal{H}_\infty$ performance $\gamma > 0$, for $\imath = 1, 2, \cdots, s$, if there exist matrices $P(\imath)$, positive constants $\delta(\imath)$ and matrices $Y_j(\imath)$, $j = 1, 2, \cdots, r$ such that the following ε-independent linear matrix inequalities hold:

$$EP(\imath) + P(\imath)D > 0 \tag{18}$$
$$\Psi_{ii}(\imath) < 0, \quad i = 1, 2, \cdots, r \tag{19}$$
$$\Psi_{ij}(\imath) + \Psi_{ji}(\imath) < 0, \quad i < j \leq r \tag{20}$$

where $EP(\imath) = P^T(\imath)E$, $P(\imath)D = DP^T(\imath)$, $E = \begin{pmatrix} I & 0 \\ 0 & 0 \end{pmatrix}$, $D = \begin{pmatrix} 0 & 0 \\ 0 & I \end{pmatrix}$,

$$\Psi_{ij}(\imath) = \begin{pmatrix} \Phi_{ij}(\imath) & (*)^T & (*)^T & (*)^T \\ \mathcal{R}(\imath)\tilde{B}_{1_i}^T(\imath) & -\gamma\mathcal{R}(\imath) & (*)^T & (*)^T \\ \Upsilon_{ij}(\imath) & 0 & -\gamma\mathcal{R}(\imath) & (*)^T \\ \mathcal{Z}^T(\imath) & 0 & 0 & -\mathcal{P}(\imath) \end{pmatrix} \tag{21}$$

$$\begin{aligned} \Phi_{ij}(\imath) =& A_i(\imath)P(\imath) + P^T(\imath)A_i^T(\imath) + B_{2_i}(\imath)Y_j(\imath) \\ &+ Y_j^T(\imath)B_{2_i}^T(\imath) + \lambda_{\imath\imath}\tilde{\tilde{P}}(\imath), \end{aligned} \tag{22}$$

$$\Upsilon_{ij}(\imath) = \tilde{C}_{1_i}(\imath)P(\imath) + \tilde{D}_{12_i}(\imath)Y_j(\imath), \tag{23}$$

$$\mathcal{R}(\imath) = \text{diag}\left\{\delta(\imath)I, I, \delta(\imath)I, I\right\}, \tag{24}$$

$$\begin{aligned} \mathcal{Z}(\imath) =& \Big(\sqrt{\lambda_{\imath 1}}\tilde{\tilde{P}}(\imath) \ \cdots \ \sqrt{\lambda_{\imath(\imath-1)}}\tilde{\tilde{P}}(\imath) \\ & \sqrt{\lambda_{\imath(\imath+1)}}\tilde{\tilde{P}}(\imath) \ \cdots \ \sqrt{\lambda_{\imath s}}\tilde{\tilde{P}}(\imath)\Big), \end{aligned} \tag{25}$$

$$\begin{aligned} \mathcal{P}(\imath) =& \ \text{diag}\Big\{\tilde{\tilde{P}}(1), \cdots, \tilde{\tilde{P}}(\imath-1), \\ & \tilde{\tilde{P}}(\imath+1), \cdots, \tilde{\tilde{P}}(s)\Big\}, \end{aligned} \tag{26}$$

$$\tilde{\tilde{P}}(\imath) = \frac{P(\imath) + P^T(\imath)}{2} \tag{27}$$

with

$$\begin{aligned} \tilde{B}_{1_i}(\imath) =& \begin{bmatrix} I & I & I & B_{1_i}(\imath) \end{bmatrix} \\ \tilde{C}_{1_i}(\imath) =& \Big[\gamma\rho(\imath)H_{1_i}^T(\imath) \ \sqrt{2}\aleph(\imath)\rho(\imath)H_{4_i}^T(\imath) \\ & 0 \ \sqrt{2}\aleph(\imath)C_{1_i}^T(\imath)\Big]^T \\ \tilde{D}_{12_i}(\imath) =& \Big[0 \ \sqrt{2}\aleph(\imath)\rho(\imath)H_{5_i}^T(\imath) \\ & \gamma\rho(\imath)H_{3_i}^T(\imath) \ \sqrt{2}\aleph(\imath)D_{12_i}^T(\imath)\Big]^T \end{aligned}$$

$$\aleph(\imath) = \left(I + \rho^2(\imath) \sum_{i=1}^{r} \sum_{j=1}^{r} \left[\| H_{2_i}^T(\imath) H_{2_j}(\imath) \| \right] \right)^{\frac{1}{2}}$$

then there exists a sufficiently small $\hat{\varepsilon} > 0$ such that the inequality (5) holds for $\varepsilon \in (0, \hat{\varepsilon}]$. Furthermore, a suitable choice of the fuzzy controller is

$$u(t) = \sum_{i=1}^{r} \mu_j K_j(\imath) x(t) \tag{28}$$

where

$$K_j(\imath) = Y_j(\imath)(P(\imath))^{-1}. \tag{29}$$

Proof: The detail of the proof is omitted for brevity. ■

IV. Illustrative Example

Consider a modified series dc motor model based on [30] as shown in Fig. 1 which is governed by the following difference equations:

$$\begin{array}{rcl} J\frac{d\tilde{\omega}(t)}{dt} & = & K_m L_f \tilde{i}^2(t) - (D + \Delta D)\tilde{\omega}(t) \\ L\frac{d\tilde{i}(t)}{dt} & = & -R\tilde{i}(t) - K_m L_f \tilde{i}(t)\tilde{\omega}(t) + \tilde{V}(t) \end{array} \tag{30}$$

where $\tilde{\omega}(t) = \omega(t) - \omega_{ref}(t)$ is the deviation of the actual angular velocity from the desired angular velocity, $\tilde{i}(t) = i(t) - i_{ref}(t)$ is the deviation of the actual current from the desired current, $\tilde{V}(t) = V(t) - V_{ref}(t)$ is the deviation of the actual input voltage from the desired input voltage, J is the moment of inertia, K_m is the torque/back emf constant, D is the viscous friction coefficient, and R_a, R_f, L_a and L_f are the armature resistance, the field winding resistance, the armature inductance and the field winding inductance, respectively, with $R \triangleq R_f + R_a$ and $L \triangleq L_f + L_a$. Note that in a typical series-connected dc motor, the condition $L_f \gg L_a$ holds. When one obtains a series-connected dc motor, we have $i(t) = i_a(t) = i_f(t)$. Now let us assume that $|\Delta J| \leq 0.1J$.

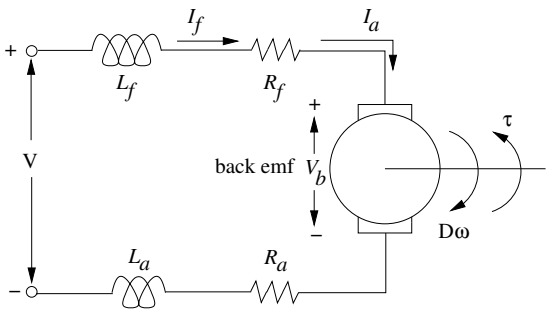

Fig. 1. A modified series dc motor equivalent circuit.

Giving $x_1(t) = \tilde{\omega}(t)$, $x_2(t) = \tilde{i}(t)$ and $u(t) = \tilde{V}(t)$, (30) becomes

$$\begin{bmatrix} \dot{x}_1(t) \\ \varepsilon\dot{x}_2(t) \end{bmatrix} = \begin{bmatrix} -\frac{D}{(J+\Delta J)} & \frac{K_m L_f}{(J+\Delta J)} x_2(t) \\ -K_m L_f x_2(t) & -R \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u(t) \tag{31}$$

where $\varepsilon = L$ represents a small parasitic parameter. Assume that, the system is aggregated into 3 modes as shown in Table I:

TABLE I
System Terminology.

Mode $\imath$	Moment of Inertia	$J(\imath) \pm \Delta J(\imath)$ (kg·m^2)
1	Small	0.0005 ±10%
2	Normal	0.005 ±10%
3	Large	0.05 ±10%

The transition probability matrix that relates the three operation modes is given as follows:

$$P_{\imath k} = \begin{bmatrix} 0.67 & 0.17 & 0.16 \\ 0.30 & 0.47 & 0.23 \\ 0.26 & 0.10 & 0.64 \end{bmatrix}.$$

The parameters for the system are given as $R = 10\ \Omega$, $L_f = 0.005$ H, $D = 0.05$ N·m/rad/s and $K_m = 1$ N·m/A. Substituting the parameters into (31), we get

$$\begin{array}{rcl} \begin{bmatrix} \dot{x}_1(t) \\ \varepsilon\dot{x}_2(t) \end{bmatrix} & = & \begin{bmatrix} -\frac{0.05}{J(\imath)} & \frac{0.005}{J(\imath)} x_2(t) \\ -0.005 x_2(t) & -10 \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} \\ & & + \begin{bmatrix} 0 & 0 \\ 0.1 & 0 \end{bmatrix} w(t) + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u(t) \\ & & + \begin{bmatrix} -\frac{0.05}{\Delta J(\imath)} & \frac{0.005}{\Delta J(\imath)} x_2(t) \\ 0 & 0 \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} \\ z(t) & = & \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u(t) \end{array} \tag{32}$$

where $x(t) = [x_1^T(t) \quad x_2^T(t)]^T$ is the state variables, $w(t) = [w_1^T(t) \quad w_2^T(t)]^T$ is the disturbance input, $u(t)$ is the controlled input and $z(t)$ is the controlled output.

The control objective is to control the state variable $x_2(t)$ for the range $x_2(t) \in [N_1\ N_2]$. For the sake of simplicity, we will use as few rules as possible. Note that Fig. 2 shows the plot of the membership function represented by

$$M_1(x_2(t)) = \frac{-x_2(t) + N_2}{N_2 - N_1} \quad \text{and} \quad M_2(x_2(t)) = \frac{x_2(t) - N_1}{N_2 - N_1}.$$

Knowing that $x_2(t) \in [N_1\ N_2]$, the nonlinear system (32)

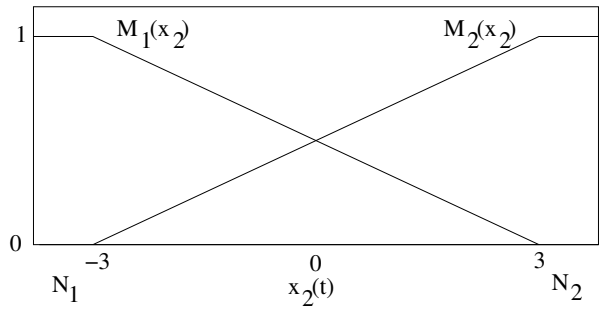

Fig. 2. Membership functions for the two fuzzy set.

can be approximated by the following TS fuzzy model

$$\begin{aligned} E_\varepsilon \dot{x}(t) &= \sum_{i=1}^{r} \mu_i \Big[[A_i(\imath) + \Delta A_i(\imath)]x(t) \\ &\quad + B_{1_i}(\imath)w(t) + B_{2_i}(\imath)u(t) \Big], \quad x(0) = 0, \\ z(t) &= \sum_{i=1}^{r} \mu_i \Big[C_{1_i}(\imath)x(t) + D_{12_i}(\imath)u(t) \Big], \end{aligned}$$

where μ_i is the normalized time-varying fuzzy weighting functions for each rule, $i = 1, 2$, $x(t) = \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix}$, $E_\varepsilon = \begin{bmatrix} 1 & 0 \\ 0 & \varepsilon \end{bmatrix}$, $\Delta A_1(\imath) = F(x(t), \imath, t)H_{1_1}(\imath)$, $\Delta A_2(\imath) = F(x(t), \imath, t)H_{1_2}(\imath)$,

$$A_1(1) = \begin{bmatrix} -100 & 10N_1 \\ -0.005N_1 & -10 \end{bmatrix},$$

$$A_2(1) = \begin{bmatrix} -100 & 10N_2 \\ -0.005N_2 & -10 \end{bmatrix},$$

$$A_1(2) = \begin{bmatrix} -10 & N_1 \\ -0.005N_1 & -10 \end{bmatrix},$$

$$A_2(2) = \begin{bmatrix} -10 & N_2 \\ -0.005N_2 & -10 \end{bmatrix},$$

$$A_1(3) = \begin{bmatrix} -1 & 0.1N_1 \\ -0.005N_1 & -10 \end{bmatrix},$$

$$A_2(3) = \begin{bmatrix} -1 & 0.1N_2 \\ -0.005N_2 & -10 \end{bmatrix},$$

$$B_{1_1}(\imath) = B_{1_2}(\imath) = \begin{bmatrix} 0 & 0 \\ 0.1 & 0 \end{bmatrix},$$

$$B_{2_1}(\imath) = B_{2_2}(\imath) = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \; C_{1_1}(\imath) = C_{1_2}(\imath) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix},$$

$$\text{and} \;\; D_{12_1}(\imath) = D_{12_2}(\imath) = \begin{bmatrix} 0 \\ 1 \end{bmatrix},$$

with $\|F(x(t), \imath, t)\| \leq 1$. Then we have

$$H_{1_1}(\imath) = \begin{bmatrix} -\frac{0.05}{J(\imath)} & \frac{0.05}{J(\imath)}N_1 \\ 0 & 0 \end{bmatrix}$$

$$\text{and} \;\; H_{1_2}(\imath) = \begin{bmatrix} -\frac{0.05}{J(\imath)} & \frac{0.05}{J(\imath)}N_2 \\ 0 & 0 \end{bmatrix}.$$

In this simulation, we select $N_1 = -3$ and $N_2 = 3$. Using the LMI optimization algorithm and Theorem 1 with $\varepsilon = 0.005$, $\gamma = 1$ and $\delta(1) = \delta(2) = \delta(3) = 1$, we obtain the results given in Fig. 3, Fig. 4 and Fig. 5.

Remark 2: Employing results given in [18]-[22] and Matlab LMI solver [28], it is easy to realize that when $\varepsilon < 0.005$ for the state-feedback control design, LMIs become ill-conditioned and Matlab LMI solver yields an error message, "Rank Deficient". However, the state-feedback fuzzy controller proposed in this paper guarantee that the inequality (5) holds for the system (32). Fig. 3 shows the result of the changing between modes during the simulation with the initial mode at mode 1 and $\varepsilon = 0.005$. The disturbance input signal, $w(t)$, which was used during simulation is given in Fig. 4. The ratio of the regulated output energy to the disturbance input noise energy obtained by using the $\mathcal{H}_\infty$ fuzzy controller is depicted in Fig. 5. The ratio of the regulated output energy to the disturbance input noise energy tends to a constant value which is about 0.0094. So $\gamma = \sqrt{0.0094} = 0.0970$ which is less than the prescribed value 1. Finally, Table II shows the performance index, γ, for different values of ε. □

V. Conclusion

This paper has investigated the problem of designing a robust $\mathcal{H}_\infty$ state-feedback controller for a class of uncertainty Markovian jump nonlinear two-time scale systems that guarantees the $\mathcal{L}_2$-gain from an exogenous input to a regulated output to be less or equal to a prescribed value. First, we approximate this class of uncertain Markovian jump nonlinear two-time scale systems by a class of uncertain Takagi-Sugeno fuzzy models with Markovian jumps. Then, based on an LMI approach, LMI-based sufficient conditions for the uncertain Markovian jump nonlinear two-time scale systems to have an $\mathcal{H}_\infty$ performance are derived. The proposed approach does not involve the separation of states into slow and fast ones and it can be applied not only to standard, but also to nonstandard nonlinear two-time scale systems. An illustrative example is used to illustrate the effectiveness of the proposed design techniques.

TABLE II

The performance index γ for different values of ε.

	The performance index γ
ε	State-feedback control design
0.005	0.0970
0.10	0.4796
0.30	0.8660
0.40	0.9945
0.41	> 1

***Abstract*- According to IEC 60-1(1989) [1], the maximum ratio of absolute humidity (h) to the air density factor (δ) which is accepted under DC breakdown in the standard is 13 g/m^3. However, in Thailand, the absolute humidity varies from about 10 g/m^3 to about 26 g/m^3. Therefore, this paper deals with experimental study under positive DC breakdown [2-3] of characteristics of air-gap varied with atmospheric conditions such as temperature and humidity [4-6]. Also, the effect of electrode different shape of rod-rod gaps at humidity between 11-16 g/m^3 was studied. Three different shapes of rod-rod gaps are tested. Rod with tip angles of 15^0 is tested with the gap distance of 2-16 cm. Also, square cut and hemispherical rod with the gap distance of 2-10 cm were used. All test electrodes are made of copper. The breakdown voltage was plotted as a function of the gap distance at different humidity values. Finally, it can be seen that the humidity factor K_h in IEC 60-1[1] is an important factor for the breakdown in the rod-rod gap under DC breakdown**

Keywords: electrode shape, positive DC Breakdown

I. INTRODUCTION

It is well known that humidity in air has considerable influence on flashover voltages of air gaps. The maximum ratio of absolute humidity (h) to the air density factor (δ) which is accepted under DC breakdown in the standard is 13 g/m^3. However, in Thailand, the absolute humidity varies from about 10 g/m^3 to about 26 g/m^3. Therefore, this paper deals with experimental study under positive DC breakdown of characteristics of air-gap varied with atmospheric conditions such as temperature and humidity under positive DC voltage.

II. EXPERIMENTAL SET-UP

A. *Test objects*

Three rod gaps with different shapes at various gap distances were used in this present work as follows:

1) Sharp rod-rod gaps 15^o; electrodes were tested at gap distance of 2, 4, 6, 8, 10, 12, 14, 16 cm. The rods were made of copper with the length of 20 cm. The tip angles of the rods were 15^o.

2) Hemispherical rod-rod gaps; electrodes were tested at gap distance of 2, 4, 6, 8, 10 cm. The rods were made of copper with the length of 20 cm and diameter is 2 cm.

3) Square cut-square cut gaps; electrodes were tested at gap distance of 2, 4, 6, 8, 10 cm. The rods were made of copper with the length of 20 cm with cross section area of 1.2 x 1.2 cm. All rods are shown in Fig.1.

Figure1. Rod electrodes

B. *Experimental Circuit*

The experimental circuit consisted of AC source 220V, variac 0-240V, transformer 220 v/100 kV, diode 150 kV/1.5 A, damping resistor(Rd) 27 kΩ, capacitor 25 nF, water resistance (Rw) 1.4 MΩ, protection sphere gap of 1.5 cm diameter and test gaps as shown in Fig.2.

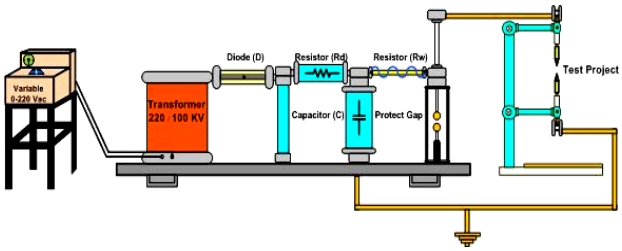

Figure2. Experimental circuit

C *Test Procedures*

$U_{50\%}$ in this present work was obtained by "up and down" method. Each U_{50} value corresponded to applying DC voltage 10 times. Temperature, pressure and relative humidity were also measured.

III. RESULTS

In this work, the results of positive breakdown voltage were separated into two cases. The first case is that the breakdown voltage ($U_{50\%}$) was the actual breakdown voltage obtained from the experiment. The other one was the breakdown voltage corrected with the atmospheric factor (K_t) which is the product of air density factor (δ) and humidity factor (h) as recommended in IEC 60-1[1].

A. Sharp rod-rod gaps 15°; Table I showed the results of breakdown voltage of the sharp rod-rod gaps 15° at 16 g/m^3. The breakdown voltage of the sharp rod-rod gaps 15° without correction and corrected with K_t were plotted as a function of gap length in Fig.3 and 4 respectively. The results showed that the trend of breakdown voltages of sharp rod-rod gaps 15° at different absolute humidities were very similar. Also, it indicated that increase in humidity caused the breakdown voltage higher.

TABLE I

THE BREAKDOWN VOLTAGE OF THE SHARP ROD-ROD GAPS 15° AT 16 G/M^3 WITHOUT CORRECTION AND CORRECTED WITH K_T AT VARIOUS GAP DISTANCES.

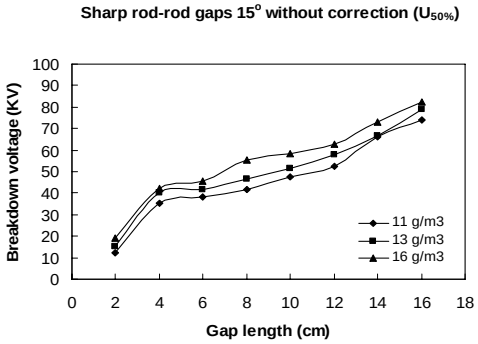

Figure3. Breakdown voltage of the sharp rod-rod gaps 15° without correction as a function of gap length.

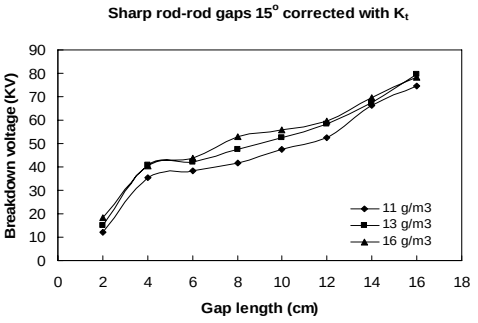

Figure4. Breakdown voltage of the sharp rod-rod gaps 15° corrected with K_t as a function of gap length.

B. Hemispherical rod-rod gaps; Table II showed the results of breakdown voltage of the hemispherical rod-rod gaps at 16 g/m^3. The breakdown voltage of the hemispherical rod-rod gaps without correction and corrected with K_t were plotted as a function of gap length in Fig.5 and 6 respectively. The results showed that the trend of breakdown voltages of hemispherical rod-rod gaps at different absolute humidities were very similar. Also, it indicated that increase in humidity caused the breakdown voltage higher.

TABLE II

10	77.3	73.7	7.7	7.3

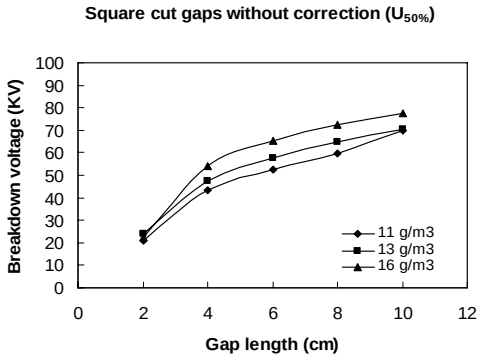

Figure7. Breakdown voltage of the square cut-square cut gaps without correction as a function of gap length.

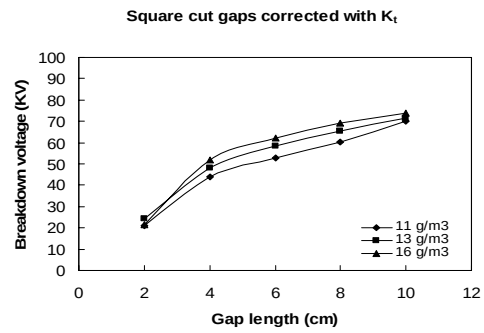

Figure8. Breakdown voltage of the square cut-square cut gaps corrected with K_t as a function of gap length.

E. The electric field stress; the average electric field stress at 16 g/m^3 of the hemispherical rod-rod gaps is higher than that of square cut-square cut gaps and sharp rod-rod gaps 15^o respectively in Table I-III. All values the electric field stress of the rods gaps are shown in Fig.9.

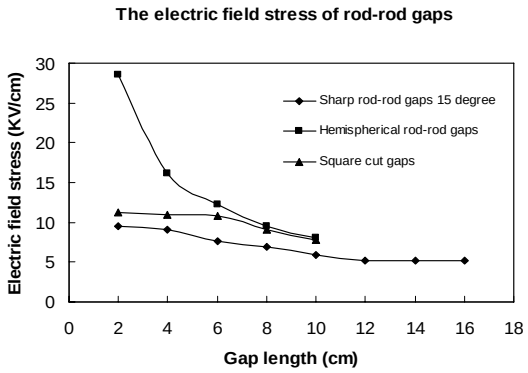

Figure9. The electric field stress of rod-rod gaps with gap length.

IV. DISCUSSIONS

From results in Tables I-III, the breakdown voltage of sharp rod-rod gaps 15^o at 16 g/m^3 less than square cut-square cut gaps and hemispherical rod-rod gaps. From Figure 9, the electric field stress at 16 g/m^3 of hemispherical rod-rod gaps is much higher than that of square cut-square cut and sharp rod-rod gaps 15^o at the gap distance of 2 and 4 cm. This is due to, at gap length of 2 cm and 4 cm, the hemispherical rod-rod gaps has characteristics of uniform field. However, as the gap distance increases to 6, 8 and 10 cm, the effect of the hemispherical tip decreases. This can be seen from its breakdown voltage is close to that of the sharp rod-rod and square cut - square cut gaps. From Tables I-III, it can imply that

- As absolute humidity increases, the breakdown voltage increases.
- The breakdown voltage increases as the gap distance increases.

This was in agreement with S. Chotigo and T. Boonwern [7] which was the results on the rod-rod gap with the tip angles of 30^o, 45^o and 60^o.

However, in this present work h/δ is greater than 13 g/m^3 which is the limit of applying K_h recommended in IEC 60-1. From results in Tables IV and V, %different of $U_{50\%}$ corrected with K_t at 16 g/m^3 and 11 g/m^3 are very high compared to that between 13 g/m^3 and 11 g/m^3. Actually, the value of this breakdown voltage should be closer when it is corrected to the standard condition. This indicates that the atmospheric correction factor K_t recommended in IEC 60-1 is not suitable when h/δ is above 13 g/m^3. It should be noted that the value of h/δ in present work is 16.4, 13.6 and 11.1 g/m^3 when the absolute humidity is 16 g/m^3, 13 g/m^3 and 11 g/m^3

respectively. This may imply that the atmospheric correction factor for rod-rod gaps under positive DC voltage in Thailand has to be found out.

TABLE IV
% DIFFERENCE OF THE BREAKDOWN VOLTAGE CORRECTED WITH K_T AT 13 G/M^3 AND 11G/M^3 OF THE ROD GAPS.

Gap distance (cm)	%difference of $V_{50\%}$ corrected with K_t at 13 g/m^3 and 11 g/m^3		
	Rod 15^o	square cut	hemisphere
2	25.3	15.4	14.5
4	14.3	10.1	6.5
6	9.8	11.2	5.2
8	13.5	8.7	4.3
10	9.9	1.7	3.8

$$\%difference = ((V_{13g/m^3} - V_{11g/m^3}) / V_{11g/m^3}) \times 100$$

TABLE V
% DIFFERENCE OF THE BREAKDOWN VOLTAGE CORRECTED WITH K_T AT 16 G/M^3 AND 11G/M^3 OF THE ROD GAPS.

Gap distance (cm)	%difference of $V_{50\%}$ corrected with K_t at 16 g/m^3 and 11 g/m^3		
	Rod 15^o	square cut	hemisphere
2	49.7	33.3	32.2
4	13.1	17.9	12.7
6	14.0	18.1	13.0
8	26.9	15.2	8.4
10	17.0	4.9	10.0

$$\%difference = ((V_{16g/m^3} - V_{11g/m^3}) / V_{11g/m^3}) \times 100$$

V. CONCLUSION

Three shapes of the rod electrodes were used for investigating the effects of humidity under positive DC voltage. The results can be concluded as follows:

1. The electrode shape has an influence on positive DC breakdown voltage.
2. The breakdown voltage increases as the absolute humidity increases.
3. The breakdown voltage of rod gaps without correction and corrected with K_t increases as the gap distance increases.
4. The electric field stress of hemispherical rod-rod gaps is higher than that of square cut-square cut and sharp rod-rod gaps 15^o
5. The atmospheric correction factor for rod-rod gaps under positive DC voltage recommended by IEC 60-1 is not suitable to apply in Thailand. This can be seen from %difference in Tables IV and V which is really high.

A Preliminary Study of Dissipation Factor (tan δ) in Dielectric of Cables Produced in Thailand

A. Aurairatch and S. Kleesuwan
Department of Electrical Engineering, Faculty of Engineering
King Mongkut's Institute of Technology North Bangkok, Bangkok 10800, Thailand
Email: aurirat@gmail.com

***Abstract*–The investigation of the temperature and the voltage influence with dry and wet service conditions of the new and the used XLPE cables produced in Thailand is proposed. This paper also presents the effect of accelerated aging of the cable insulations on changing its dissipation factor (tan δ). During tests, the cables conductor temperature was 20 °C to 100 °C and the electrical field on conductor screen was 6.93 kV to 27.7 kV.**

I. INTRODUCTION

Underground distribution and transmission cable systems are a major investment for electrical utilities. These cables must be highly reliable in order to decrease lost revenues suffered from a premature failure. From a operators point of view, it is of the great importance to be continuously informed of the decrease in electrical strength. Electrical utilities are faced with decisions to maintain, repair, refurbish, or replace their cable systems. In order to make these decisions, the condition of the cable system needs to be determined by knowing [1]:

- How the different components of the system age, i.e. aging factor;
- The system operating conditions;
- How to measure the aging by diagnostics;
- Criteria for "repair, refurbish or replace."

The cause of cable failures stem from electrical, thermal and environmental stresses. Temperature, age, humidity, water content, load and usage all contribute deterioration of underground cable systems. A common cause of cable failures is the wearing and breakdown of the insulation. Insulating materials are dielectrics, which prevent the flow of current when an input voltage is applied. The major insulation used in cables are cross linked polyethylene (XLPE) [2].

The possibility of in situ diagnosis of underground distribution lines has always been actively sought after by utilities across the world. As a matter of fact, an estimation of the remaining useful life of cables in service may prevent high cost, due to unpredicted outages, by replacing them just in time. Also such a possibility of diagnosing cables will increase safety as well as confidence for the crewmen having to work close to the equipment.

Distribution factor measurements base on Schering bridge of XLPE cables produced in Thailand and accelerated aging in the laboratory are presented. Typical distribution XLPE cables have been used for the investigation. The new and the used cables were assembled in the laboratory and were tested such as the main objective measured the dissipation factors of conventional XLPE materials as a function of electric field and temperature. Measurements of the dissipation factor tan δ were performed on 12/20 (24 kV) cable samples in the temperature range 20 °C to 100 °C, up to a maximum voltage of $2U_0$ (27.7 kV).

II. XLPE CABLES

Crosslinked polyethylene (XLPE) cables have been used as power cable insulation for several decades. In the late 1960's to 1970's, XLPE enjoyed tremendous growth in this application, and is still the preferred material [3]. Although the XLPE used today is similar to that developed many years ago, a number of small but progressive modifications have been made to its physical, chemical and electrical properties in order to optimize the performance in medium and high voltage applications.

The physical and electrical properties of XLPE are shown in Table I [4]. The dielectric losses of any high voltage cable are directly proportional to the square of the operating voltage, to the dielectric constant and to the dissipation factor of the insulation.

TABLE I
TYPICAL PROPERTIES OF XLPE CABLE

Physical	**XLPE**
Density, g.cm-3	0.92
Tensile Strength, MPa	19
Elongation, %	500
Modulus of Elasticity, MPa	121
Heat Distortion, %	20
Thermal Conductivity w/m°C at 90 °C	0.27

Dielectric Constant	2.3
Dissipation Factor, % at 23 °C 90 °C	 <0.03 <0.03
Volume Resistivity, Ωm At 23°C	1016
Shout – term AC Breakdown on Miniature Cable, kv/mm	48

III. DISSIPATION FACTOR

The dissipation factor, also called tan δ or loss angle, is a diagnostic method of testing cables to determine the quality of the cable insulation. This is done in order to predict the remaining life expectancy and to prioritize cable replacement.

If the insulation of a cable is free from defects, like water trees, electrical trees, moisture and air pockets, etc, the cable approaches the properties of a perfect capacitor. It is very similar to a parallel plate capacitor with the conductor and the neutral being the two plates separated by the insulation material.

In a perfect capacitor, the voltage and current are phase shifted 90 degrees and the current through the insulation is capacitive. If there are impurities in the insulation, like those mentioned above, the resistance of the insulation will decrease with resulting in an increase of resistive current through the insulation. It is no longer a perfect capacitor. The phase angle between the current and the voltage will be less than 90 degrees, which is indicative of the level of insulation contamination, hence quality/reliability.

Figure 1 is a representation of a cable. The tangent of the angle δ is measured. This will indicate the level of resistance in the insulation. By measuring I_R/I_C, we can determine the quality of the cable insulation. In a perfect cable, the angle would be closed to zero. An increasing angle indicated an increase in the resistive current through the insulation, meaning contamination. If the angle is greater, it will be the worse the cable.

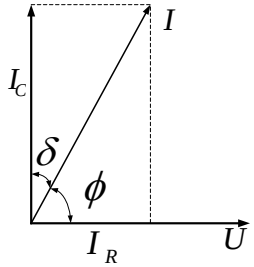

Figure 1. The cable equivalence circuit

If a cable's insulation is perfect, the loss factor (tan δ) will not change as the applied voltage is increased. The capacitance and loss will be similar with 1kv or 10 kV applied to the cable. If the cable has water tree contamination, thus changing the capacitive/resistive nature of the insulation, then the tan δ numbers will be higher at higher voltages. Rather than a flat curve for the loss number versus voltage, the curve will be non linear see the graph in figure 2.

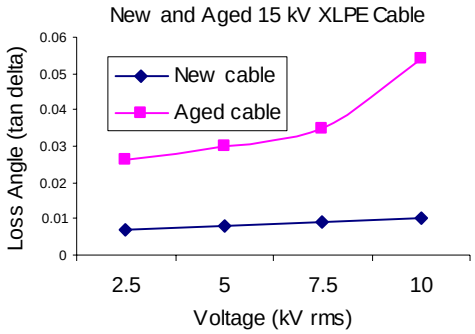

Figure 2. The dissipation factor of the new and the used XLPE cables

Dissipation factor measurements were all preformed at 50 Hz using a Tettex Schering bridge (type 2801) with automatic guard potential regulator [5].

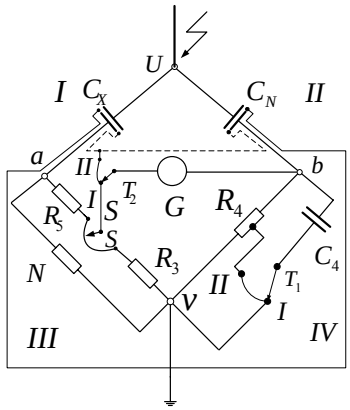

Figure 3. The circuit diagram of the Schering bridge

The Schering bridge involves a measurement carried out in a bridge arrangement, figure 3, comparing the cable samples with a thoroughly loss free standard capacitor, with the capacity and loss factor, tan δ know. The bridge is balanced by setting the resistance, R_4 and R_3 as well as the capacitance C_4 until the indicator on the screen is horizontal. The loss factor is calculated as follows [6-7].

$$\tan\delta = \omega \cdot C_4 \cdot R_4 \qquad (1)$$

IV. EXPERIMENTAL DETAIL

In order to investigate the influence of voltages and temperatures of underground XLPE cables, the new cables, the 5-year used cables and the 10-year used cables were selected. The dissipation factor measurements were all performed on 6 m long, 12/20 (24kV) underground XLPE cable samples with 50 mm^2 stranded copper conductors, all produced by the same cable manufacturer.

The sample of completed cable was heated by cylinder core transformer. The tan δ measured with an alternating voltage of $0.5U_0$, U_0, $1.5U_0$ and $2U_0$ with the temperature of 20°C to 100°C. Figure 4 shows the dissipation factor measuring.

Figure 4. The dissipation factor measuring setup

In order to investigate the influence of moisture, age and time, also studies by others, two cable were selected the new cable and the 10-year used cable. The cables were placed in the cylindrical insulating tank. The water temperature was maintained at 90°C. The voltage of U_0 (13.86 kV AC) was applied conductor to ground continuously during aging. The samples for the evaluation were measured every 100 hours. It is planned to continue the aging time for 1000 hours. In figure 5, the new cable and the 10-year used cable under wet condition were tested.

Figure 5. Cable under wet condition tested.

V. Results and Discussion

A. *Tan δ measurement for the new and the used cable*

The dissipation factor of 12/20 (24 kV) XLPE new cable is shown in figure 6. It is the function of the conductor temperature. The graph shows the dissipation factor is less than 0.8%. At 100°C, the dissipation factor is also less than 0.8%, which accord with the IEC 60502-2 specifications on dissipation factor for conventional XLPE (tan $\delta < 80 \times 10^{-4}$).

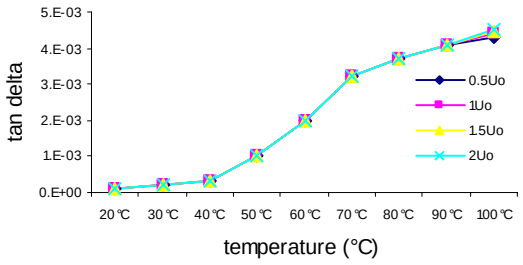

Figure 6. The dissipation factor of 12/20 (24 kV) XLPE new cable

Figure 7 shows a similar pattern with the dissipation factor between 0.43 to 0.45% at 100°C. Power cables rarely operate at above 90°C. The most important parameters are the cable life and the long term stability of the dissipation factor as the cable ages.

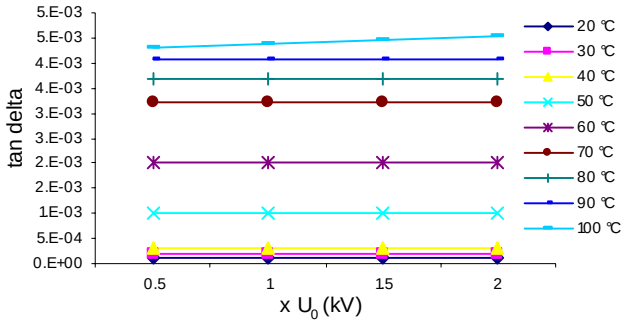

Figure 7. The dissipation factor of 12/20 (24 kV) XLPE new cable

The dissipation factor did not change as the applied voltage was increased. So, a cable's insulation has been perfect.

Figure 8 and 9 show the stability of the dissipation factor for 12/20 (24 kV) 5-year used and 10-year used XLPE cables at 20°C to 100°C temperatures are well.

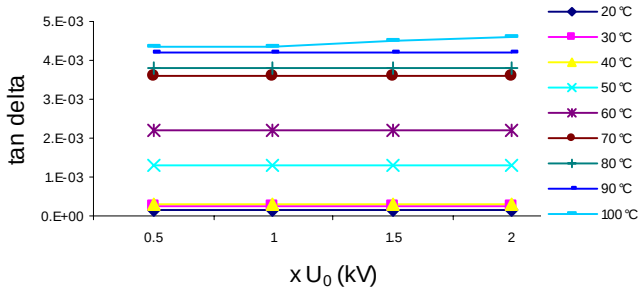

Figure 8. The dissipation factor of 12/20 (24 kV) XLPE 5-year used cable

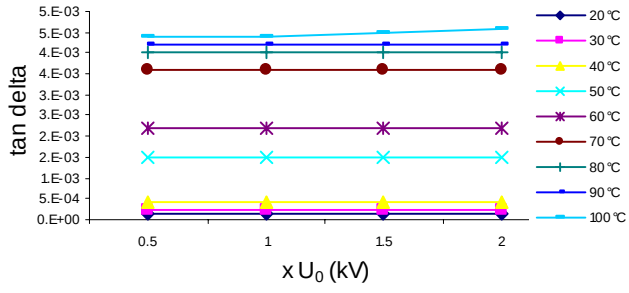

Figure 9. The dissipation factor of 12/20 (24 kV)XLPE 10-year used

B. Cable aging program

The new cable and the 10-year used cable under wet condition tested result for 100 to 400 hours are shown in Figure 10. The tan δ still remains constant after 500 hours. It had a little increase of follow with voltage rise and less than 0.8% that is durable even when the long time tested with the wet condition.

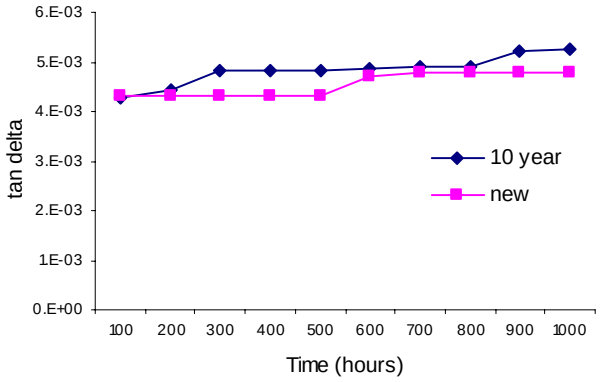

Figure 10. The dissipation factor of 12/20 (24 kV) XLPE new and 10-year used cable under wet condition

At the end of aging period, the cables were removed from the tank and the tan δ was measured. The dissipation factor for this cable is pointed out in figure 11 as functions of conduction temperature.

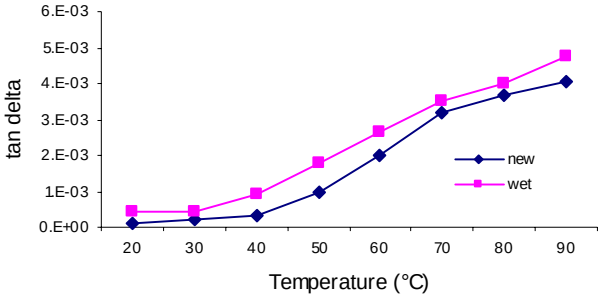

Figure 11. The dissipation factor of 12/20 (24 kV) XLPE new and 10-year used cable under wet condition

This figure presents a comparison of the real valve of the dissipation factor of the new cable and the 10-year used cable (cable aging program) as a function of temperature at a frequency of 50 Hz, 13.86 kV ac. It suggests the new XLPE has a smaller dissipation factor than the 10-year used XLPE.

Figure 12 shows a comparison of the dissipation factor of new cable, 5-year used, 10-year used, new cable wet condition and 10-year used cable wet condition tested as a function of temperature. The tan δ increased lightly following the temperature rise. Except the 10-year use under wet condition tested, it increased immediately following the temperature rise. However, the tan δ of all tests was less than 0.8%.

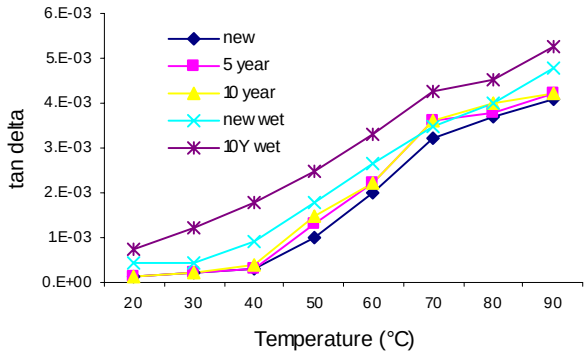

Figure12. The dissipation factor of new cable, 5-year used, 10-year used, new cable wet condition and 10-year used cable wet condition tested

VI. CONCLUSION

If the medium voltage cables, insulated with XLPE, are used in the wet condition after the service time, the tan δ may increase. The probability such a defect is determined by the cable design, the raw materials used, the production process, etc. The results obtained in this investigation have been summarized as follows:

- The tan δ of the XLPE cables has increased follow the temperature rise.
- The influence of moisture, temperature and time affected the increasing of the tan δ of the XLPE cables.
- The XLPE cables with produced in Thailand were durable even those which were in long time used and long time tested, the tan δ did not increased following voltages rise.

Abstract: **This paper presents a partial discharge (PD) measurement for cable terminators of XLPE power cable. The power cable of rated voltage 24 kV and a cross sectional area of 240 mm^2 was used in the experiment. The partial discharge level and dielectric loss are very important factors to indicate the insulation quality of power cable. Therefore, measurement techniques of partial discharge and dielectric loss are required in high voltage applications. This paper proposes a design and construction of a cable terminator by using acrylic tube. Inside of cable connector, the maximum high pressure air can be compressed more than 3 bar. In order to implement the partial discharge and the dielectric loss (tanδ) techniques, the cable terminator has to be tested according to IEC standards No.60502, No.835-3 and No.270. It can be found that the cable terminator testing gives the satisfactory and reasonably accurate results from the measurement techniques. In addition, the cost of construction is much cheaper than a commercial module.**

I. INTRODUCTION

Electrical solid insulations have been used extensively in electrical power devices, particularly in power cables. Most solid insulations are developed from polymeric materials. There are two important electrical characteristics for polymeric insulations, which are the partial discharge level and the dielectric loss (tan δ) [1,2]. It is necessary for cable manufacturers to perform tests on the partial discharge level as well as on the dielectric loss. In order to perform such tests, a cable connector is required [1]. The cable connector is available in the commercial sectors. However, it is difficult for small laboratories to acquire this device due to its price. This paper aims to present a development and a construction of the cable connector using local components available in ASEAN countries. Three types of insulating materials: air, palm oil (vegetable cooking oil) and transformer oil, are used in the connector. Then, the connector is implemented for partial discharge and dielectric loss tests with a power cable.

The rest sections in this paper are organized as follows; Section 2 presents a design and construction of cable terminator. A technique of partial discharge measurement is presented in Section 3 by using partial discharge detector. Section 4 shows a dielectric loss measurement using Schering bridge circuit. Finally, the conclusion and discussion are given in Section 5.

II. CABLE TERMINATOR

When performing partial discharge tests and dielectric loss tests with a cable, outer parts of the cable must be taken off. Next, the conductor of the cable is covered by a terminator and connected to terminals of a transformer, which is a supply for performing partial discharge and dielectric loss tests. The requirement of the cable termination is that the termination needs a sufficient clearance distance between a conductor and a ground part. The inner part of the connector was designed to have a sufficient length to cover all the bare conductor of the cable. The inner part was filled with the insulating medium. The material used for the inner part was acrylic tube so that the inner part was transparent for checking a level of the insulating medium. Solid cylindrical aluminium was connected at the end of the inner part of the connector in order to provide a socket for one terminal from the transformer. The joint between the acrylic tube and the cylindrical aluminium was sealed by using polyester resin in order to reduce the electric stress around the joint, and also protected the leakage of the insulating medium. At the joint between the inner part and the terminal from the transformer, a stress control device in a toroid shape was placed. The outer part of the connector was PVC, and this was a base to support the inner part of the connector. Fig. 1 and Fig. 2 show details of the constructed cable connector while Fig. 3 illustrates an arrangement of the connector for performing cable tests. To reduce the electric stress at the end of the terminator, a toroid is connected to increase the area of cable end terminator as shown in Fig. 3. At the other side of the terminator, the place cover was installed for preventing the air leakage. The pressure gauge is also installed in this cover to indicate the pressure value. Fig. 4 illustrates the set of cable terminator that have already been connected with the power cable inside the shape.

Fig. 2 Connected terminal of power cable

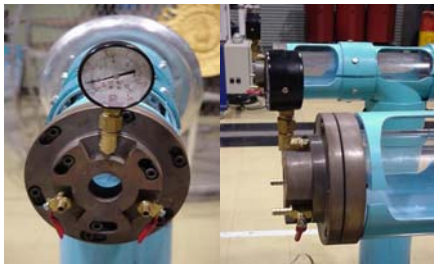

Fig. 3 The place cover and toroid of cable terminator

Fig. 4 A set of cable terminator

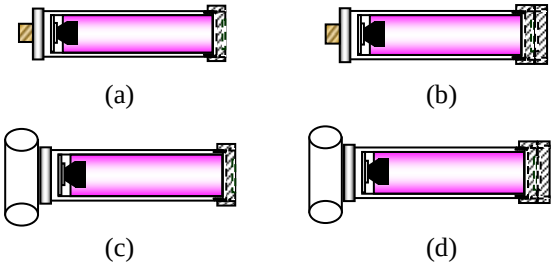

Fig. 5 Each test model of cable terminator

III. Terminator Test Procedure

There are 2 procedures for cable terminator testing, the first is dielectric loss and the second is partial discharge level. Because of no instrument that can directly measure the dielectric loss, the Schering bridge circuit is used to find this value. Two factors can present in this circuit that are capacitance and dissipation factor ($\tan\delta$). The dielectric losses of cable terminator can be found by using Equation (1) as follows:

$$P_d = \omega \cdot C \cdot U^2 \cdot \tan\delta \qquad (1)$$

where, P_d is the dielectric loss in Watt, ω is angular frequency (rad/s), U is tested voltage in kV and $\tan\delta$ is dissipation factor.

Then, a partial discharge level is measured in order to implement the constructed cable terminator. Insulating materials inside the terminator is the controlled-pressure air. Partial discharge tests were performed at the voltage levels of 12 kV and 24 kV. In general standard, the partial discharge level should be less than 5.0 pC [4]. It can be carried out by using the partial discharge detector, PD-TE571, which is calibrated under IEC standard [5].

This paper is classified the terminator into four shapes as follows:
Type A: Cable terminator without a cover and cable connector, Fig. 5(a)
Type B: Cable terminator with cable connector without a cover, Fig. 5(b)
Type C: Cable terminator including toroid, without place cover and cable connector, Fig. 5(c)
Type D: Cable terminator including toroid, with place cover and cable connector, Fig. 5(d)

11.81	49.90	108.60	1.845	87.751
11.81	49.90	107.55	1.867	88.827
23.93	49.90	108.80	1.859	363.683
23.92	49.80	108.68	1.875	366.102
23.92	49.80	109.70	1.886	371.706
23.92	49.83	108.34	1.851	367.163
36.59	49.80	109.61	1.827	841.866
36.35	49.80	109.80	1.824	830.932
36.29	49.80	108.47	1.835	823.093
36.35	49.83	108.74	1.853	831.963

Table 1 and table 2 present the test results of cable terminator type C and type D, respectively. They are tested with a standard voltage varied from 12 kV (U_0) to 36 kV. During this process, the power cable was not inserted inside the cable terminator. It can be found that the capacitance value and dissipation factor do not change. This means that the dielectric loss is directly proportion to the input voltage ($P_d \propto U$). Because the dielectric loss of type D is close to type C, the cable terminal with a cover did not produce loss. Therefore, a cover can be installed for testing a cable terminator.

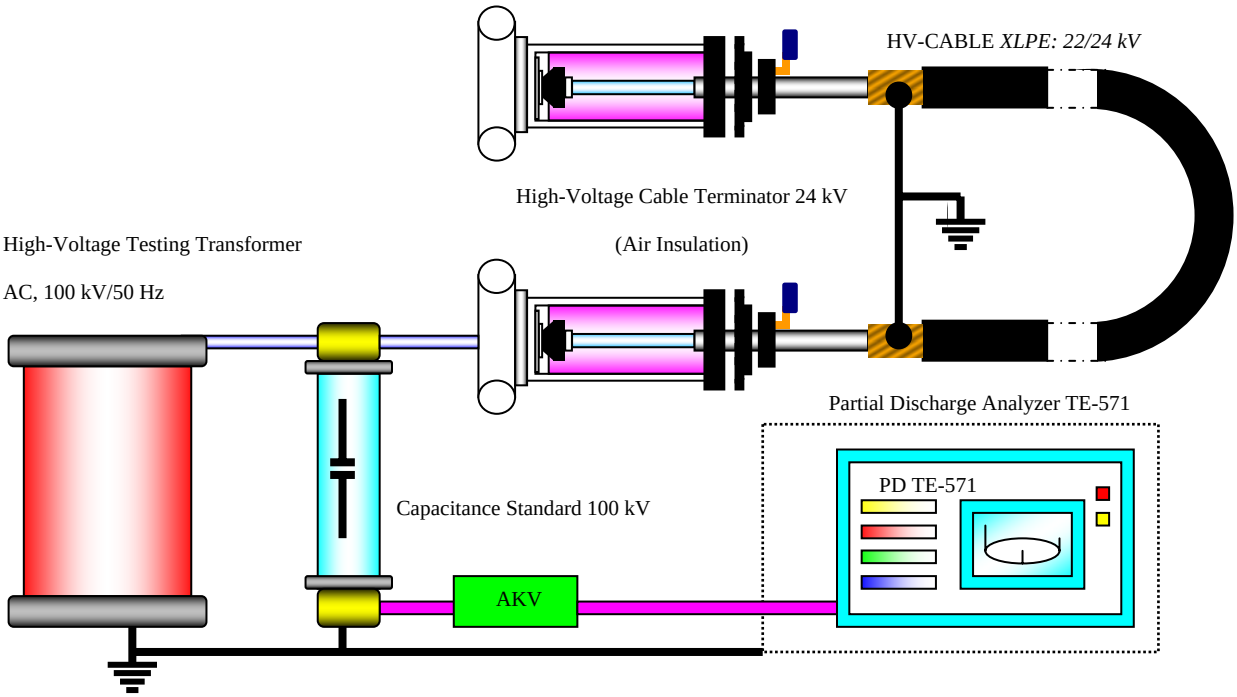

Fig. 6 Test circuit for partial discharge measurement of power cable with compressed air cable terminator

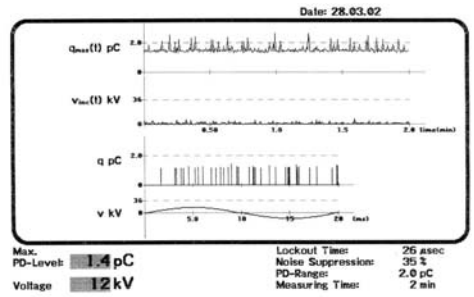

Fig. 7 Partial discharge level of Type D at 12 kV

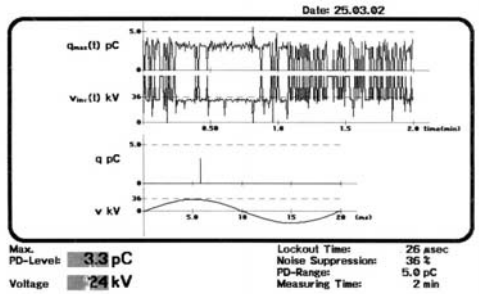

Fig. 8 Partial discharge level of Type D at 24 kV

The partial discharge levels of type-D cable terminator are illustrated in Fig. 7 and Fig. 8. From experiment results, the partial discharge level of type D also depends on input voltage. The partial discharge level in cable terminator can be controlled by the rated voltage at its operation level. The partial discharge is increased when overvoltage or impulse voltage occurred. The protection scheme of voltage must be ensured to protect the cable terminator by design engineers.

IV. Power Cable Procedure

As already mentioned in the previous section, the partial discharge level and dielectric loss depend on the input voltage. In this section, the 240 mm^2 power cable with terminator was tested. The length of power cable is 10 metres. For the terminator tube, the air pressure was controlled within 1 bar to 3 bar. The dielectric loss and partial discharge are carried out by using instrument as described in the previous section. The voltage levels are 12 kV and 24 kV. The dielectric losses of cable are not presented in this section, but they are calculated by using Equation (1). Obviously, it can be noticed that the dielectric loss depends on rated voltage and material inside the tube (power cable). The dielectric loss will be changed according to the variation of the power cable size.

The partial discharge levels are measured by using a test circuit shown in Fig. 6. Fig. 9 to Fig. 11 show partial discharge levels of cable terminator at 1.0 bar, 2.0 bar and 3.0 bar compressed air, respectively. Fig. 12 to Fig. 14 also show partial discharge levels of cable at the same compressed air.

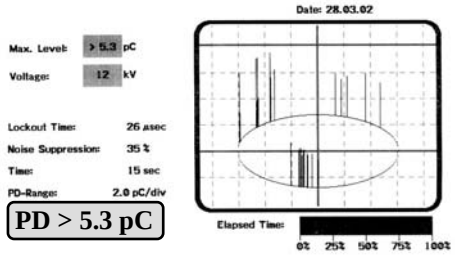

Fig. 9 PD level of terminator with 1.0 bar compressed air and 12 kV rated voltage

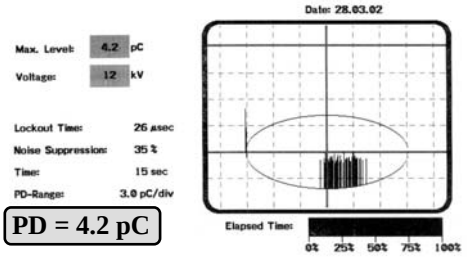

Fig. 10 PD level of terminator with 2.0 bar compressed air and 12 kV rated voltage

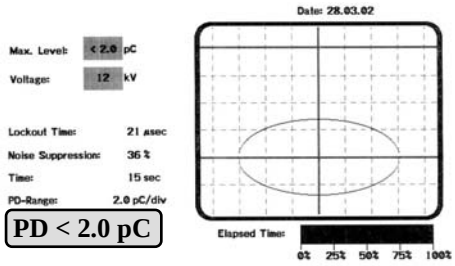

Fig. 11 PD level of terminator with 3.0 bar compressed air and 12 kV rated voltage

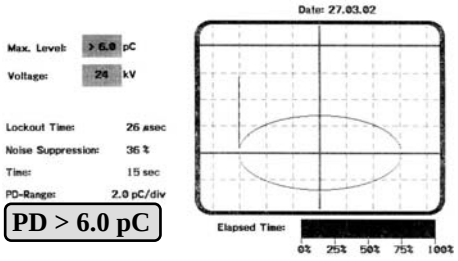

Fig. 12 PD level of terminator with 1.0 bar compressed air and 24 kV rated voltage

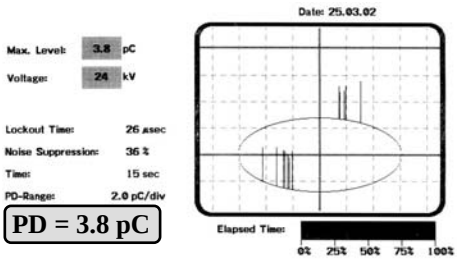

Fig. 13 PD level of terminator with 2.0 bar compressed air and 24 kV rated voltage

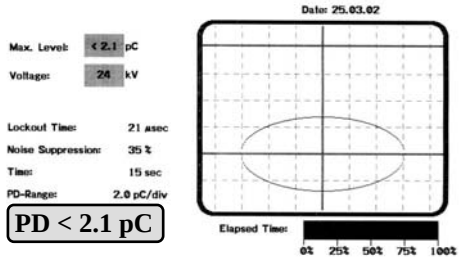

Fig. 14 PD level of terminator with 3.0 bar compressed air and 24 kV rated voltage

The PD level is decreased when the compression of air is increased and it is independent on the voltage rating. As shown in Fig. 11 and Fig. 14, the compression of air is about 3.0 bar. There is no partial discharge value in cable terminator and the PD level is about 2 pC at the different voltage levels. The partial discharge level and dielectric loss given in this paper are primary data for the design engineers before designing of the terminator. Comparing with another material, the using of air as insulation is cheaper than another and simple construction.

V. CONCLUSION

A cable terminator has been constructed and tested with a partial discharge detector and a Schering bridge. Components used in the terminator are available from local suppliers in ASEAN countries. The terminator proposed in this paper has been implemented by partial discharge tests and dielectric loss tests for cable terminator and power cable. The insulating air has been used in the terminator tube. The results obtained from partial discharge tests and dielectric loss tests ensure the use of the developed terminator in the satisfactory level.

***Abstract*- This paper presents the design of Dielectric Heat for gluing wood. Principle of Dielectric Heating is the use of High-Frequency High-Electric field for heating insulating materials by their own dielectric losses. This type of heating has the advantage of being able to heat insulator well, quickly and uniformly. The material to be heated is placed between two electrodes that form a capacitor. The designed Dielectric Heater (DH) employs triode tube 7T84RB for generating frequency at 27 MHz. The DC input voltage is 5 kV. The power output can be adjusted by adjusting coupling capacitor. This technique can replace the phase control for adjusting input voltage supply. The maximum rated output is 4 kW. The test results showed that it can glue two pieces of wood with the same thickness of 0.315 inches with the size of 0.984 inches by 8.66 inches in less than 6 seconds.**

I. INTRODUCTION

Dielectric heating is the use of high-frequency electric fields for heating insulating materials by their own dielectric losses. This type of heating has the advantage of being able to heat good heat insulators quickly and uniformly. The material to be heated must be placed between two electrodes to form a capacitor. The capacitance current flowing through the material generates heat in the material by dielectric loss. The capacitor structure is shown in Fig. 1, with a small rectangular prism of unit cross-sectional area indicated at a location of uniform electric field. The capacitance of this elementary section of the condenser can be calculated from [7]

$$C = \frac{0.225e}{d} \quad pF \tag{1}$$

If the dielectric constant e of the material between the plates is known and the dimensions are given in inches.

When the radio-frequency voltage E is applied across the plates of this condenser, the power absorbed by the rectangular prism is

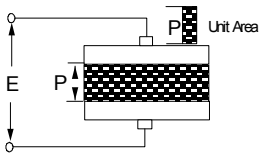

Figure.1 Condenser with dielectric material between plates.

$$P = \left(\frac{E^2}{\sqrt{R^2+X^2}}\right)(\cos q) \quad W \tag{2}$$

Where R and X is ohms are, respectively, the resistive and reactive components of the impedance for this elementary condenser and cos q is the power factor.

Equation (2) can be rewritten in the form of (3) and (4).

$$P = \left(\frac{E^2}{X}\right)\left(\frac{X}{\sqrt{R^2+X^2}}\right)(\cos q) \quad W \tag{3}$$

$$P = \left(\frac{E^2}{X}\right)\left(\sqrt{1-\cos^2 q}\right)(\cos q) \quad W \tag{4}$$

where

$$\frac{X}{\sqrt{R^2+X^2}} = \sin q = \sqrt{1-\cos^2 q} \tag{5}$$

By using the computed value of C from (1), the value of X in this equation for a frequency of f megacycles may be found from $X = \frac{1}{2pfC}$. By substituting this into (4), the equation then can be written as

$$P = \frac{\left(1.415\times10^{-6} feE^2\right)}{d\sqrt{1-\cos^2 q}\,\cos q} \quad W \tag{6}$$

For the power concentration P_c in watts per cubic inch, (6) reduces to

$$P_c = 1.415\times10^{-6} fe\left(E_g\right)^2\sqrt{1-\cos^2 q}\,\cos q \quad W/in.^3 \tag{7}$$

Where E_g is the voltage gradient across the condenser in volts per inch.

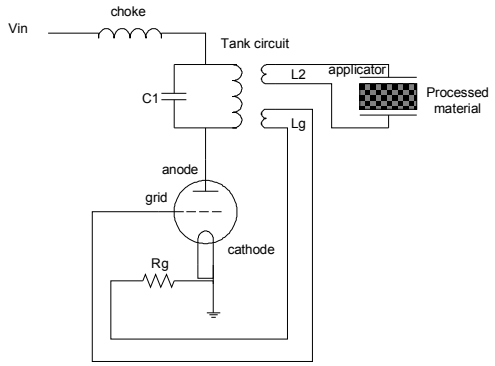
In a specific application of dielectric heating, the permissible voltage across the condenser is limited by such factors as configuration of electrodes, dielectric strength, presence of moisture with possible generation of steam, or irregularities in the wood such as knots. Since the power concentration will usually be fixed by oscillator output and volume of material being heated, a helpful revision of (7) is its solution in terms of the voltage gradient E_g as shown in (8) [7]:

$$E_g = 841\left[\frac{P_c}{fe\sqrt{1-\cos^2 q}\,\cos q}\right]^{1/2} \quad V/in. \tag{8}$$

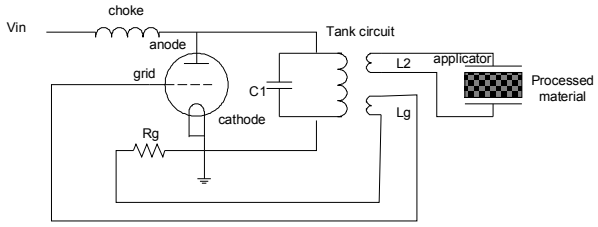
II. MATERIALS AND METHODS

Radio Frequency (RF) heating in industrial (at 13.56 MHz and 27.12 MHz) is an established technique for processing various materials [1, 2]. Applications range from drying of textiles to moisture leveling of biscuits and from the welding of plastics to the heating of woolen bales.

There are two basic technologies characterized the design of equipment in this industry. Self-excited oscillators operated under class C conditions represent of the equipment operating in industry, while the 50 Ω technology employed a crystal oscillator with subsequent amplification through a vacuum amplifier.



(a) Conventional self-excited oscillators circuit



(b) Conventional self-excited oscillators circuit
Figure. 2 Self-excited oscillator circuits

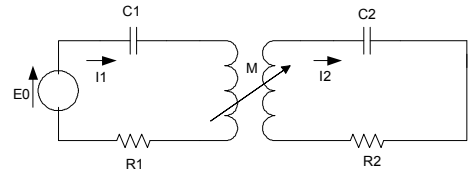


Figure. 3 Equivalent circuit representation of the tank and applicator circuit

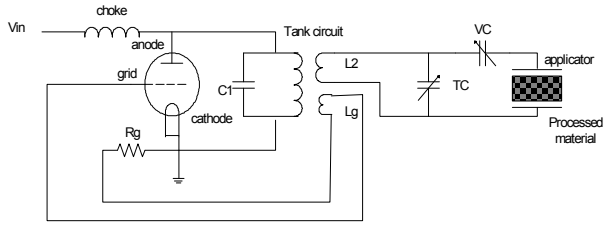

Figure. 4 The proposed self-excited oscillator circuit

This is primarily because of the 50 Ω technology's superior frequency stability. The most commonly arrangement used for dielectric heating installations are the series and shunt fed self-excited tuned anode oscillator circuits as shown in Fig. 2, (a) and (b) respectively. The tank circuits can take the form of either lumped elements as shown in Figure 3 or distributed inductance resonant cavities.

III. Coupling between The Tank and Applicator Circuits

The plate separation of the applicator is varied to enable the applicator and tank circuit resonant frequencies to approach each other so that the state of coupling and matching between the two circuits may be assessed. In this paper only the power coupling efficiency is considered. Therefore the vacuum triode and the associated feedback parts of the circuit can be ignored, reducing the equivalent circuit to that shown in Fig. 3, An ideal sinusoidal voltage source E_0 of frequency $w_0/2p$ excites the coupled resonant circuits. The analysis is carried out for the series tank circuit configuration but a similar treatment would apply to parallel resonant circuits.

The equation (9) and (10) describing the steady-state forced oscillations of the system shown in Fig. 3

$$E_0 = Z_1 I_1 + jMw_0 I_2 \quad (9)$$

$$0 = Z_2 I_2 + jMw_0 I_1 \quad (10)$$

where

$$Z_1 = R_1 + j\left(w_0 L_1 - \frac{1}{w_0 C_1}\right) = R_1 + jX_1 \quad (11)$$

$$Z_2 = R_2 + j\left(w_0 L_2 - \frac{1}{w_0 C_2}\right) = R_2 + jX_2 \quad (12)$$

The suffixes 1 and 2 refer to the tank and applicator circuits, respectively. Solving these equations gives an expression for the primary current I_1

$$I_1 = \frac{E_0}{Z_1 + \frac{M^2 w_0^2}{Z_2}} = \frac{E_0}{Z_{12}} \quad (13)$$

When Z_{12} is the equivalent impedance of the whole system referred to the primary circuit, and is equal to

$$Z_{12} = Z_1 + \frac{M^2 w_0^2}{Z_2} \quad (14)$$

The secondary current is given by

$$I_2 = \frac{-jMw_0 E_0}{Z_1 Z_2 + M^2 w_0^2} = \frac{-jMw_0 E_0}{Z_2 Z_{12}} \quad (15)$$

The circuit is said to be at critical coupling when the following condition is satisfied [14].

$$M^2 w_0^2 = R_1 R_2 \quad (16)$$

At high power level, so it is imperative to ensure that their power transfer efficiency is at its maximum possible value. The input power to the tank circuit is given by

$$P_{in} = \mathrm{Re}\{E_0 I_1^*\} \quad (17)$$

The output power to the load is defined as

$$P_{out} = |I_2|^2 R_2 \quad (18)$$

and the power transfer efficiency h is equal to

$$h = \frac{P_{out}}{P_{in}} = \frac{\left|\frac{Mw_0E_0}{Z_2Z_{12}}\right|^2 R_2}{\mathrm{Re}\{E_0 I_1^*\}} = \frac{1}{1+\frac{R_1\left(R_2^2+X_2^2\right)}{M^2 w_0^2 R_2}} \quad (19)$$

In order to have maximum power transfer efficiency, we need to minimize the following ratio [13].

$$\frac{R_1\left(R_2^2+X_2^2\right)}{M^2 w_0^2 R_2} \quad (20)$$

By differentiating this ratio with respect to w_0 and setting it to zero we obtain the condition for maximum power transfer efficiency as

$$w_0^2 = \frac{w_2^2}{1-\frac{1}{2Q_2^2}} \quad (21)$$

Where w_2 and Q_2 are the angular resonant frequency and Q-factor of the applicator circuit, respectively.

IV. Matching Using The Adjusted by Adjusting Coupling Capacitor

Instead of having a variable inductor inside the generator, our method employed a variable capacitor. This will be series with the load capacitance, given a resultant capacitance which is less than that of the variable one. This resultant capacitance has to tune with the inductance of the coupling coil and the external connecting loads. This method has the advantage that there are no external low loss capacitors which can be damaged, and in principle makes the operation of tuning easier. The test result based on the same mentioned conditions shows that out method can glue two pieces of wood with the same thickness of 0.315 inches with the size of 0.983 inches by 8.66 inches in the time less than 6 seconds. Fig. 5, 6 and 7 shows plate voltage, plate current and grid current of triode tube 7T84RB, respectively. Table I and Table II. The result of gluing wood show that radio frequency heating compared with two hot plate heating.

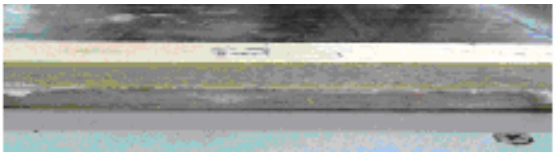

Figure.10 Gluing wood finished.

TABLE I

RESULT OF GLUING WOOD SIZE 0.236 INCHES. 2 PIECES.

Radio Frequency Heating					Two hot plates (2 x 1000 W)	Result
No.	$I_{P(FL)\,(A)}$	I_G (mA)	V_{Load} (V)	Time (per piece)	Time (per piece)	
1-50	0.7	250	1800	6 sec.	3 min.	Glue Completed
51-100	0.8	300	2100	3 sec.		Glue Completed

TABLE II

RESULT OF GLUING WOOD SIZE 0.315 INCHES. 2 PIECES.

Radio Frequency Heating					Two hot plates (2 x 1000 W)	Result
No.	$I_{P(FL)\,(A)}$	I_G (mA)	V_{Load} (V)	Time (per piece)	Time (per piece)	
1-50	0.65	200	1850	11 sec.	4 min.	Glue Completed
51-100	0.75	250	2000	5 sec.		Glue Completed

IV. CONCLUSION

When two hot plates are used, the speed of gluing is determined by the maximum usable plate temperature, that is, the scorch temperature of the wood. It is shown that radio-frequency heating is faster. As the wood section increases in thickness, the argument in favor of radio-frequency heating becomes stronger.

In radio-frequency heating, the central section of the wood is the hottest but for hot-plate gluing the central section is the coolest. Thus if a temperature of say 240 degrees Fahrenheit is needed for gluing in the center of the wood, the remainder of the wood will be at a temperature less than 240 degree, while in two-hot-plate gluing, the remainder of the wood will be at a temperature greater than 240 degrees. Obviously, with lower surface temperatures and shorter heating times, the surface of the wood will not be dried or subjected to surface strains in radio-frequency heating to the extent that occurs in hot-plate heating.

***Abstract*-This paper presents experiments and results of two methods for voltage control for a single-phase ac chopper. These methods are average-value voltage control and instantaneous-value voltage control. In average-value control scheme, an instantaneous peak-value of the output voltage is used as the feedback signal and the controller is of the PI type. The instantaneous-value control scheme, previously proposed by the authors, is based on a modified carrier SPWM and instantaneous value voltage and current feedback control system. The purposes of the experiments are to compare the performance of the two methods and to demonstrate the validity of the proposed instantaneous-value voltage control.**

I. INTRODUCTION

Phase controls controlled with thyristors are used for AC power regulation circuits. The output voltage of the circuit is changed by shifting firing angle of the thyristors. As a result, the distortion of the output voltage enlarges, and the circuit requires filters with large capacitance for eliminating the distortion. It also has a disadvantage that the input power factor is low. To overcome these problems, an AC chopper circuit with the pulse-width control is developed. AC chopper has many advantages such as high-quality output voltage with small low-pass filter requirement, fast dynamic response and high input power factor.

In recent works [1], [2], [3], the amplitude of the output voltage is regulated by feedback control of the effective value or instantaneous peak value of the output voltage using PI controller. The controller output, which is a DC signal, is then compared to the sawtooth carrier pulse to make a PWM signal. This method is called here as the average-value voltage control. The advantage of this method is that the control signal is DC so a simple PI controller can be used. Disadvantages of this method are as follows. Owning to the delay in the detection of the effective value or peak value of the output voltage, the feedback controller cannot be designed for fast dynamic response. Otherwise it risks de-stabilizing the closed loop control. Moreover, because the feedback dc signal does not carry the wave-shape quality information of the output voltage, the quality of the output voltage is out of control. When a nonlinear load is connected to the output of the ac chopper, the output voltage becomes distorted.

The author has proposed a novel voltage control for a single-phase ac chopper in [5]. The proposed control method was based on the modified carrier sinusoidal pulse-width modulation and instantaneous value feedback of the output voltage and current signals. This method is called here as the instantaneous-value voltage control. The simulation results confirmed that the proposed method provided very fast dynamic response against both sudden supply voltage and load change. The proposed control method also demonstrated nearly sinusoidal output waveform even under nonlinear load.

In this paper, experiments are carried out on a single-phase ac chopper using both average-value and instantaneous-value voltage controls. The experimental results will be compared to demonstrate the advantages of the proposed instantaneous-value voltage control of the ac chopper. In the following sections the configuration of single-phase ac chopper and methods for voltage control are firstly reviewed. Secondly, the details of the experiment setup are explained. Finally, the experimental results using both control methods are reported and compared.

II. CONFIGURATION OF A SINGLE-PHASE AC CHOPPER

Fig. 1 shows configuration of a single-phase ac chopper for experiments. Typical gate signals of the four switches and the chopped output voltage before filtering are shown in Fig. 2. Let the input supply voltage is defined as follows:

$$v_s = V_m \cos(\omega t), \tag{1}$$

where ω and V_m are the angular frequency and magnitude of the supply voltage, respectively.

The chopped output voltage can be expressed by (2).

$$v_r = DV_m \cos(\omega t) + \sum_{k=1}^{\infty} \frac{V_m \sin kD\pi}{k\pi} \cos(k\omega_s \pm \omega)t, \tag{2}$$

where D and ω_s are the duty ratio and angular switching frequency, respectively. The first term in the right-hand side of (2) is the fundamental component and the second term is the harmonic content distributing around the switching frequency.

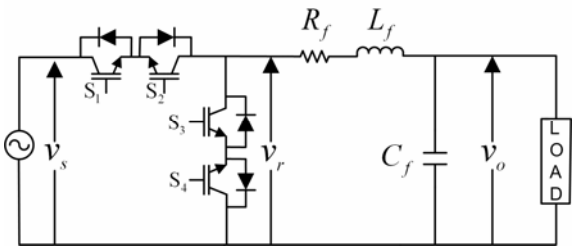

Figure 1. Configuration of a single-phase ac chopper

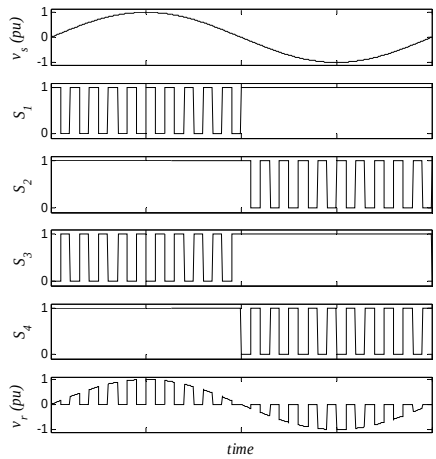

Figure 2. AC chopper waveforms

For a high switching frequency, the harmonic content can be filtered out using appropriated small-size low-pass filter. In steady-state, the filtered output voltage of the ac chopper can be approximately expressed as follows:

$$v_o = DV_m \cos(\omega t - \varphi_1), \tag{3}$$

where φ_1 denotes the fundamental phase delay due to the low-pass filter.

As a result of (3), the amplitude of the output voltage is linearly controlled by the duty ratio of the PWM signal.

III. Controlling of The Output Voltage

A. *Average Value Control Method*

Fig.3 illustrates block diagram for average-value control of the ac chopper. The instantaneous peak value of the output voltage is used as the feedback signal. Calculation of the instantaneous peak value is performed by phase-shifter and multiplier as shown in Fig. 4. The source of the delay of the feedback signal comes from the phase-shifter circuit. The output of the PI controller is used as the modulated signal for the comparator to generate PWM signal.

B. *Instantaneous Value Control Method*

The instantaneous-value voltage control is based on the modified carrier sinusoidal pulse width modulation and

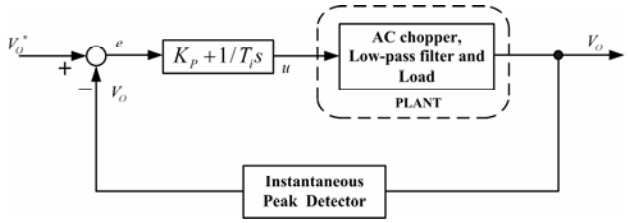

Figure 3. Block diagram for average-value control

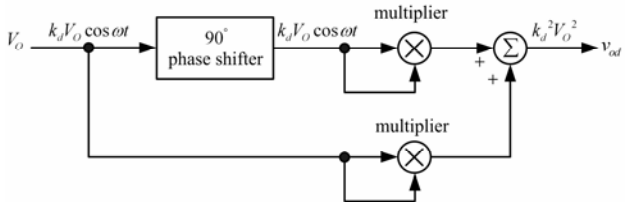

Figure 4. Instantaneous peak detector

instantaneous value feedback of the output voltage and current signals. The modification of the sinusoidal pulsewidth modulator is made at the sawthoot carrier signal generaion. The carrier signal will have its amplitude varying with the instantaneous value of the supply voltage. Fig. 5 illustrates a simplified schematic diagram of the sawtooth carrier pulse generator. This circuit uses a non-inverting integrator in stead of an inverting integrator as in the previously proposed circuit [4], however the principle of operation is the same. The absolute-value of the supply voltage signal is used as the input of the integrator circuit. If the supply voltage is defined by (1), it can be shown as in (4) that the output voltage at t_1+T instant is equal to the amplitude of the supply voltage at t_1+T /2 instant.

$$v_c(t_1 + T) = V_m \cos\omega(t_1 + T/2), \tag{4}$$

where, T is the period of the sawtooth signal. From (4), the amplitude of the sawtooth pulse varies with the amplitude of the T/2-second delayed supply voltage. Because the magnitude of the sawtooth pulse is very low around the zero-crossing of the supply voltage, this could lead to fully-on of the switches and makes it unable to control the output voltage around the zero crossing of the supply voltage. To correct this, small dc voltage is added to the integrator input to increase the slope of the triangle pulse around zero-crossing. The advantage of this circuit is that the output voltage is independent of the supply voltage as long as the duty ratio is less than a unit.

The block diagram of the feedback control of the output voltage is shown in Fig. 6. The plant model of the ac chopper is devired using the state-variable average model method described in [5], where the output current is model as external disturbance. In Fig. 6 the effect of output current is rejected by the feedback of the signal u_{fd} derived from output current. If the parameters of the model match with those of the actual plant the closed loop transfer function of the system becomes

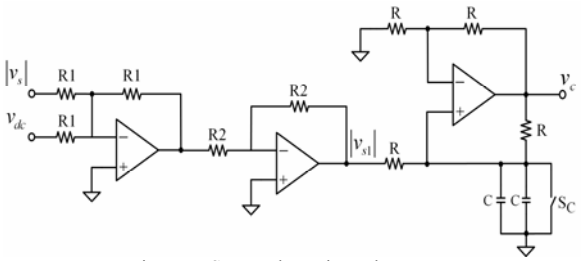

Figure 5. Sawtooth carrier pulse generator

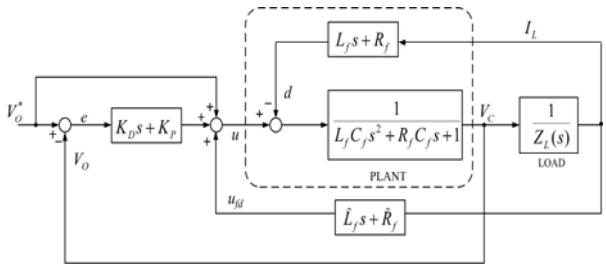

Figure 6. Block diagram for the control system of the output voltage.

$$\frac{V_o(s)}{V_o^*(s)} = \frac{K_D s + K_P + 1}{L_f C_f s^2 + \left(K_D + R_f C_f\right) s + K_P + 1}, \quad (5)$$

where K_D and K_P are the derivative and proportional gain of the PD controller, respectively.

The poles of the closed-loop control system are

$$s_{1,2} = -\zeta\omega_n \pm j\omega_n\sqrt{1-\zeta^2}, \quad (6)$$

where

$$\omega_n = \sqrt{(K_p + 1)/(L_f C_f)}, \quad (7)$$

and

$$\zeta = \frac{1}{2}\left(K_D + R_f C_f\right)\Big/\sqrt{\left(K_P + 1\right) L_f C_f} \quad (8)$$

are the natural frequency and damping factor of the closed-loop system, respectively.

The desired closed-loop control characteristics can be specified by properly selecting the gains K_D and K_P. The absolute value of the controller u and the modified carrier signal v_c is used as the inputs for the comparator to generate PWM signal.

IV. Experimental Results

The experiments have been carried out on the follwing topics; the step response of the referrence signal, the effect of nonlinear load and the effect of sudden supply voltage changes. Both average-value and instantaneous-value voltage control are applied for comparison. The details of the experiment parameters are summarized in Table I.

TABLE I
IMPORTANT PARAMETERS FOR EXPERIMENTS

AC chopper	
Supply voltage	220 V, 50 Hz
Switching frequency	20 kHz
Load-side low-pass filter	
L_f	500 μH
R_f	0.05 Ω
C_f	5 μF
Supply-side filter	
C_s	16 μF
Controller parameters	
K_D	0.00005
K_P	3.6
Conventional PI controller	
K_i	0.005
K_P	0.2
Nonlinear load (Diode rectifier with dc reactor)	
Filter capacitor	2600 μF
Load resistance	18 Ω
DC reactor	15 mH
IGBT	
S1-S4	G20N60B3D, 600V 40A

A. *Step response*

Fig. 7 illustrates the step responses of the ac chopper using the average-value voltage control, Fig. 7(a), and the proposed instantaneous value voltage control, Fig. 7(b), respectively. In the case of instantaneous voltage control the output voltage track in referrence voltage precisely and exhibit only small overshoot while in the case of average value control large overshoot appears at the output voltage.

B. *Effect of nonlinear load*

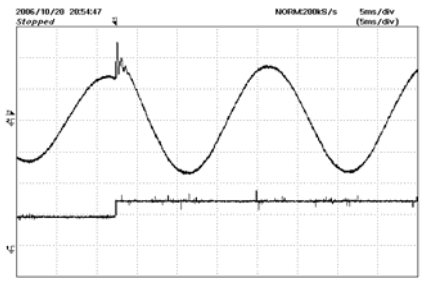
Fig. 8 illustrates the effect of nonlinear load using both control methods. The output voltage is nearly a sinusoidal wave in the case of the intantaneous value control and it is distorted by the nonlineality of the output current under average value control.

C. *Effect of supply voltage variation*

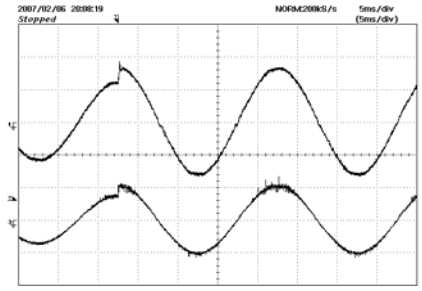
Fig. 9 shows the results when the supply voltage dipped from 100% to 70%. With the instantaneous value control, the output voltage remained unaltered while with the average value control the output voltage dipped at first and then climbed to the reference value as time passed. Also a large overshoot of the output voltage is observed at the end of voltage dip in the case of average value control.

V. Conclusion

The experiments on average-value and instantaneous-value voltage control of a single-phase ac chopper have been carried out. The purpose of the experiments is to compare the performance of both control schemes. The comparison focus on the four topics including step response, effect of nonlinear load and effect of supply voltage variations. From the experimental results, the proposed instantaneous value voltage control provides improved dynamic response, robustness to the supply variation and less sensitivity to the nonlinear load.



(a) In case of average value control (output voltage, upper trace, 100V/div; reference voltage, lower trace, 5V/div)



(b) In case of Instantaneous value control (output voltage upper trace, 100V/div; reference voltage, lower trace, 5V/div)

***Abstract*- This paper proposes a fuel cell emulator used to replace a real fuel cell system during the development stage of a fuel-cell inverter system. The power stage of this new fuel cell emulator consists of a current source converter (buck rectifier) and a dc-to-dc buck converter. With the collaboration of these two power electronics circuits and the controller, the proposed fuel cell emulator provides both an emulated fuel cell response and the high-quality output voltage and current. This research mainly focuses on emulating the behavior of two well-known types of fuel cell systems: Proton Exchange Membrane Fuel Cell (PEMFC) and Solid Oxide Fuel Cells (SOFC). The suggested fuel cell emulator can effectively perform in all three operation regions, i.e. activation, ohmic and concentration. Analysis, modeling and control strategy are presented. The performance of the proposed fuel cell emulation is finally verified by simulation results.**

***Index Terms* – Fuel Cell Simulator, Fuel Cell Inverter.**

I. INTRODUCTION

Today, fuel cell is one of the most promising renewable power sources due to its cleanness, high power density and low emission. Fuel cells can be used as a source of renewable power including transport, portable and residential applications. In addition, the standalone aspect of distributed resource technology makes fuel cells particularly useful in areas not served by a national power grid or where the national grid is unreliable and backup power is required.

Six main types of fuel cells are alkaline, direct methanol, molten carbonate, phosphoric acid, proton exchange membrane (PEM) and solid oxide (SO). Each type has its own advantages for different applications. For example, the most popular fuel cell type for automotive is PEM fuel cell. While, the SO fuel cell is suitable for stationary power source.

The output DC voltage profile of fuel cells depends on the amount of load current and the fuel flow rate. The power conditioning, therefore, is necessary. In general, a fuel cell power supply system consists of a fuel cell stack, a fuel supply system, a power electronic-based inverter and a master controller. The total system performance of the fuel cell system mainly relies on the characteristics of the inverter and a great response of the master controller. Thus, a fine tune process for the system is essential. Moreover, the major cost of the development period of a fuel cell system is the fuel cell stack. Therefore, the objective of this research is to develop a voltage source such that it can properly and efficiently replace a real fuel cell system during this period.

Several attempts to emulate electrical characteristic of fuel cells have been previously made. However, there are some disadvantages. The voltage of the DC link of circuit in [1] is quite high relatively to the output voltage, which can be varied from 20 V to 50 V. This means that the duty cycle for the buck converter is in the range of 0.06 to 0.16. Practically, such low duty cycle lowers the entire system efficiency and introduces an electromagnetic interference problem. In contrast, [2] applied basic electronics components such as bipolar junction transistors, diode and other passive components. The advantage of this kind of circuit is its simplicity. However, the drawback is that the system is inflexible. The circuit must be redesigned when types of fuel cell or operating points are changed. In [3], the system provides very precise fuel cell character. It can be used for various kinds of fuel cell. Nevertheless, the system implementation is somewhat questionable.

This research, therefore, proposes a fuel cell emulator that solves the previous problems. The main advantages of the proposed system are flexibility to provide a wide range of operating point, high efficiency and simplicity in both control stage and power stage.

II. FUEL CELL ELECTRICAL CHARACTERISTICS

To explain the basic characteristics of fuel cells, PEM fuel cell is used as an example. PEM fuel cells basically combine oxygen and hydrogen over a platinum catalyst to produce electrochemical energy. Byproducts of this process are heat and water, which make the fuel cell a clean source. Dash line in Fig. 1 shows the actual voltage-current characteristic of a single cell operating at room temperature and normal air pressure [4]. The variation of voltage for an individual cell is derived from the maximum cell voltage (sometimes called EMF) and the different voltage loss states. Various factors play an important role to the voltage drop in an actual fuel cell that causes the cell voltage to be less than the no load voltage (ideal potential). These losses, which are also called overvoltage, polarization and irreversibility, originate primarily from three sources: a) activation polarization, b) ohmic polarization, and c) concentration (mass transport) polarization.

By using PEM fuel cell as an example, at a given temperature with partial pressure of the reactants and products known, the ideal voltage or no load potential is the maximum voltage that each cell in the stack can produce. For the PEM fuel cell, in general, its ideal terminal voltage can be calculated based on Gibbs free energy, and it is approximately 1.2 V at 25°C, where pure hydrogen and air are used.

This research is supported by The Thailand Research Fund and Commission on Higher Education. Grand no. MRG48-Siriroj Sirisukprasert

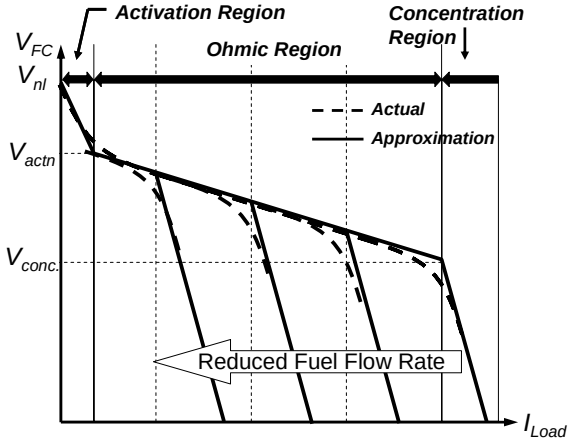

Figure 1. Voltage-Current relationship of PEM fuel cell.

The activation polarization loss is present when the rate of the electrochemical reaction at an electrode surface is controlled by sluggish electrode kinetics. It is dominant at low current density. The higher load current is, the higher activation loss.

With the parasitic resistance of the polymer electrolyte membrane to the ions and the imperfect electrodes, the ohmic polarization loss is present. In this region, the fuel cell terminal voltage linearly decreases with the increasing load.

Concentration polarization (mass transportation) loss relates to the changes in the reactants concentration at the surface area of the electrodes as the fuel is being used. The concentration of the oxidant and the fuel is decreased at various points in the fuel-cell gas channels and is less than the concentration at the inlet value of the stack. This loss becomes significant at higher load currents when the fuel and the oxidant are used at higher rates, while the concentration in the gas channel is a minimum.

The proposed fuel cell emulator follows the actual behavior of a fuel cell by the approximated characteristic (solid line) in Fig. 1. In other words, the proposed system used the solid linear line as a control objective.

III. The Proposed System

The proposed fuel cell emulator system is based on the power electronics technology. The system consists of two main parts: power stage and control stage. As shown in Fig. 2, the power stage receives AC input and then generates a DC output, which can follow the V-I characteristic of fuel cells.

The power stage can be divided into two parts: 1) a three-phase buck rectifier or a three-phase current source inverter (CSI) and 2) a buck converter or a step-down dc-to-dc converter. The three-phase CSI was selected as the input stage of the proposed system because of its high power capability and small ripple DC link. Therefore, a smaller DC link capacitor can be employed. In comparison, a three-phase system can supply three times as much of maximum power and generates three times as less voltage ripple as a single-phase does.

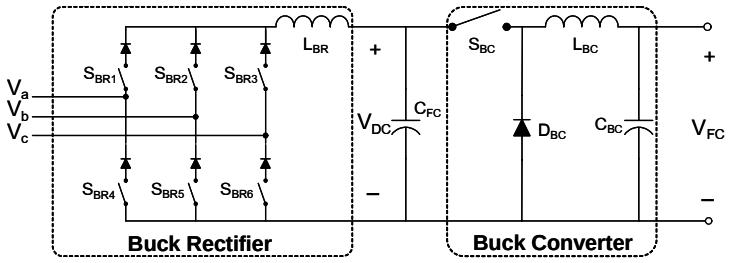

Figure 2. Power stage of the proposed system.

The front end of the proposed power stage is a three-phase buck rectifier. Buck rectifiers converse the three-phase AC voltage to the adjustable DC voltage, which can be varied from 0 V to $0.866 \cdot V_p$, where V_p is peak of the AC input line voltage. Usually, the DC link voltage in this application is set to no-load terminal voltage of fuel cell stack. This buck rectifier comprises 6 main switches (S_{BR1} to S_{BR6}) and 6 series diodes. L_{BR} and C_{FC} are used as a low-pass filter. Main function of the buck rectifier is to emulate the V-I characteristic of fuel cell when flow rate and pressure of fuel (Hydrogen, for example) are changed as shown in Fig 1. The concentration region is where the buck rectifier takes the action. The dynamic characteristic of the output voltage and current can also be emulated by the buck rectifier. Moreover, the very low duty cycle problem in [1] can be solved by using a stepped-down DC link in this stage.

The output end of the power stage for the proposed fuel cell emulator is a buck converter. The function of the buck converter in this system is to generate the output DC voltage consistent with the V-I relationship of a fuel cell stack. The buck converter mainly takes action in both activation and ohmic regions. The buck converter is composed of a main switch, S_{BC}, and free-wheeling diode, D_{BC}. L_{BC} and C_{BC} are used as a low-pass filter.

IV. Power Stage Modeling and Controller Design

The block diagram of the main controller of the proposed system is shown in Fig. 3. At the front end, two line-to-line input voltages are sensed for control synchronization. To control the output DC voltage, the output voltage, V_{FC}, and the output current, i_{Load}, are measured.

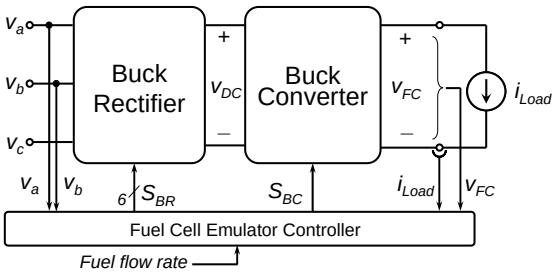

Figure 3. Power stage of the proposed system.

A user command for this system is fuel flow rate, which is a main command of the buck rectifier. The outputs of the controller are switching signals for six switches of the buck rectifier and the switch of the buck converter.

A. Power Stage Modeling

Due to the large output voltage and current variation, the open-loop control is employed for the buck converter. However, to regulate V_{FC}, a closed-loop control on the buck rectifier is used to complete this task instead.

To design the feedback control, the first step is developing a small signal model for the buck rectifier. The following steps are the technique used in this research: 1) developing a switching model 2) developing an average model in abc-coordinates 3) developing an average model in dq0-coordinates and 4) developing a small-signal model in dq0-coordinates. In the dq0 space, the power stage can then be controlled by using the classical linear control theory.

To further simplify the front end controller, the voltage vector in the abc space is arranged to inline with D axis as shown in Fig. 4. By doing so, quadrature components are eliminated. Fig. 5 shows an average model of the proposed power stage. From the average model, the following relationship can be derived:

$$V_{DC} = d_d \cdot V_d. \quad (1)$$

This means that the DC link can be adjusted by varying the direct duty cycle, d_d. From Fig. 5 and (1), the steady-stage transfer function of the proposed power stage is as follows:

$$V_{FC} = d_{BC} \cdot d_d \cdot V_d. \quad (2)$$

B. Controller Design

As shown in Fig. 6, the proposed controller can be divided into 2 parts, i.e. buck converter controller and buck rectifier controller. The controller for buck rectifier is designed in such a way that its control response is much slower than the buck converter.

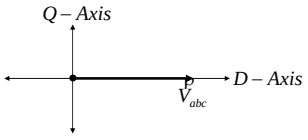

Figure 4. Voltage vector in abc space inline with D axis .

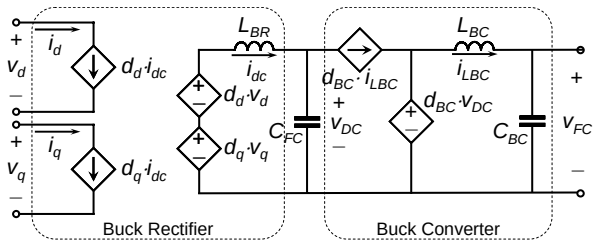

Figure 5. Average model of the proposed power stage.

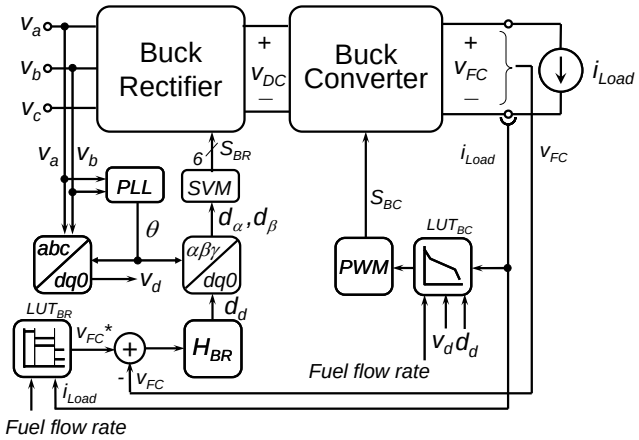

Figure 6. Block diagram of the proposed controller.

The buck converter is working mostly in activation and ohmic regions, while the buck rectifier is working in the concentration region. In the activation and ohmic regions, the duty cycle d_d is kept constant. To avoid control interference between these two loops, the duty cycle d_{BC} maintains unchanged during the concentration region.

As mentioned previously, the buck converter is open-loop controlled. The current, i_{Load}, V_d, d_d and the fuel flow rate command are fed into a look up table, LUT_{BC}. Without the DC link voltage sensor, the DC link can be approximated by multiplying V_d by d_d. The output of LUT_{BC} that is the duty cycle for the buck converter is fed into the pulse width modulation (PWM) to generate the switching signal for the main switch. The estimated technique used in the proposed system is shown by the solid line in Fig. 1. LUT_{BC} contains two linear lines, i.e., one for the activation region and the other one for the ohmic region. In most of fuel cell stacks, the slope of the output voltage in the activation region is higher than that in the ohmic region. As shown in Fig.1, the slope for the activation region can be derived from V_{nl} and V_{actn}, while the slope for ohmic region can be derived from V_{actn} and V_{conc}. The relationship of the voltage and the current in LUT_{BC} depends on the electrochemical characteristics of various fuel cells. Due to the open-loop control, the voltage drop is taken into account and is compensated in LUT_{BC}.

By utilizing dq0 control, two input phase voltages (V_a and V_b) are used as a three-phase synchronous signal. The phase lock loop (PLL) mathematically generates the angle of the input voltage vector, which is used in abc-to-dq0 transformation. Another look up table applied in this control loop is LUT_{BR}. The fuel flow rate command and the load current are the inputs of this look up table. The output of LUT_{BR} is the output voltage command, V_{FC}*. The output voltage command is compared with the feedback output voltage command and the error is compensated by a PI controller (H_{BR}). Later, the command duty cycle, d_d, is derived. By using the inversed transformation matrix, d_d is converted to d_α and d_β. The 0-channel components are all omitted based on the assumption of the balanced three-phase system. The d_a, d_b

and d_c are derived by using a space vector modulation (SVM) for the current source converter.

V. Simulation Results

To verify the performance of the proposed system, the power stage and the controller (shown in Fig. 6) are simulated by a personal computer. The main simulation parameters are shown in table 1. The load is a current source with 2A increment. Voltage-current characteristics used in the simulation are adapted from [3]. The reference V-I characteristic is typical for PEM fuel cells. Four data sets used in the simulation are for the fuel flow rates of 25%, 50%, 75% and 100%. For 100% fuel flow rate, the fuel cell emulator terminal voltage at no load is about 55 V and is about 22 V at full load.

The switching frequency of the buck converter is 30 kHz, which is about three times higher than that of the buck rectifier. To assure the performance of the controller, the bandwidth of control loop for the buck rectifier is about 1 kHz.

TABLE I
Simulation parameters

Parameters	Value
Power Stage	
- Buck rectifier switching frequency	10 kHz
- Buck converter switching frequency	30 kHz
- Input voltage	220 V - 3Φ
Fuel Cell Stack	
- Type of fuel cell stack	PEM
- Maximum power	1.5 kW
- Fuel flow rate (%)	25, 50, 75, 100
- Terminal voltage range	22 V to 55 V
- V-I characteristic	Reference [3]

The simulation results for the fuel flow rates of 25%, 50%, 75% and 100% are shown in Fig.7 to Fig.10, respectively.

VI. Conclusions

The proposed fuel cell emulator is used to replace a real fuel cell system during the development stage of a fuel-cell inverter system. The main advantages of the proposed system are flexibility to provide a wide range of fuel cell characteristics, high efficiency and simplicity in both control stage and power stage. The performance of the proposed fuel cell emulation is finally verified by simulation results. The simulated V-I characteristic is acceptably consistent with the reference characteristics. Now, the prototype of the proposed system is designed and implemented. The complete experimental results will be presented in the next paper.

Abstract - **The cross regulation in multiple-output flyback converters is affected by leakage inductances of the transformer. The suitable winding arrangements of the transformer will lead to the improved cross regulation. This paper presents the comparative study of the four different winding arrangements in the four winding flyback transformer. The cross regulation model is considered in a form of the resistance matrix that is related to the leakage inductance parameters. The design guidelines for the transformer for improving cross regulation are given based on the experimental results.**

Keywords : Cross regulation , Flyback converters , Leakage inductance

I. Introduction

The multiple-output switching converter is generally used in low power applications for electronic equipments that need different levels of output voltages such as a computer. One of the most favorite used configurations is a multiple-output flyback converter, due to its low component counted, cost-effective structure, and large dynamic range.

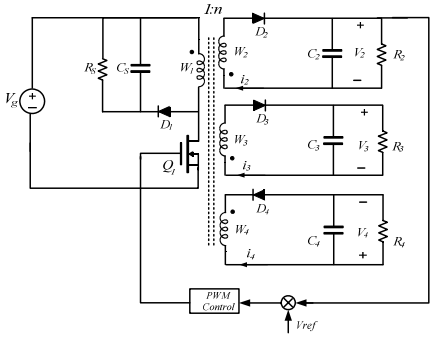

Fig. 1 The Experimental three output flyback converters

Typically, as shown in Fig. 1, the main output voltage of the converter is directly sensed by the feedback network and regulated to the desired value. The auxiliary outputs are not directly regulated, but are fixed with respect to the principle output voltage by the coupling between the transformer windings, which is called cross regulation. The cross regulation analytical models and the methods for improving cross regulation in multiple-output converters are proposed in many forms [2, 3, 4 and 5]. However, it still lacks general sense because they are only considered for one simple magnetics structure. In [6], it presents the effects of several different magnetics structures of the high frequency transformers on cross regulation. It shows that the different magnetic structure of a transformer hardly affects on cross regulation in a multiple-output flyback converter.

In this paper, we present a comparative study and design guidelines of a high frequency transformer to improve cross regulation of a multiple output flyback converter. The winding arrangements are reasonably performed in order to control leakage inductance in such a way to improve cross regulation. The experiments results are illustrated and the transformer design guidelines are concluded to be simple rules to improve cross regulation in multiple-output flyback converter.

II. Analytical model of cross regulation in a multiple flyback converter

a. The Extended Cantilever Model

The behaviors of a multiwinding high frequency transformer can be analyzed using the cantilever model as shown in Fig.2.

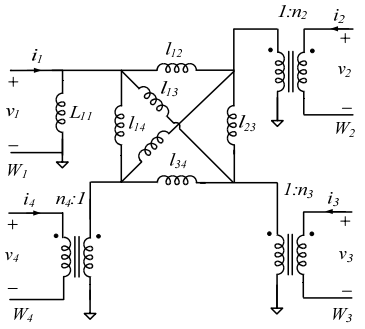

Fig. 2 The Extended cantilever model of four winding Transformer

The extended cantilever model contains *n(n+1)/2* independent parameters including leakage inductance parameters. L_{11} is a self-inductance and l_{jk} is a leakage inductance between winding j[th] and k[th]. All parameters can be directly measured by using a two port technique. For example the effective turn ratio is equal to

$$n_k = \frac{v_k}{v_1} \tag{1}$$

Additionally, the value of leakage inductance parameter l_{jk} is obtained by driving winding W_j with voltage source V_j with all other winding are short-circuited. The current i_k in

winding W_k is measured. The effective leakage inductance l_{jk} is given by

$$l_{jk} = \frac{v_j(s)}{s n_j n_k i_k(s)} \qquad (2)$$

b. The N-port Model

The extended cantilever model is also closely related to *N*-port description of the transformer. The *N*-port model is useful in computer simulation and simple analysis of the multiple-output flyback converter. The primary winding of the *N*-port is modeled as a current controlled Norton equivalent network as illustrated in Fig. 3. The inductance of this port is the primary self-inductance L_{11}. The current controlled current source (CCCS) is equal to the sum of the secondary winding currents. The secondary windings are modeled as voltage controlled Thevenin equivalent networks. Equation (3) is the expression of a series inductance of winding *k*, L_{ok}, which is equal to effective leakage inductance connected to winding *k* as

$$L_{ok} = n_k^2 \left(l_{1k} \| l_{2k} \| \ldots \| l_{(k+1)k} \| l_{(k+1)k} \| \ldots \| l_{Nk} \right) \qquad (3)$$

and the voltage controlled voltage source is given by

$$V_{Tk} = \frac{L_{ok}}{n_k l_{1k}} v_1 + \frac{L_{ok}}{n_1 n_2 l_{2k}} v_2 + \ldots + \frac{L_{ok}}{n_k n_{k-1}} v_{k-1} + \frac{L_{ok}}{n_k n_{k+1} l_{(k+1)k}} v_{k+1} + \ldots + \frac{L_{ok}}{n_k n_N l_{Nk}} v_N \qquad (4)$$

The analysis of the multiple-output flyback converter using the *N*-port model shows that the rate change of the secondary output current i_k is given by

$$\frac{di_k}{dt} = \frac{1}{n_k l_{1k}} v_1 + \frac{1}{n_k n_{k+1} l_{k(k+1)}} v_{k+1} + \ldots + \frac{1}{n_k n_N l_{kN}} v_N - \frac{1}{L_{ok}} v_k \qquad (5)$$

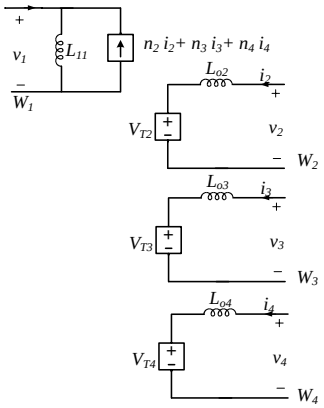

Fig. 3 The four type N-port model

For example, Eq. (6) expresses the rate change of a secondary output current in winding 2 in terms of leakage inductances in the extended cantilever model by

$$\frac{di_2}{dt} = \frac{1}{n_2 l_{12}} v_1 - \frac{1}{L_{o2}} v_2 + \frac{1}{n_2 n_3 l_{23}} v_3 + \frac{1}{n_2 n_3 l_{24}} v_4 \qquad (6)$$

III. The winding arrangements of the high frequency transformers

a. Winding arrangement designs of high frequency transformers

The leakage inductances in the high frequency transformer play important role in the multiple-output flyback converter. Therefore, the control of values of the specific leakage inductances can improve the cross regulation in the converter. As we know, the value of leakage inductance depends on the winding arrangement in the core. Changing position of the winding will change the value of the effective leakage inductance. In this section, the four different top-to-bottom winding arrangements of the four-winding transformer are constructed with the ferrite core of ETD49/25/16 and foil copper winding 1.5 mm thickness as shown in fig. 4(a) - 4(d). The specification input voltage of the converter is 40V. The main output voltage of 5V, and auxiliary output voltage of 12V and -12V. The switching frequency is 100 kHz and a duty ratio of 0.5.

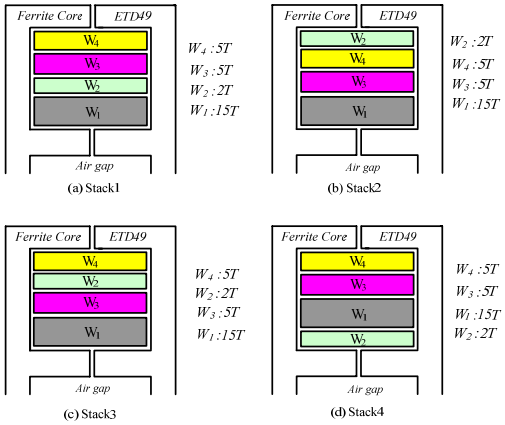

Fig. 4 Experimental winding geometries in flyback transformer

Fig. 5 Experimental high frequency transformers

b. Measurement of Leakage Inductances

Measured leakage inductance values of four winding arrangements are shown in Table 1 using the method mentioned previously. Secondary output current waveforms of the experimental transformers with the main output current I_2 of 3A and auxiliary output currents I_3 and I_4 of 1A are shown in Fig. 6 -9. The slopes of the main output current of

experimental transformers are all positive while the slopes of the auxiliary output currents are all negative.

Table1. Summary of flyback transformer parameter measurements

Inductance parameter	Measure values			
	Stack1	Stack2	Stack3	Stack4
n_2	0.15	0.13	0.15	0.15
n_3	0.3	0.3	0.3	0.3
n_4	0.3	0.3	0.3	0.3

IV. The cross regulation results of the experimental transformers in a multiple output flyback converter

Each designed transformer is connected to the experimental three-output flyback converter. The cross regulation is determined by the change of the output voltages of the converter while varying the main output current form 0.5A to 3.5A with keeping other output currents constant at 1A. The expression is in a form of $\Delta\mathbf{V} = -\mathbf{R}\Delta\mathbf{I}$. $\mathbf{R}$ is a resistance matrix model. The converter operates in continuous conduction mode (CCM) for all operating points. Comparatively, Fig. 12 shows the changes of output voltages when varying the main output current of each designed transformer.

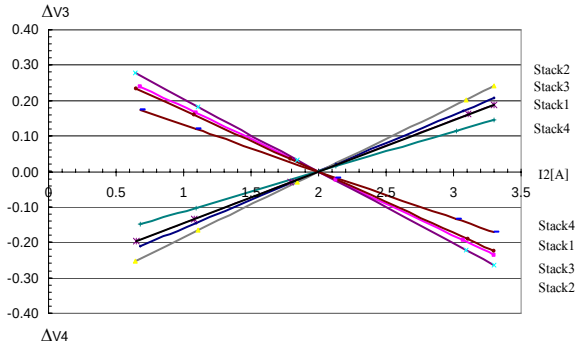

Fig. 12 The comparison of cross regulation in a multiple output flyback converter

The resistance matrix model of each designed transformers can be determined as Eq. (7) – (10).

$$\text{Stack1} = \mathbf{R}_{expriment} = \begin{bmatrix} 0.31 & 0.17 & 0.16 \\ 0.16 & 1.06 & 0.46 \\ -0.18 & -0.52 & -0.95 \end{bmatrix} \Omega \quad (7)$$

$$\text{Stack2} = \mathbf{R}_{expriment} = \begin{bmatrix} 0.33 & 0.16 & 0.16 \\ 0.17 & 0.89 & 0.44 \\ -0.20 & -0.41 & -0.63 \end{bmatrix} \Omega \quad (8)$$

$$\text{Stack3} = \mathbf{R}_{expriment} = \begin{bmatrix} 0.35 & 0.17 & 0.16 \\ 0.15 & 0.95 & 0.41 \\ -0.17 & -0.46 & -0.87 \end{bmatrix} \Omega \quad (9)$$

$$\text{Stack4} = \mathbf{R}_{expriment} = \begin{bmatrix} 0.35 & 0.14 & 0.13 \\ 0.11 & 0.66 & 0.41 \\ -0.12 & -0.21 & -0.79 \end{bmatrix} \Omega \quad (10)$$

The cross regulation in the auxiliary output voltages is considered from non-diagonal elements of the matrix. The small values are required for the improved cross regulation. From experimental results, the designed transformer: Stack 4 is the best among other designs. Since the cross regulation at auxiliary output voltages *V3* and *V4* has been affected by the leakage inductance parameters between windings *W3* and *W4* and the main output winding *W2* (l_{23} and l_{24}). Therefore, controlling the leakage inductance values among those windings will be able to control the cross regulation. In the designed Stack 4, the auxiliary windings are placed away from the main winding. The corresponding leakage inductance values of the designed Stack 4 shown in Table 1 are large results in the small values in non-diagonal elements in the matrix. Hence, based on the experimental results, the transformer design guidelines for improving cross regulation in a multiple-output flyback converter can be given as following:

- The leakage inductances between primary and secondary windings (l_{12} ,l_{13} and l_{14}) should be small to minimize magnetic flux.
- The leakage inductances between secondary and secondary windings (l_{23}, l_{24}, and l_{34}) should be maximized to reduce the effect of magnetic flux between windings when the load changes.
- The main output winding should be positioned near transformers core to reduce the leakage inductance.
- The primary and secondary windings should be in proximity while each secondary windings should be placed away as much as possible.

V.Conclusion

The cross regulation in multiple-output flyback converters is affected by leakage inductances of the transformer. The suitable winding arrangements of the transformer will lead to the improved cross regulation. This paper presents the comparative study of the four different winding arrangements in the four winding flyback transformer. The cross regulation model is considered in a form of the resistance matrix that is related to the leakage inductance parameters. The design guidelines for the transformer for improving cross regulation are given based on the experimental results.

***Abstract*-This research is aimed to design and build a small size, light weight AC power supply. Voltage to frequency converter (VFC) is used to control switching devices of a full-bridge series-loaded resonant converter, which operates in discontinuous conduction mode for reducing switching power losses and also high switching frequency can reduce the size of passive device in the circuit. The proposed approach has been built to deliver sinusoidal AC output voltage at 220 volts 50 Hz with 200 Watts output power.**

Keywords- AC Power pack, Voltage to frequency converter, full-bridge series-loaded resonant converter

I. INTRODUCTION

Normally a DC to AC converter is used for converting DC voltage to AC voltage to supply AC electrical loads. For instance it converts power from a battery (mostly 12 VDC) to standard household AC power (220VAC). The output waveform can be sinusoidal, square, stepped or triangular wave. Pure sinusoidal waveform is the best one, as it is the shape of an (ideal) AC electrical power from utility. The highest-quality inverter must produce the pure sine wave output. This type of output waveform is normally found only in higher-end product.

In this paper, a portable AC Power pack with full bridge series-loaded resonant converter is designed, simulated and built to produce sinusoidal output voltage waveform. The inductor current is controlled to operate in discontinuous conduction mode (DCM), which aims to reduce switching power losses of switching devices in the circuit. Switching frequency is controlled by voltage to frequency converter (VFC) and keeps the highest switching frequency at 100 kHz. The circuit diagram of the system is shown in Fig. 1 [1]-[3].

The power supply was designed to provide 220 V 50 Hz output voltage and 200 W power output. The model was simulated by using Matlab program before implementing in a laboratory.

II. PROPOSED TOPOLOGY

A. Voltage to Frequency Converter

The VFC has become quite popular due to their low cost and can be used in variety of electronic control and measurement systems [4]. VFC compose of an oscillator whose frequency is linearly proportional to control voltage. In the purpose system, it changes an absolute sinusoidal wave to a pulse signal with frequency variation proportional to the amplitude of input voltage. If the input voltage is high, the output frequency is also high and vice versa. The variable-frequency pulse-width can be modified by keeping constant turn on time to suit the operation of the series-load resonant topology. Matlab model of VFC is shown in Fig. 2 the model can be adjusted the turn on time by changing parameter of clock. In the implementation an IC chip number VFC320 is used for designing the VFC. The advantage of this IC is easy to use and convenient for the circuit connection.

B. Discontinuous Mode of Operation

The series load resonant converter which consist of power switching devices Q_1 to Q_4 and series resonant circuit element, L_r and C_r. The circuit is designed to operate in the discontinuous mode. The energy in resonant inductor (L_r) is consumed before the second switching period. There are six stages of operation in one switching cycle as shown in Fig. 3.

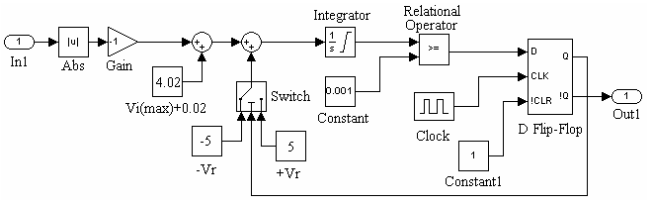

Fig. 2. Matlab model of VFC

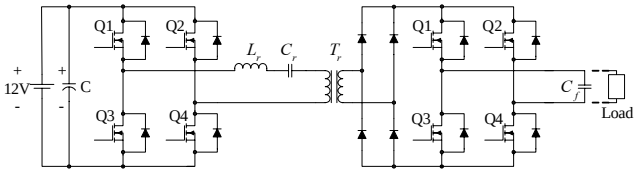

Fig. 1. Circuit schematic of AC power supply

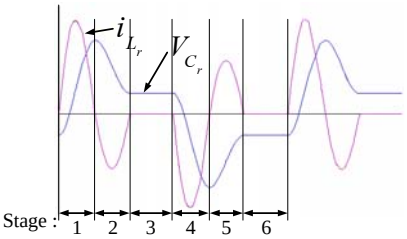

Fig. 3. Switching waveforms for discontinuous mode full-bridge series-loaded resonant converter

In the stage 1 and 2 the switching devices Q1 and Q4 are controlled to be on, and stage 4 and 5 Q2 and Q3 are on. During stage 3 and stage 6, all the switching devices remain off for maintaining the operation is in the discontinuous. The characteristic of this mode leads to zero current switching; so that the switching power losses can be minimized [5].

III. THE MODELING OF ALL SYSTEM

A. Design Switching Frequency and Resonant Frequency

In order to have small size of resonant inductor (L_r) and resonant capacitor (C_r), the resonant frequency and the switching frequency should be high. Choose maximum switching frequency 100 kHz, and turn on time (t_{on}) is $5\,\mu s$. Let assign the resonant frequency time period to 4/3 of the turn on time to guarantee the discontinuous conduction mode, so that resonance frequency is 150 kHz ($6.667\,\mu s$). The relation of switching frequency turn on time and resonant frequency is shown in Fig. 4.

B. Design L_r C_r

The series resonant tank, L_r and C_r are chosen from the well-known equation as in (1)

$$\omega = \frac{1}{\sqrt{L_r C_r}} \quad \text{and} \quad \omega = 2\pi f_r$$

so

$$f_r = \frac{1}{2\pi\sqrt{L_r C_r}} \tag{1}$$

where f_r is resonance frequency, Choose $C_r = 1\mu F$, so that form (1), $L_r = 1.126\mu H$. Use these parameters to make a model for simulation as shown in Fig. 5. The inductor current of the series resonant is

$$i_{Lr}(t) = \frac{V}{Z_O}\sin(\omega t) \tag{2}$$

where $Z_O = \sqrt{\frac{L_r}{C_r}}$

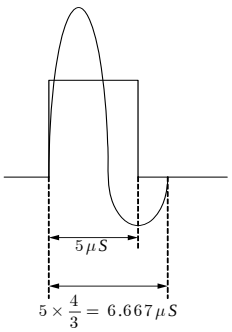

Fig. 4. Resonance frequency

C. AC Power Pack Model

The schematic diagram of AC power supply in Fig. 1, can be built as a model as shown in Fig. 6. The voltage from secondary side of transformer is rectified to be absolute value by bridge rectifier and then convert to be AC signal at the frequency 50 Hz, after that sent to a low pass filter. The first order low pass filter is designed by

$$V_O = \frac{1}{RCS + 1} \tag{3}$$

where $RC = \frac{1}{2\pi f}$

The corner frequency of the filter is selected at 100 Hz, so that RC = 0.0015.

IV. SIMULATION RESULTS

The parameters which have been designed in the section 3 are used in developing simulation model of the proposed AC power supply. The simulated results are discussed below.

A. VFC

The simulated result of the model in Fig. 2 is presented in Fig. 7-8. The absolute sine wave voltage is converted to frequency which proportional to the voltage level.

B. Discontinuous Mode

The current through inductor and voltage cross capacitor of AC power supply (Fig. 5) is shown in Fig. 9. It can be seen that the inductor current is discontinuous.

C. Output Signals

The output of full-bridge block in Fig. 5 which rectified the signal from the secondary side of transformer is converted to absolute value, so that all signals are positive as shown in Fig. 10.

V. EXPERIMENTAL RESULTS

The prototype circuit has been built to verify the simulation results. The measurement waveforms are shown in Fig. 13 – 15. The switching control signals is shown in Fig. 13, which indicates that the width of signal is approximately $5\mu S$ as the desired.

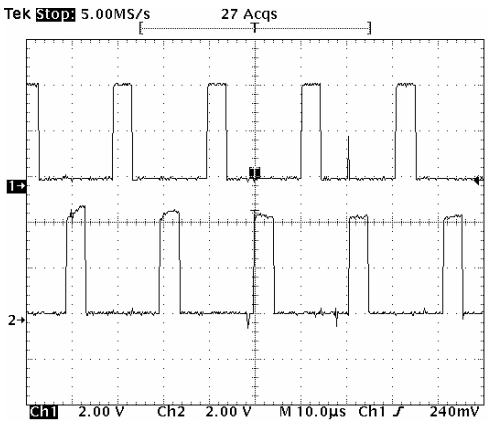

Fig. 13. Waveform of the switching frequency Q_1, Q_4 and Q_2, Q_3

Fig. 14 shows the waveform of the inductor current, and capacitor voltage. The inductor or resonant currents are always discontinuous, and the resonant frequency is also approximately 150 kHz.

Fig. 15 shows the AC output voltage and current when the system supply by a 12 Vdc to a 100 W linear load output. The output voltage and current are sinusoidal. The amplitude of output voltage is $311 V_P$ and frequency 50 Hz. The peak output current is 0.6 A. In Fig. 16 shows step load from 100 W to 200 W

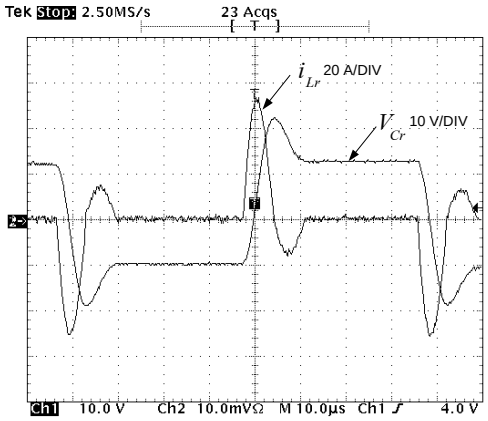

Fig. 14. Waveform of the inductor current, and capacitor voltage

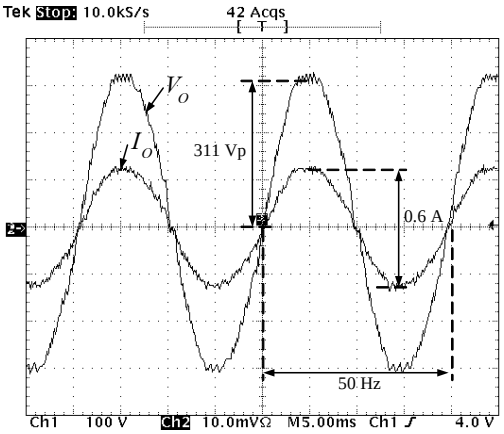

Fig. 15. Waveforms of the output voltage and output current

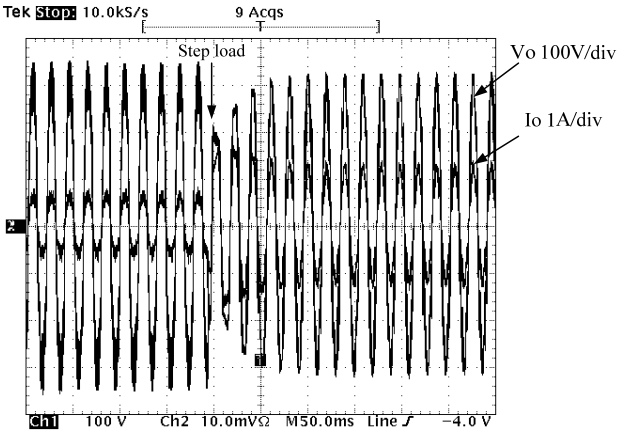

Fig. 16. Step load from 100 W to 200 W

VI. CONCLUSION

The DC-AC converter in this paper is analyzed simulated and built for having a good quality AC output voltage waveform and low power losses. The results show that the sinusoidal AC output voltage waveform can be met. However, it is expecting that after some improvement of design and fabrication, the size and weight of the system shall be small and light as required. By the demand in market, cost and size are important factor for making decision to have a produce.

VII. APPENDIX

The AC power supply (Fig 1) was tested with the following parameters: The DC input voltage V_S =12V, IC VFC320 for VFC circuit, The maximum switching frequency 100 kHz, turn on time (t_{on}) 5 μs , L_r = 0.66 μH , $C_r = 1.7 \mu F$, turn ratio of transformer 6:136, C_f = 0.47 μF /630V, and C = 5000 μF /50V.

ACKNOWLEDGMENT

To my parents, thank you for their love and to my advisor, Assoc.Prof. DR. Viboon Chunkag instilling within me the quest for excellence and providing unlimited support

Abstract—**This paper proposes a particle swarm optimization (PSO) algorithm for optimal placement of distributed generation (DG) in a primary distribution system to minimize the total real power loss. Initially, the algorithm randomly generates the particle positions representing the size and location of DG. Each particle will move from its current position using the velocity and the distance from current best local and global solution reached. The velocity consists of inertia of the particle, memory, and cooperation between particles. Four types of DG are considered and the distribution load flow is used to calculate the exact loss. The results obtained from the 33-bus and 69-bus radial distribution test systems show that the proposed algorithm can perform optimal sites and sizes for each type of DGs with minimum loss compared to other techniques.**

***Index Terms*— Distributed Generation, DG types, Optimal DG size, Particle Swarm Optimization**

NOMENCLATURE

P_i	Net real power injection in bus i.
Q_i	Net reactive power injection in bus i.
R_{ij}	The line resistance between bus i and j.
V_i	The voltage at bus i.
δ_i	The angle at bus i .
$Loss_k$	Distribution loss at section k.
N_{SC}	Total number of sections.
P_L	The real power loss in the system.
P_{DGi}	The real power generation DG at bus i.
P_{Di}	The power demand at bus i.
S^k	Current searching point.
S^{k+1}	Modified searching point.
V^k	Current velocity of agent i.
V^{k+1}	Modified velocity of agent i.
v_{pbest}	Velocity based on pbest.
v_{gbest}	Velocity based on gbest.
n	Number of particles in a group.
m	Number of members in a particle.
$pbest_i$	pbest of agent i.
$gbest_i$	gbest of the group.
ω_i	Weight function for velocity of agent i.
c_i	Weight coefficients for each term.
ω_{min}	The minimum weights.
ω_{max}	The maximum weights.
k	The current iteration.
k_{max}	The maximum iteration.

I. INTRODUCTION

DISTRIBUTED Generation (DG) is a small electric power generator embedded throughout a power system network, providing the electricity locally to customer loads [1]. DG makes use of the latest modern technology which is efficient, reliable, and simple enough so that it can compete with traditional large generators in some areas [2] and [3]. Distributed generation systems can reduce the system loss and defer investment on transmission and distribution expansion. Placement of DGs is an interesting research area due to economical reason. Appropriate size and optimal site are the keys to achieve it [4] and [5].

Many techniques were proposed for distributed generation placement in a primary distribution such as heuristic search [6], power flow algorithm [7] and [8], linear programming [9], genetic algorithm (GA) [10] – [12]. Those researches considered the placement of only one type of a DG which supply only real power (Type 1). However, in [13], the author has presented a new technique, PSO, to determine the optimal sites and sizes of three types multi-DGs to minimize the total real power loss of the distribution systems. They are the DG Type 1, the DG which capable of supplying only reactive power (Type 2), and the DG which capable of supplying real power but consuming proportionately reactive power (Type 3). An additional type of DG (Type 4), the DG that is capable to regulate the terminal bus voltage, is proposed in this paper.

II. PROBLEM FORMULATION

The real power loss reduction in a distribution system is required for efficient power system operation. The loss in the system can be calculated by equation (1) [14], given the system operating condition,

$$P_L = \sum_{i=1}^{n}\sum_{j=1}^{n} A_{ij}(P_iP_j + Q_iQ_j) + B_{ij}(Q_iP_j - P_iQ_j) \quad (1)$$

where,

$$A_{ij} = \frac{R_{ij}\cos(\delta_i - \delta_j)}{V_iV_j}$$

$$B_{ij} = \frac{R_{ij}\sin(\delta_i - \delta_j)}{V_iV_j}$$

The objective of the placement technique is to minimize the total real power loss. Mathematically, the objective function can be written as:

$$\text{Minimize} \qquad P_L = \sum_{k=1}^{N_{SC}} Loss_k \quad (2)$$

Subject to power balance constraints

$$\sum_{i=1}^{N} P_{DGi} = \sum_{i=1}^{N} P_{Di} + P_L \quad (3)$$

voltage constraints: $|V_i|^{\min} \le |V_i| \le |V_i|^{\max}$ (4)

current limits: $|I_{ij}| \le |I_{ij}|^{\max}$ (5)

The DG Type 4 we consider in this case can regulate bus voltage. It will be treated as generator bus in the load flow analysis. Many DG technologies will fit under this category. Real power injected by the DG is found using equation (6) and corresponding reactive power required to support the bus voltage is found by keeping the voltage fixed.

$$P_i = P_{DGi} - P_{Di} = -\frac{1}{A_{ii}}\sum_{\substack{j=1 \\ j\neq i}}^{n}\left(A_{ij}P_j - B_{ij}Q_j\right) \quad (6)$$

III. Particle Swarm Optimization

Particle swarm optimization (PSO) is a population-based optimization method first proposed by Kennedy and Eberhart in 1995, inspired by social behavior of bird flocking or fish schooling [15]. The PSO as an optimization tool provides a population-based search procedure in which individuals called particles change their position (state) with time. In a PSO system, particles fly around in a multidimensional search space. During flight, each particle adjusts its position according to its own experience (This value is called Pbest), and according to the experience of a neighboring particle (This value is called Gbest), made use of the best position encountered by itself and its neighbor (Fig.1).

This modification can be represented by the concept of velocity. Velocity of each agent can be modified by the following equation:

$$v_{id}^{k+1} = \omega v_{id}^{k} + c_1 rand \times \left(pbest_{id} - s_{id}^{k}\right) + c_2 rand \times \left(gbest_d - s_{id}^{k}\right) \quad (7)$$

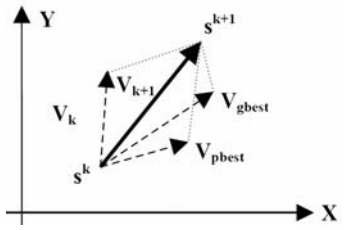

Fig. 1. Concept of a searching point by PSO

Using the above equation, a certain velocity, which gradually gets close to pbest and gbest can be calculated. The current position (searching point in the solution space) can be modified by the following equation:

$$s_{id}^{k+1} = s_{id}^{k} + v_{id}^{k+1}, \quad i = 1, 2, \ldots, n, \quad d = 1, 2, \ldots, m \quad (8)$$

The following weight function is used:

$$\omega_i = \omega_{\max} - \frac{\omega_{\max} - \omega_{\min}}{k_{\max}}.k \quad (9)$$

Appropriate value ranges for C_1 and C_2 are 1 to 2, but 2 is the most appropriate in many cases. Appropriate values for ω_{min} and ω_{max} are 0.4 and 0.9 [16] respectively.

IV. Proposed PSO Methodology

The PSO-based approach for solving the optimal placement of distributed generation problem to minimize the loss, as the flowchart in Fig.2, takes the following steps:

Step 1: Input line and bus data, and bus voltage limits.

Step 2: Calculate the loss using distribution load flow based on backward-forward sweep.

Step 3: Randomly generates an initial population (array) of particles with random positions and velocities on dimensions in the solution space. Set the iteration counter $k = 0$.

Step 4: For each particle if the bus voltage is within the limits, calculate the total loss in equation (1). Otherwise, that particle is infeasible.

Step 5: For each particle, compare its objective value with *the individual best*. If the objective value is lower than *Pbest*, set this value as the current *Pbest*, and record the corresponding particle position.

Step 6: Choose the particle associated with the minimum *individual best Pbest* of all particles, and set the value of this *Pbest* as the current *overall best Gbest.*

Step 7: Update the velocity and position of particle using (7) and (8) respectively.

Step 8: If the iteration number reaches the maximum limit, go to Step 9. Otherwise, set iteration index $k = k + 1$, and go back to Step 4.

Step 9: Print out the optimal solution to the target problem. The best position includes the optimal locations and size of DG or multi-DGs, and the corresponding

fitness value representing the minimum total real power loss.

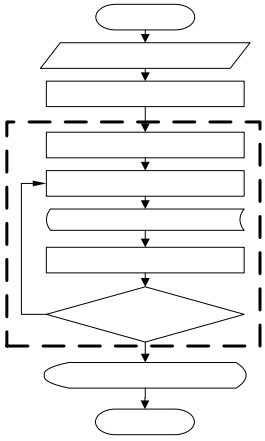

Fig. 2. PSO computational procedure

V. Numerical Results

The distribution test systems are the 33 bus [17] and 69 bus [18] systems. The 33 bus system has 32 sections with the total load 3.72 MW and 2.3 MVar shown in Fig.3 . The original total real power loss and reactive power loss in the system are 221.4346 kW and 150.1784 kVar, respectively. The 69 bus system has 68 Sections with the total load of 3.80 MW and 2.69 MVar, shown in Fig.4 . The original total real and reactive power losses of the system are 230.0372 kW and 104.3791 kvar, respectively. For PSO parameters, population size=200, Maximum generation (k_{max}) = 100. The maximum number of DG is three. The algorithm for solving the test systems is implemented on Matlab7 platform and on 1.6 GHz Pentium, 480-MB of RAM laptop.

The numerical results in Table I shown that the PSO can search the optimal sites and sizes of three DGs, both for 33 bus and 69 bus system, with minimum real power loss compared to the case of load flow analysis without DG about 86.56% and 96.81% respectively. With a DG installed at the same bus, the PSO algorithm can perform lower losses compared to a heuriatic search technique as well.

Table II show the losses when three DGs are installed for the 33 bus and the 69 bus systems compared to the case that without DG. The minimum losses occur when DGs Type 4 are installed. The improvement in the voltage profile after optimally placing the DGs is shown in Fig.5 . Without DG, the bus no. 64 has the lowest voltage of 0.8891 p.u. and the bus voltage has improved to 0.9772 p.u. after installing three type-4 DGs. Moreover, branch currents have reduced and chances of line limit violation have decreased as shown in Fig.6 .

Current in Branch 1 (branch after the root node) has decreased to 0.2516, 0.1963 and 0.1427 p.u. from 0.5008 p.u. after installing one DG , two DGs and three DGs, respectively.

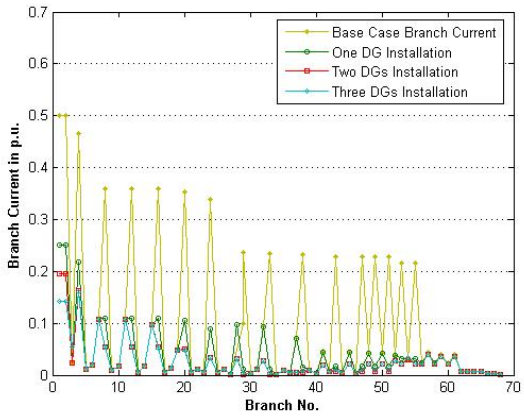

Fig. 6. Branch current before and after DGs Installation for DG type 4

Table II
COMPARISON OF LOSSES WHEN OPTIMAL THREE DGS PLACEMENT USING PSO

Case	P loss (kW)	Q loss (kVar)
For a 33 bus system		
Without DG	221.4346	150.1784
With DGs placement		
- DG Type 1	76.1691	52.9743
- DG Type 2	144.9050	98.7541
- DG Type 3	166.8321	117.0974
- DG Type 4	29.7697	21.3455
For a 69 bus system		
Without DG	230.0372	104.3791
With DGs placement		
- DG Type 1	70.8786	35.6864
- DG Type 2	148.3148	69.1167
- DG Type 3	161.6938	73.9429
- DG Type 4	7.3433	8.1907

VI. CONCLUSION

In this paper, a particle swarm optimization for optimal placement of multi-DGs is efficiently minimizing the total real power loss satisfying transmission line limits and constraints.

The proposed a particle swarm optimization is capable of determining the near global solution. The methodology is fast and accurate in determining the sizes and locations of DGs.

***Abstract*-This paper presents a method for reliability improvement of a distribution system by using photovoltaic (PV) grid-connected systems. An experimental setup is prepared to measure the system operating characteristics. The system consists of a PV array and a grid-connected inverter. The measured data are used to investigate the effects of a PV system installation on system reliability. We form an objective function with practical constraints to study distribution system's reliability. A graph theory approach is employed in selecting the installation location. The study has shown that, in an event of a permanent fault follows by a restoration sequence; PV generators can be used to recover system loading capability in the isolated area. This results in less customers with power outage and therefore, better system reliability.**

I. INTRODUCTION

Distribution service reliability is directly related to service interruptions which are caused by events such as storms, accidents and vandalism. The service interruptions can have a profound economic impact on customers. Historically, customers requiring high levels of reliability have depended on equipment such as uninterruptible power supplies and backup generators. Recently, PV systems have received much attention due to major advantages of infinite availability of the prime energy source and no polluted emission. The amount of PV generation is growing rapidly both in size and complexity [1]. This is due to the inherent benefits of the PV systems that can be used as a distributed generation (DG) to the electric utilities. Another advantage of the PV generator is from its close location to the customers which significantly reduces transmission and distribution costs. They can also be used to level the system load curve, improve the voltage profile, reduce line losses and transformer's loading [2]. However, to achieve the mentioned benefits, the PV generators must be of appropriate penetration level and at suitable locations [3]. In practice, its so-called infinite source is a variable energy source. The injected output power to the distribution system varies greatly on the weather conditions of a specific day. There is no guarantee that the mentioned benefits can be fully realized. The operation of the PV grid-connected systems and their responses to disturbances and/or conditions of the power distribution system has increasingly raised concerns, especially in high penetration of PV systems [3]. Regardless of the uncertain characteristics of the generated output power, the PV systems can be used to improve system reliability for radial distribution networks. Extensive research on a reliability evaluation of interconnected power system has been conducted in the past years [4-7]. Considerable efforts in the past have been spent to optimize restoration sequence. The service restoration problem is formulated as a constrained multi-objective optimization problem in [8]. In [5], a switch placement algorithm is proposed along with a distributed generator to improve the distribution system's reliability. With a network reconfiguration through an operation of a tie switch/line, portions of the outage network can receive power from other branches or feeders. By allowing the DGs to support the recovered portions of the system, the amount of customers with power outage can be reduced. Even though, the system reliability may be improved, the voltage and line capacity constraints become important concerns because in a restructured distribution system, lines are usually operated close to the capacity limit, even overloaded.

Unlike other kinds of DGs, when a fault occurs, all PV grid-connected inverters must detect the islanding and stop energizing. From this aspect, a thorough investigation of the PV systems must be performed to assure satisfactory operations. In this paper, we consider issues concerning distribution system's reliability with PV grid-connected systems in the event of faults. A PV grid-connected setup is prepared to experimentally measure the system output characteristics which have effects on the distribution system. The measured data are used in computer simulation to evaluate the distribution system's reliability. A graph theory approach is proposed to select amount and installation locations. A radial distribution system is represented using a tree data structure. The obtained results are compared with a predetermined list method based on loading level.

It should be noted that traditional reliability indices, SAIDI and SAIFI [6], are not appropriate in this work since, they are static indices and, in an event of fault, alternate supply routes are available through a tie line/switch. Therefore customers experiences only momentary interruptions. This paper is organized as follows. Section II describes experimental measurement of PV grid-connected system characteristics.

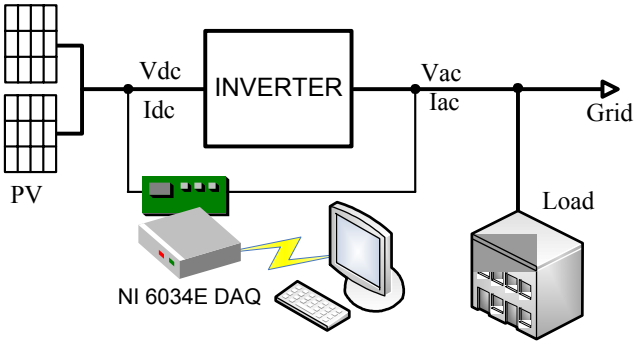

Fig. 1 PV grid-connected system setup

In section III, modeling issues of the PV systems are discussed. Section IV describes the restoration sequence during fault. Section V discusses the reliability improvement issues including problem formulation and proposed search methods. Numerical studies on a test system are given in section VI. Section VII concludes the work.

II. PV Measurement Details

In order to characterize the output of the PV grid-connected system, a measurement setup is prepared. The test system consists of 1.5 kW Amorphous PV array and a 1.7 kW grid-connected inverter from SMA Technologies AG. The system supplies electricity for the building uses consisting of fluorescent lighting, air conditioning units and water pumping. The load is essentially inductive. The system configuration is shown in Fig. 1. Voltage and current measurements on both dc and ac sides are automated using an NI6034E data acquisition (DAQ) card. A program is developed in Labview to calculate necessary values such as power factor, harmonics and frequency. The system automatically records data every minute from 06.00AM to 06.00PM. The inverter's real and reactive powers shown in Fig. 2 are averaged values of the collected data over a month (May 2006). The reactive power is relatively small compared to the real power, especially around noon time. Fig.3 shows the measured voltage and current on the ac side. We note that the measured voltage is the utility's voltage. It is clearly seen that the inverter's real power and current assume similar shape because the voltage varies in a small window except around 10.00 AM where a local heavy load has been turned off.

III. System Modeling

To investigate the power distribution behavior accurately, appropriate models for each of the system components must be employed. The following component modeling is used in the study.

A. PV Grid – Connected System

The majority of the grid-connected inverters produced nowadays are based on the voltage-source inverter with closed-loop current control. In practice, PV modules inject

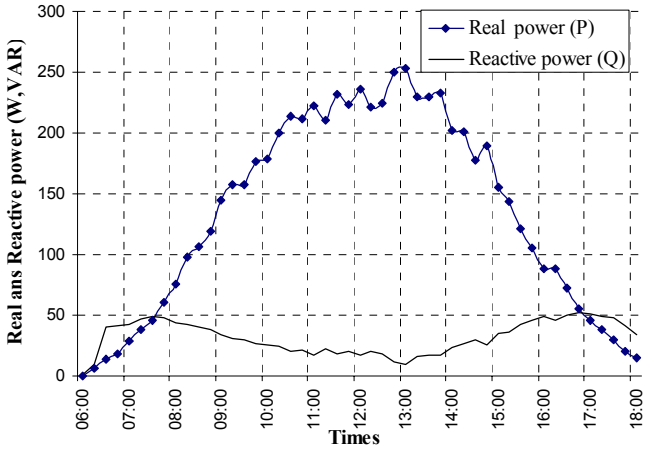

Fig. 2 Output real and reactive powers

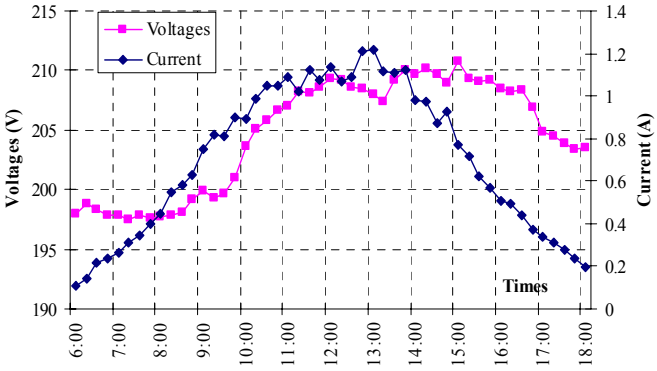

Fig. 3 Inverter's output current and voltage

power to the utility's grid through an inverter with capability of detecting islanding operation. This means that the inverter requires the utility grid voltage for its operation and it cannot operate in an isolated area as other distributed generator because of islanding requirement of the inverter. From the experimental results in section III, a PV grid-connected system has shown to effectively inject active power to the distribution feeder. In addition, its output voltage is governed by the grid voltage. This is reflected by modeling the PV grid-connected systems as PQ loads with negative real power drawn from the distribution system.

B. Lines and Tie Switches

Lines are the predominant branch connections existing in distribution networks. The tie switch's function is to alter network topology in order to provide alternate routes for supplying power to loads when necessary. In this study, standard model admittance matrices for distribution lines and tie switches are used [9]. However, it should be noted that the line charging is not included due to the overall length of the lines.

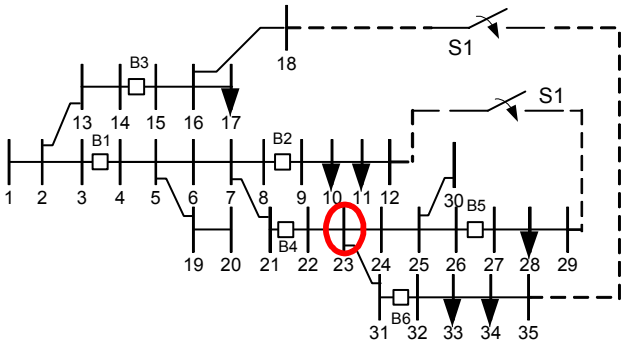

Fig. 4 A typical radial distribution network

C. *Load Models*

For any given amount of real and reactive load at each phase of a bus, three types of representation are used; constant impedance, constant current and constant power loads. In some buses the loads are represented as a linear combination of the three-load types.

IV. Restoration Sequence

A typical radial distribution system consists of distribution lines, transformers, circuit breakers, and manual disconnecting switches. When a fault occurs, protection devices are triggered to clear the fault. The affected area is determined based on the system configuration and protection scheme. The process is illustrated in Fig. 4. It is assumed that the tie lines S1 and S2 are normally open. When a fault occurs on bus 23, the circuit breaker B4 would open to isolate the fault. As a result, customers on buses 28, 33 and 34 experience power outage. This step essentially depends on the setting of protection schemes. Next, a search is performed on the downstream until circuit breakers B5 and B6 are found and the fault can be isolated. With the operations of the tie lines, S1 and S2, the loads on buses 28, 33 and 34 are recovered. In many cases, a tie line may not be able of supplying power to the isolated area. With the PV system installation, the loading level of S1 and S2 can be alleviated and the system can operate under this configuration until the fault is cleared. Therefore, the system reliability is improved. However, with limited availability of the PV systems, the installation locations must carefully be selected.

V. Issues on Reliability Improvement

A. *Problem Formulation*

Our aim in this work is to evaluate the system reliability in the presence of PV grid-connected systems. The objective functions considered are: (1) to minimize the loading level of the tie line, (2) to minimize the system loss and (3) to minimize the number of PV system installations. In summary, the constrained reliability improvement problem using PV system is formulated as follows.

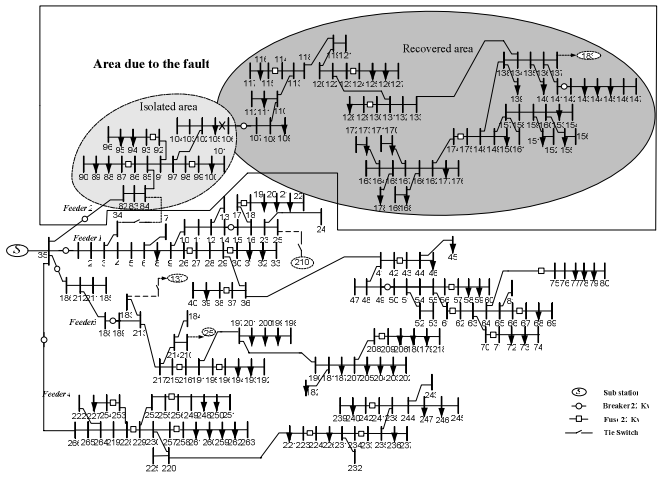

Fig. 5 One-line diagram of the test system

$$\begin{aligned} &\min I_{tie} \\ &\min \sum_{k \in N_L} S_{loss}^{3-\phi} \\ &\min N_{pv} \end{aligned} \tag{1}$$

subject to

$$\begin{cases} V_k^{\min} < \left| V_k^p \right| < V_k^{\max} \\ S_{ik}^{\min} \le S_{ik}^{3-\phi} \le S_{ik}^{\min} \end{cases} \tag{2}$$

where

I_{tie} is the current flows in a tie line

$S_{loss}^{3-\phi}$ is the total system losses

N_{PV} is the number of PV installation

V_k is the voltage at bus k

$S_{ik}^{3-\phi}$ is the complex power flow from bus i to bus k.

B. *Search Methods*

The installation location can be determined using well established graph theory approaches. The following search methods in graph theory are considered.

1) Breadth-first search (BFS) traverses neighboring buses that is, outgoing branches of the bus in the search, before any outgoing branches of the bus. Then for each of those nearest buses, it traverses unexplored neighboring buses, and so on.

2) Depth-first search (DFS) traverses outgoing branches of a bus before processing neighboring buses in the search.

In addition, a list method is also considered where the list is constructed based on the amount of load on each bus, starting from maximum to minimum loading. It is then compared with the results obtained from the above search methods.

VI. Numerical Studies

The test system is a 266-bus radial distribution system of the Provincial Electricity Authority (PEA) of Thailand as shown in Fig. 5. The amount of total system load under

normal operation is 53.60 MW and 33.27 MVar. The system consists of 69 load buses and 2 tie lines (25-210 and 137-183). When a fault occurs on the system, it is isolated by the circuit breaker upstream and the restoration sequence mentioned in section IV is performed. The measured results of the PV systems are scaled up to units of 200 kW and 400 kW, respectively. A fault is assumed to be on the line between bus 105 and 106 and remain fixed. The basic information of the test system during fault is found in Table I. The proposed search methods are used to solve the problem formulated in section V. We note that for the case with no installation of PV systems, the tie carries 620.85A while its ampacity limit is at 600A. To demonstrate the proposed algorithms, each method is compared through the number of PV installations and system loss once the tie line loading is in the limit.

For the case of 200 kW PV systems, the loading list and DFS methods have resulted in the same amount of PV required (5×200 kW) to achieve the tie line limit. However, they provide different installation locations and around 400W difference of loss. The BFS method provide the best result in requiring only (4×200 kW) with similar loss.

We also scale the PV system up to 400 kW each to simulate the situation where a larger PV system is available. The 3 methods result in the same amount of PV required (3×400 kW). It seemed that when the PV is scaled up, the number of PV systems required are the same with relatively close values of loss and tie-line loading even though, the installation locations are different. From the results obtained, the BFS may be a good choice compared to the others. It is also observed that all methods that have been tested provided similar results in terms of installation location. Buses 125, 126 and 127 are often the choices of installation.

TABLE I.
INFORMATION OF THE TEST SYSTEM DURING FAULT

Faults branch	105-106
Load in the recovered area	16.485 MW / 10.215 MVar
Capacity of tie line	600Amp
Number of load buses in recovered area	20
Tie line location	137-183

TABLE II.
THE RESULTS FOR 200 KW INSTALLATIONS

Method	PV installation (kW)	Installation location	System losses (kW)	Tie line loading (A)
		No PV installation	207.65	620.85
BFS	800	126, 127, 109, 173	200.26	596.83
DFS	1000	126 (4 sets) and 127	199.80	596.82
Loading list	1000	125, 126, 153, 145, 151	200.21	596.83

TABLE III.
THE RESULTS INSTALLATION PV 400 KW BY DEPTH FIRST SEARCH

Method	PV installation (kW)	Installation location	System losses (kW)	Tie line loading (A)
		No PV installation	207.65	620.85
BFS	1200	126, 127, 116	198.68	592.05
DFS	1200	126 (2 sets) and 127	198.40	592.05
List	1200	125, 126, 153	198.86	592.05

This can be expected since those buses are heavily loaded buses and they are located at the end of the feeder. The proposed methods can be used in system planning when DGs, especially PV generators, are of interest.

VII. CONCLUSIONS

We investigate the output characteristics of the PV grid-connected system. The measured results are used to examine the issues related to reliability improvement for a radial distribution system. Graph theory approaches, BFS and DFS methods, can be used to improve system reliability. It has been shown that with the action of a tie switch, the system losses and loading level of the tie switch can be reduced with appropriate amount and installation location. The proposed methods have resulted in PV installation at heavily loaded buses and buses located at the end of the feeder.

ACKNOWLEDGMENT

The authors wish to thank the CES Solar Cells Testing Center (CSSC), KMUTT and the Provincial Electricity Authority (PEA), Thailand for their support.

***Abstract*-This paper deals with two-dimensional computation of AC losses in a superconducting transmission line by using a numerical method. For that, we used the finite element method. We observe the effect of the different superconductor models to the evaluation of the instantaneous losses and also the value of the average losses. Moreover, the current density and the magnetic field distributions in the superconducting transmission line will be studied too.**

I. INTRODUCTION

One important characteristic of the superconductors is the absence of the electrical resistivity when the direct current flows through. However, the superconductors generate losses through Joule effect when the alternating current flows through, called Joule losses or AC losses. Even if these losses are relatively small, it is advisable to evaluate them with the precision. The use of superconductors at high critical temperature for transporting the alternating current is now real by using the electrical power transmission lines and the evaluation of losses in proper field is so necessary.

Our objective was to study of the losses in proper field in a superconducting transmission line at high critical temperature. In reality, the characteristic curve of the electrical field E versus the current density J differs rather clearly from that of the theoretical model, called the Bean's model [1]. In order to get a well-behaved curve, the Bean's model is altered by a progressive function [2] [3] and then called the extended Bean's model (Fig. 1).

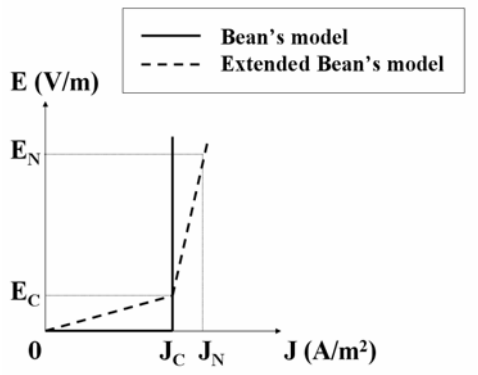

Figure 1. Altering Bean's model to get a well-behaved curve.

Initially, we present a general method for computing the losses in superconducting transmission line described by an extended Bean's model, and then we compare the results of numerical computation of the losses carried out by method presented for different models of extended Bean's model.

II. PROBLEM PRESENTATION

We calculate the losses in a superconducting transmission line, carrying a sinusoidal current of frequency f and of amplitude I_{max}. The characteristics of this transmission line (Fig. 2) are as follows: critical current I_C = 100 A, cross-sectional area S = 22 mm^2, length L = 1 km, inner radius R_i = 4 mm and outer radius R_o = 4.8 mm.

The electromagnetic behavior of the superconductors is dominated by the Maxwell's equations [4]:

$$\nabla \times \vec{E} = -\partial \vec{B} / \partial t \quad (1)$$

$$\nabla \times \vec{B} = \mu_0 \vec{J} \quad (2)$$

$$\nabla \cdot \vec{E} = 0 \quad (3)$$

$$\nabla \cdot \vec{B} = 0 \quad (4)$$

where μ_0 is the permeability of the air and B is the magnetic induction. These equations must be supplemented by the relation equations between B and H (magnetic field), and E and J. For B and H, we have $B = \mu_0 H$. For E and J, we use the extended Bean's model.

Classically, the estimate of the losses is done by using formulas deduced from the Bean's model, well adapted to characterize the superconductors. It is defined by an electrical characteristic $E(J)$ in the form of a step:

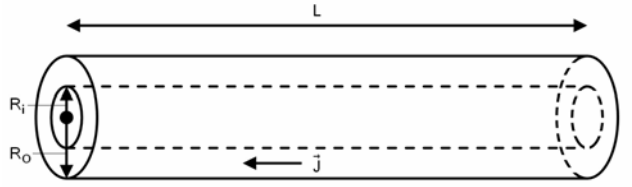

Figure 2. 3D geometry of the superconducting transmission line.

$$E = 0 \quad : \quad 0 \le J \le J_C$$
$$E \neq 0 \quad : \quad J = J_C \tag{5}$$

where J_C is the critical current density.

But for transporting the alternating electrical current at high critical temperature, the real characteristic $E(J)$ differs rather clearly from that of the Bean's model. A more realistic model is obtained by a progressive function of the form:

$$E = \frac{E_C}{J_C} \times J \quad : \quad 0 \le J \le J_C$$
$$E = \frac{(E_N - E_C)}{(J_N - J_C)} \times (J - J_C) + E_C \quad : \quad J_C \le J \le J_N \tag{6}$$

where E_C , E_N and J_N are defined in Fig. 1. These parameters are chosen so that the behavior law $E(J)$ approaches to the experimental characteristic. Let us notice that when E_C approaches to zero and J_N approaches to J_C , we find the Bean's model.

In this model, we are unaware of the one-dimensional aspect of the problem and we suppose that the electrical field and the current density have only one component following the axis of the transmission line, noted respectively E and J. The scalar equation to be solved is written [4]:

$$\partial J / dt = \nabla \cdot \left(\mu_0^{-1} \nabla E\right) = \mu_0^{-1} \nabla^2 E \, . \tag{7}$$

Equation (7) is solved by using the finite element method in space and the Crank-Nicolson method in time. With each step of time, a convex functional is minimized by an iterative procedure of nonlinear Gauss-Seidel. The proposed method takes into account the free boundary in an implicit manner. It seems to be robust and fast to be able to effectively estimate the losses in superconducting transmission line.

The instantaneous losses in Watt can be calculated by using the general formula:

$$p(t) = \int_S jeLds \tag{8}$$

where S is the cross-sectional area.

The Joule losses or AC losses can be directly obtained from the integral of the instantaneous losses over a period of length T of the transport current, we have [5]:

$$P = \frac{1}{T}\int_0^T p(t)dt = \frac{1}{T}\int_0^T \left(\int_S jeLds \right) dt \, . \tag{9}$$

From (9), maybe we can call it the average losses in the superconducting transmission line.

III. Numerical Simulation

The total modeled domain in 2D is shown in Fig. 3. It is composed of the superconductor and the insulator. In this case, we choose to use the air which is a good insulator. Therefore, the transport current flows only in the superconductor. The symmetries of the problem make that only one sixtieth of the domain (six degrees) is modeled. Consequently, the time of calculation is reduced. The transport current is parallel to the axis of the transmission line and varies sinusoidally in time with f = 50 Hz and I_{max} = 20 to 160 A (Fig. 4).

Three different models of the extended Bean's models in Table I are used for calculating the losses. In order to obtain the critical current $I_C \approx 100$ A, the critical current density J_C is set at 4.6×10^6 A/m^2. The values of E_N and J_N are also fixed in order to bound the region for which the material remains superconductive.

IV. Numerical Results

We have realized a series of numerical simulations for a

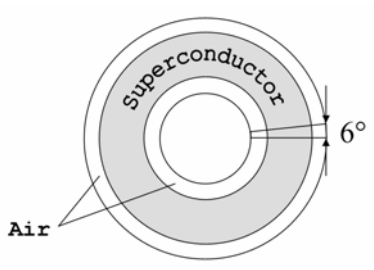

Figure 3. Computational domain in 2D.

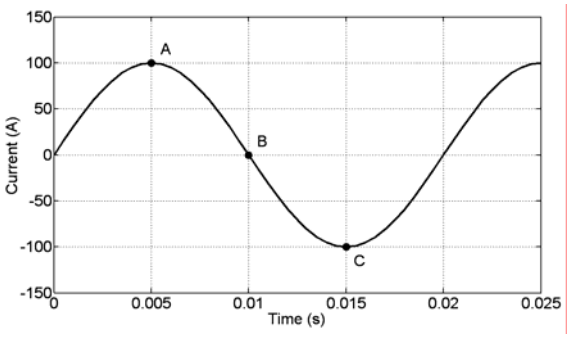

Figure 4. Transport current in superconducting transmission line.

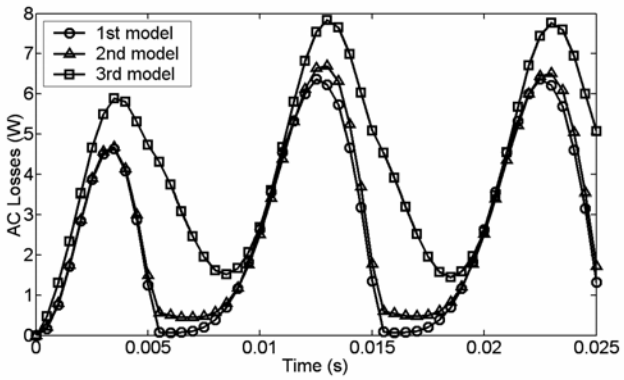
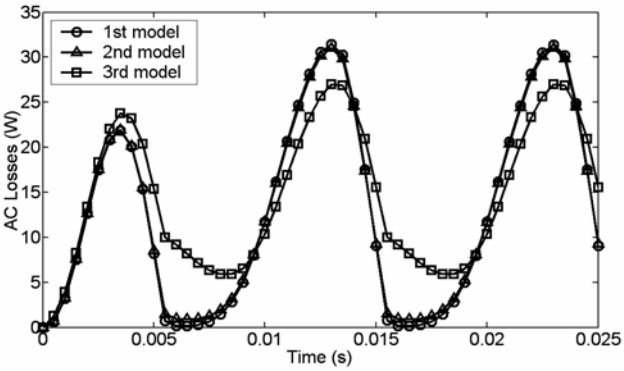
TABLE I
Various Models of Extended Bean's Model

Model	E_C (V/m)	J_C (A/m^2)	E_N (V/m)	J_N (A/m^2)
1	10^{-6}	4.6×10^6	5.3×10^{-4}	5×10^6
2	10^{-5}	4.6×10^6	5.3×10^{-4}	5×10^6
3	10^{-4}	4.6×10^6	5.3×10^{-4}	5×10^6

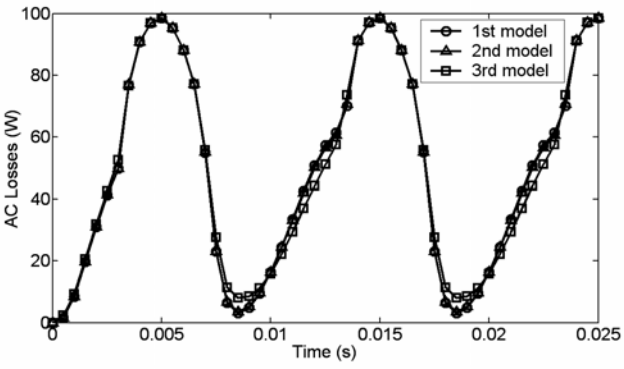
superconducting transmission line with a transport current as in Fig. 4. Fig. 5 shows the temporal evolution of the Joule losses obtained from three models in Table I for the maximum current equal to 60 A (a), 100 A (b), and 140 A (c). We observe that we obtain coherent values of the losses for the maximum current equal to 140 A which is higher than the critical current ($I_{max} > I_C$). On the other hand, we obtain different values of the losses for the maximum current equal to 60 A which is lower than the critical current ($I_{max} < I_C$).



(a) For $I_{max} = 60 < I_C$



(b) For $I_{max} = 100 = I_C$



(c) For $I_{max} = 140 > I_C$

Figure 5. Comparison of the instantaneous losses in the superconducting transmission line for the different values of the maximum current.

From the instantaneous losses in Fig. 5, we are able to determine the average losses by using the formula (9). On Fig. 6, we present the evolution of the average losses obtained numerically according to the maximum amplitude of the transport current in the superconducting transmission line. The results obtained show that when the maximum current is higher than the critical current ($I_{max} > I_C$), three models give almost the same results for the values of the average losses. For currents whose maximum amplitude is lower than the critical current ($I_{max} < I_C$), three models give the different values of the average losses.

Fig. 7 illustrates the current density distribution inside the superconducting transmission line at points A (a), B (b), and C (c), respectively as indicated in Fig. 4. These distributions can be described by the critical state model of Bean. The current density distribution can be shown by a shell. At the maximum current (point A), the current density in the superconducting transmission line is equal to the critical current density J_C (Fig. 7(a)). When the current reaches to the minimum value (point C), the current density distribution in the transmission line is the same but the direction of current flows opposed to that of Fig. 7(a) (see Fig. 7(c)). At point B which is intermediate between point A and point C, we find that the transport current is changing its direction. A new shell is created at the outside of the old shell with the transport current circulating in the direction opposed to that of the old shell (Fig. 7(b)).

In Fig. 8 from (a) to (c), we can see the penetration of the magnetic induction inside the superconducting transmission line which progresses well with the rotation whose module is equal to J_C . At point B, we find that the magnetic induction is changing its direction. This is starting from the edge of the superconducting transmission line (Fig. 8(b)).

V. CONCLUSION

Our aim is to calculate the AC losses in a superconducting transmission line. In this paper, we have compared the results of numerical simulations of the instantaneous losses and also

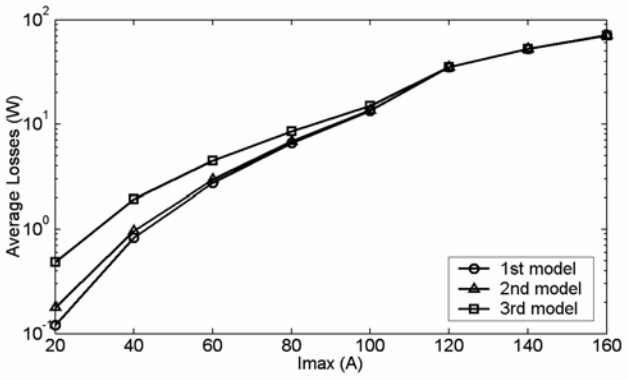


Figure 6. Comparison of the average losses in the transmission line.

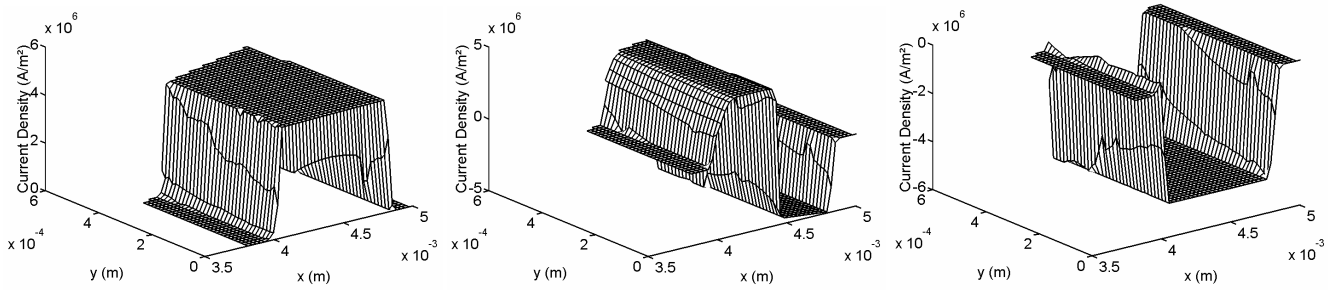

(a) At point A (b) At point B (c) At point C

Figure 7. Current density distribution in the superconducting transmission line at different points in Fig. 4.

of the average losses carried out by the proposed method for different models of the extended Bean's model. These models are modified from the critical state model of Bean.

From the results of numerical simulations, we find that all models give almost the same losses, the instantaneous losses and also the average losses, when the maximum amplitude of the transport current is higher than the critical current of the superconducting transmission line. Furthermore, the distributions of the current density and of the magnetic induction inside the superconducting transmission line show clearly a phenomenon of superconductivity.

The use of superconductors shows the possibility for real applications in the electrical area such as the electrical power transmission lines, the electrical power cables, the electrical machines (motors and generators), or the transformers. So we have to seek for the models of these materials in order to be able to study and analyze all the aspects of them.

***Abstract*—Short circuit current limitation in distribution utilities can be an effective way to improve power quality, since the expected voltage sag amplitude during faults can be dramatically reduced. In this paper, the analytical analysis of a novel fault current limiter based on DC reactor with using superconductor is presented. Its operation is investigated through computer simulation with ElectroMagnetic Transient Program (EMTP) simulation results based on a model system also show that proposed SFCL are effective for power quality improvement of electric power systems by restraining the fault current.**

I. INTRODUCTION

Voltage sags are a rather old problem in power systems that nowadays are gaining significance due to the growth of sensitive loads. Modern process controls are often sensitive to voltage sags, which may cause significant production outages [1-2]. Universal experience shows that a main reason of voltage sags affecting customers is short circuits on utility's lines, with special reference to the overhead radial distribution ones. Since the voltage sag during the fault is proportional to the short circuit current [3]. An effective fault current limitation by means of a device connected series with the radial feeders will limit the expected voltage sag and improve the system power quality [3]. Also circuit breaker operation in distribution lines causes over voltage in substation and other loads. In this paper a new type of fault current limiter based on DC reactor with using superconductor are presented. In normal operation condition the limiter has no obvious effect on loads. When fault happens, a bypass AC reactor and series resistor will insert the fault line automatically to limit the short circuit current, when the control circuit detects a short circuit fault, the solid state bridge in fault line works as an inverter and is closed as soon as possible. Subsequently the fault current is fully limited by the bypass AC reactor and series resistor. In general this type of SFCL is useful for power quality improvement when fault is occurred in distribution systems.

II. CLASSIFICATION OF VOLTAGE SAGS

Study system in this paper is shown in Fig. 1. A fault on the power system will cause both a dip in voltage magnitude and a shift in phase angle. To predict the magnitude of the voltage sag and the phase angle jump, the simple voltage divider idea proposed in [4] is adopted [5]. A simple model for calculating the resulting voltage, i.e. the voltage magnitude during the sag, can be seen in Fig. 2. This model is based on a voltage divider and it is useful for radial systems and selected from Fig. 1. However, it attends to for describing and explaining the events in a simple and clear way.

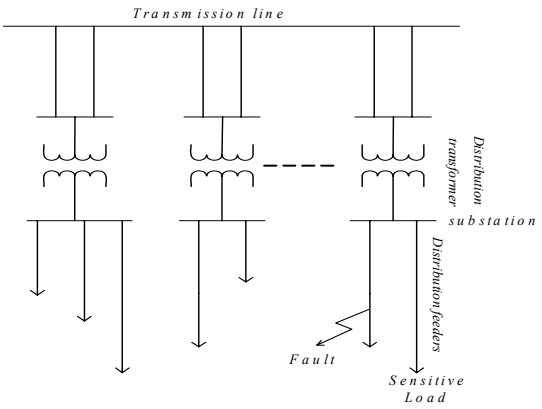

Fig. 1 study system

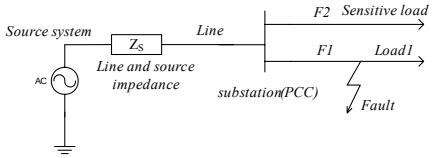

Fig. 2 Simplified diagram of the study system

In this study the load current is not neglected in the simple voltage divider method. Z_S is the source impedance at the PCC. The impedance between PCC and sensitive load define with Z_2, also the impedance between PCC and load1 define with Z_1. It is also necessary to calculate the reactance between the PCC and the fault location. Z_f defined line impedance between the PCC and fault including any fault impedance, if the fault impedance is neglected or included in Z_f. in normal operation the resulting voltage and phase angle will be:

$$Z_N = Z_1 \| Z_2 \quad (1)$$

PCC voltage defines with:

$$\overline{V}_{PCC(N)} = \frac{\overline{Z}_N}{\overline{Z}_S + \overline{Z}_N} \quad (2)$$

$$V_{PCC(N)} = \left| \frac{\overline{Z}_N}{\overline{Z}_S + \overline{Z}_N} \right| \quad (3)$$

$$\varphi_{PCC(N)} = \arctan(\frac{X_N}{R_N}) - \arctan(\frac{X_N + X_S}{R_N + R_S}) \quad (4)$$

where

$Z_1 = R_1 + jX_1$ (Load 1 and F1 impedance)

$Z_2 = R_2 + jX_2$ (sensitive load and F2 impedance)

$\overline{V}_{PCC(N)}$: Voltage phasor at the PCC at normal operation

$V_{PCC(N)}$: Voltage magnitude at the PCC at normal operation

$\varphi_{PCC(N)}$: Phase angle of voltage at the PCC at normal operation

when fault occurs the resulting voltage and phase angle can be expressed by

$$Z_F = Z_2 \| Z_f \quad (5)$$

$$\overline{V}_{PCC(F)} = \frac{\overline{Z}_F}{\overline{Z}_S + \overline{Z}_F} \quad (6)$$

$$V_{PCC(F)} = \left| \frac{\overline{Z}_F}{\overline{Z}_S + \overline{Z}_F} \right| \quad (7)$$

$$\varphi_{PCC(F)} = \arctan(\frac{X_F}{R_F}) - \arctan(\frac{X_F + X_S}{R_F + R_S}) \quad (8)$$

where

$Z_2 = R_2 + jX_2$ (sensitive load and feeder F2 impedance)

$Z_f = R_f + jX_f$ (line impedance between the PCC and fault including any fault impedance in feeder F1)

$\overline{V}_{PCC(F)}$: Voltage phasor at the PCC at normal operation

$V_{PCC(F)}$: Voltage magnitude at the PCC when fault occur

$\varphi_{PCC(F)}$: Phase angle of voltage at the PCC when fault occur

As can be seen from Eq. (8) when fault occur in feeder F2 the changing X_N/R_N ratio and $(X_N+X_S)/(R_N+R_S)$ ratio between causes a phase angle jump at the PCC. This can be referred as the initial phase angle jump. Also fault occurrence causes vital change in Z_N and in result voltage magnitude. In this paper, SFCLs will be added to the power systems to evaluate their effectiveness in reducing the initial phase angle jumps and voltage sag. The SFCL can be used to increase the impedance of the fault by introducing impedance. As the same way it does as a fault current limiter. Then when the SFCL is limiting fault current, therefore it is improve the quality of the supply by mitigating sag.

III. Proposed SFCL Circuit and Its Operation

Proposed topology of fault current limiter is shown in Fig. 3. The circuit consists of two diodes, two thyristor, AC impedance branch and a high-T_C superconducting coil. The system current passes through superconducting coil DC reactor. DC reactor will have no effect on normal operation of system. There would be a forward voltage drop across rectifier diodes V_{DF}, too. During fault condition, the fault current increases and this time varying current passes through DC reactor that increases voltage drop and decreases the fault current magnitude

The fault current will pass through DC reactor for only some milliseconds and then the bridge circuit will retreat from fault circuit.

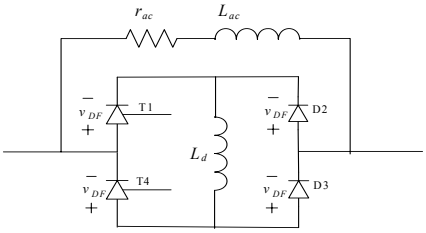

Fig. 3 Circuit diagram of bridge type SFCL

A. Control strategy

There are different control strategies but two types are used mainly in different papers. As a review, these control strategies are presented in this paper.

a) Freewheeling control

At the starting and steady stage of SFCL T1 and T4 are triggered and turned on half cycle at positive and negative phase voltage across zero respectively. In accident, DC reactor retreat from fault circuit and leaving AC reactor and resistor to limit the fault current only. In freewheeling control, remove triggered pulses of thyristor bridge arms T1 and T4. In this way, the bridge circuit will retreat from fault circuit within at most half cycle after the fault is detected, while current on DC reactor run through D2 and D3 to form free-wheeling circuit. The current in DC reactor will be reduced due to energy loss caused by voltage drop on diodes. But voltage drop is very small so that current reduction takes a long time. In this paper we used freewheeling control.

b) Reverse control

In freewheeling control, the current in DC reactor will be reduced due to energy loss caused by voltage drop on diodes. But voltage drop is very small so that current reduction takes a long time. Also if accidents take place many times, current value on DC reactor will rise. For this reasons, this control strategy is not often used.

IV. Analytical Analysis and Simulation Result of Proposed SFCL

In this section analytical analysis of the study system in Fig. 1 to show power system situations in fault condition and SFCL operation for load protection is given. For a fault at the distribution level, for example on F1, SFCL activation on the faulted feeder introduces large limiting impedance between the fault and PCC. The introduced impedance has the effect of isolating the fault from the PCC; hence sensitive loads supplied through the parallel feeder F2 will not feel any significant disturbance due to the fault. In this section for

provide a detailed analysis a similar model to section 2 is used as shown in Fig. 4. The utility voltage is a sinusoidal waveform with angular frequency ω, peak value V.

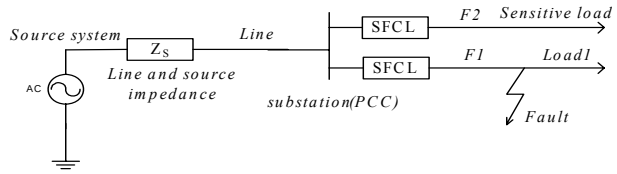

Fig. 4 Simplified diagram of the study system

A. *Time sequence of simulation*

A series of simulations were conducted to analyze the performance of the SFCL.

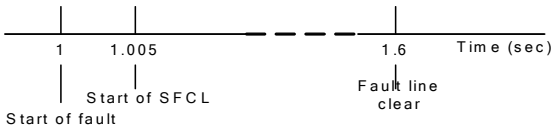

Fig. 5 time sequence of simulation

The short-circuit fault was supposed to occur on the distribution feeder F1 between PCC and load1 as shown in Fig. 4. The Simulation was carried out based on the time sequence as shown in Fig. 5. Remove triggered pulses of thyristor bridge arms T1 and T4 achieved at about 5 (msec) after fault occurrence and the clearance of the fault was supposed to be achieved at about 0.6 (sec) after the occurrence of the fault. Fig. 5 shows the time sequence of simulation.

Study system consists of two distribution feeders originating from the same substation bus. Fault is occurring in feeder F1 where feeder F2 is supplying a sensitive load. In this paper, the SFCLs are placed at the substation end of the distribution feeders, F1 and F2, as shown in Fig. 4. At these sites, the SFCL activation on the faulted feeder will help to keep the bus voltage level at acceptable value. The load is assumed to be a balance R-L load with r_L and L_L as its resistor and inductor, respectively

. Power equipment data are as follow:

Generator: 20 kV, 10 MVA, 1.608 Ω

Transformer: 20 kV/6.6 kV, 10 MVA, 0.0824 pu

Distribution feeder data:

Resistance = 0.220 Ω/km

Reactance = 0.444 Ω/km

Length of F1 = 3 km

Length of F2 = 2 km

Length of Line1 = 10 km

DC inductance of SFCL in faulty line, L_d = 0.1 H

AC inductance of SFCL in faulty line, L_{ac} = 0.1 H

AC resistance of SFCL in faulty line, r_{ac} = 20 Ω

Load data in feeder F1:

Resistance = 20 Ω

Inductance = 0.1 H

Fig. 6 shows the behavior of the distribution bus (PCC) without the SFCL present due to fault applied at time t_0. It shows that PCC voltage of the unlimited system is significantly reduced during the fault and phase angle is jumping. Also Fig. 7 shows the behavior of the distribution bus (PCC) without the SFCL and with uses of circuit breaker. It shows that PCC voltage is a little increased when line1 retreat from test system by circuit breaker operation. Fig. 6 and Fig. 7 are result in simulation analysis. However, when the SFCL is placed into the system, the bus voltage (PCC) is kept practically undisturbed and no dramatic voltage sag is visible. Also the change in phase angle is eliminated. Fig. 8 shows distribution bus (PCC) voltage with using SFCL. It shows that PCC voltage and phase angle of the limited system is kept at acceptable value during the fault and just PCC voltage have little distortion in first half cycle after fault occurrence.

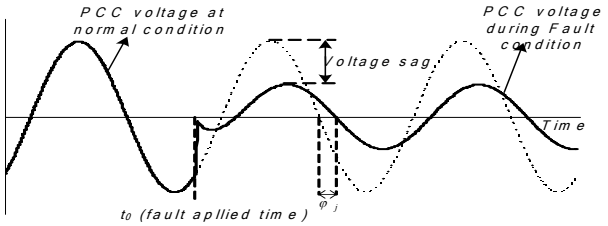

Fig. 6 PCC voltage of the unlimited system

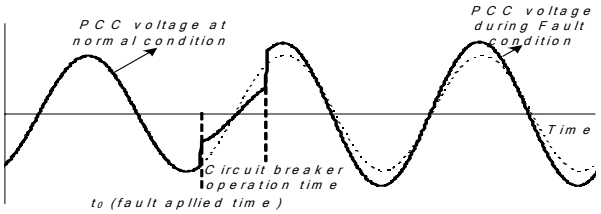

Fig. 7 PCC voltage, protected with circuit breaker

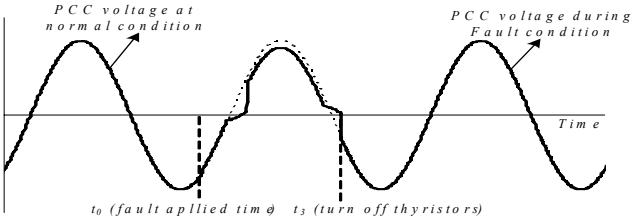

Fig. 8 distribution bus (PCC) voltage with using SFCL

Fig. 9 shows the line and SFCL currents during a fault condition. The fault occurs at $t=t_0$ and the load current begins to increase. As is shown in this figure, before fault condition, the current through inductor is an almost ripple free DC current. The produced voltage across L_d in fault condition has resulted in limiting the fault current as well as distortion of its waveform. The circuit has two modes of operation between t_0 and t_3 before DC reactor retreat from power system (thyristors turn off) as follows:

(a) Charging mode

(b) Discharging mode

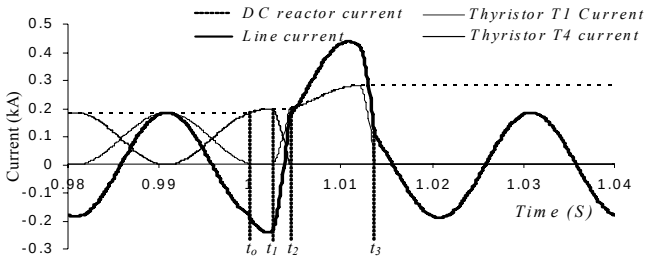

Fig. 9 line and SFCL currents during fault condition

At $t=t_0$ charging mode begins and the line current reaches the inductor current. The operation of SFCL has resulted in fault current limiting between t_0 to t_3. At $t=t_1$ discharging mode starts and it continuous until $t=t_2$. Eq. (10) shows the DC reactor current formula at time interval between t_0 to t_1

$$V\sin(\omega t) = ri_d(t) + \frac{Ldi_d(t)}{dt} + 2V_{DF} \tag{9}$$

$$i_d(t) = e^{-(r/L)(t-t_0)}\left\{i_0 - \frac{V}{z}\sin(\omega t_0 - \varphi) + \frac{2V_{DF}}{r}\right\} + \frac{V}{z}\sin(\omega t - \varphi) - \frac{2V_{DF}}{r} \tag{10}$$

where: $r=r_{SL}+r_F$, $L=L_S+L_d+L_F$, V_{DF} is the forward voltage drop of the diodes that is assumed to be constant, $i_0=i_d(t_0)$, $Z=r+jL\omega$, $Z_F=r_F+jL_F\omega$, $z=|Z|$, $\tan\varphi=\angle Z$ and L_d is the DC reactor inductance. Z_F and Z_S are defined in section (II).

Eq. (12) shows the AC branch of limiter current formula at time interval between t_0 to t_1

$$V\sin(\omega t) = ri_d(t) + \frac{Ldi_d(t)}{dt} \tag{11}$$

$$i_{ac}(t) = e^{-(r/L)(t-t_0)}\left\{i_0 - \frac{V}{z}\sin(\omega t_0 - \varphi)\right\} + \frac{V}{z}\sin(\omega t - \varphi) \tag{12}$$

where: $r=r_{SL}+r_{ac}+r_F$, $L=L_S+L_{ac}+L_F$, , $i_0=i_{ac}(t_0)$, $Z=r+jL\omega$, $Z_F=r_F+jL_F\omega$, $z=|Z|$, $\tan\varphi=\angle Z$ r_{ac} and L_{ac} are the resistance and inductance of ac branch of limiter respectively. Line voltage is given as follows

$$i_L(t) = i_d(t) + i_{ac}(t) \tag{13}$$

At $t=t_2$ thyristor T4 turns off and thyristor T1 conduct DC reactor current. Eq. (14) and Eq. (15) show the line and DC reactor current formula during discharging mode, respectively.

$$i_L(t) = e^{-(r/L)(t-t_1)}\left\{i_1 - \frac{V}{z}\sin(\omega t_1 - \varphi)\right\} + \frac{V}{z}\sin(\omega t - \varphi) \tag{14}$$

$$i_d(t) = i_{d1} - \frac{2V_{DF}}{L_d}(t - t_1) \tag{15}$$

where: $i_1=i_L(t_1)$, $i_{d1}=i_d(t_1)$ $r=r_S+r_F$, $L=L_S+L_F$.

Again at $t=t_2$ charging mode begins and it continues until $t=t_3$. At t_3 thyristor T1 turn off and DC reactor retreat from feeder F1 completely.

In Fig. 10 the effect of using DC reactor in proposed SFCL are considered clearly.

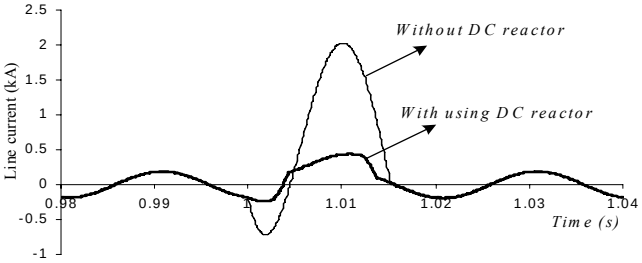

Fig. 10 effect of using DC reactor in proposed SFCL

When DC reactor retreat from feeder F1 at t_3, fault impedance will be equal with Z_1 (load1 and F1 impedance) and we have not any voltage distortion or phase angle jump in PCC as shown in Fig. 8.

V. CONCLUSION

Today the problem of power quality improvement is very real. In this paper a new type of fault current limiter based on DC reactor with using superconductor for power quality improvement are presented. Proposed SFCL is capable of mitigating voltage dips and the associated phase angle jump to acceptable levels for the distribution system considered in this work. However, in order to achieve good voltage dip mitigation (5% to 10% dips), fault currents would need to be reduced to about 2 pu. When fault happens, a bypass AC reactor and series resistor will insert the fault line automatically to limit the short circuit current. Subsequently the fault current is fully limited by the bypass AC reactor and series resistor. In general this type of SFCL is useful for power quality improvement when fault is occurred in distribution systems.

***Abstract*- This paper presents a maximum power point tracking (MPPT) for photovoltaic (PV) system, which generates signal to control solid-state switch of boost converter. The system controlled by ADMC331 a digital signal processing. The controller tracks maximum power by genetic Algorithm method. Genetic Algorithm is proposed in form of a mathematical model. This is an improved maximum power point tracking system in terms of speed and accuracy.**

I. INTRODUCTION

The people around the world are concerned about conventional sources of energy due to the fossil fuel exhaustion, their prices, and side effects of using fossil fuel. As the cost of fossil based energy is rising and the environmental problem caused by the conventional power generation is observable, renewable energy sources such as PV energy becomes a promising alternative source. Even though, PV energy source is clean, pollution-free and inexhaustible but their installation cost is high and the module efficiency is low therefore the overall system cost can be reduced by using high efficiency power conditioners which, in addition, are designed to extract the maximum possible power form the PV array, called maximum power point tracking (MPPT).

The MPP is effects by irradiation and temperature. They have been many MPPT techniques for PV power generation [1]-[8]. The task of MPPT is to track this MPP regardless of weather or load conditions so that the PV system draws maximum power from the PV system. The MPPT solution is in form of a non-linear dynamic and time-varying system. All algorithms are based on the fact that, looking at the power characteristic, at the left of the MPP the dP/dv > 0, at the right of the dP/dv < 0 and at MPP dP/dv = 0, as show in Fig. 1.

The perturbation and observation method (P&O), which moves the operating point toward the maximum power point by periodically increasing or decreasing the array voltage, is often used in many PV system [1]-[3], that the P&O method works well when the insulation does not vary quickly with time. However, the P&O method fails to quickly track the maximum power points.

The constant voltage (CV) this algorithm makes use of the fact that the MPP voltage changes only slightly with varying

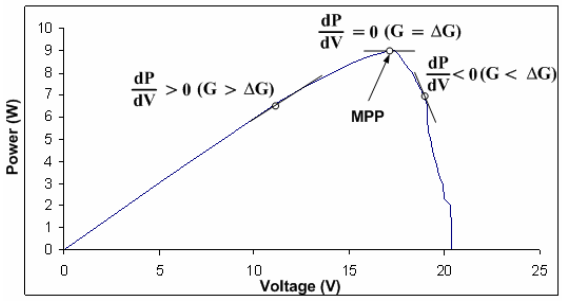

Figure 1. All algorithms are based on the fact that, looking at the power characteristic.

Irradiation [6]-[7], the ratio of VMP/VOC depends on the PV system parameters, but a commonly used value is 76%. In this algorithm the MPPT momentarily sets the PV system current to zero to allow a measurement of the PV system's open circuit voltage. The PV system operating voltage is then set to 76% of this measured value. This operating point is maintained for a set amount of time and then the cycle is repeated. A problem with this algorithm is the available energy is wasted when the load is disconnected form the PV system, also the MPP is not always located at 76% of the PV system's open circuit voltage.

The Incremental conductance method (INC) tracks the maximum power points by comparing the incremental and instantaneous conductance of the PV system [4]-[5], show in Fig. 2. The incremental conductance is estimated by measuring small changes in PV system voltage and current. These small changes may be induced by deliberate control action. A method which improves the INC method and can identify the incremental conductance of the PV system more rapidly than it has been in P&O and CV. Moreover, those search for the maximum operating conditions form the output power and voltage characteristics of PV system techniques are the hill-climbing [8], fuzzy logic control [9], and Artificial Neural Network (ANN) [10].

This paper proposes the implementation of DSP-based MPPT using low-cost low power consumption DSP to control a high efficiency boost-type dc/dc converter while genetic algorithm software has been developed for MPPT with self turning function. The DSP-Based MPPT controller is compared with the INC method to confirm the better results.

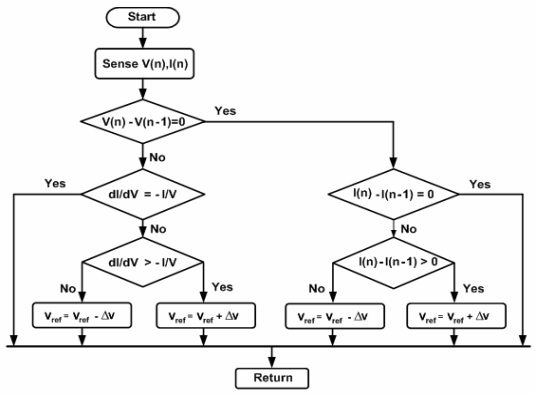

Figure 2. Flowchart INC method of MPPT control.

II. CHARACTERISTICS OF PHOTOVOLTAIC

The amount of the converted PV energy to electrical fluctuates depending on irradiation and temperature, as show in Fig. 3. It is seen that the irradiation charges affect mainly on the PV output current, while the temperature changes affect mainly on the PV output voltage. The intersection of the load-line with the PV system I-V characteristic, for a give irradiation and temperature, determines the operating point. The maximum power production is based on the load-line adjustment under varying atmospheric conditions. The equivalent circuit of the PV system is show in Fig. 4. The traditional I-V characteristic and P-V characteristic of PV system when neglecting the internal shunt resistance, is give by the following equation (1)

$$I_o = I_g - I_{sat}\left\{\exp\left[\frac{q}{AKT}\left(V_o + I_o R_s\right)\right] - 1\right\} \qquad (1)$$

Where I_o and V_o are the output current and output voltage, respectively, I_g is generated current under the irradiation, I_{sat} is the reverse saturation current, q is the electron charge, A is a dimensionless factor, K is the Boltzmann's constant, T is the temperature in (°K), R_s is the series resistance of the cell.

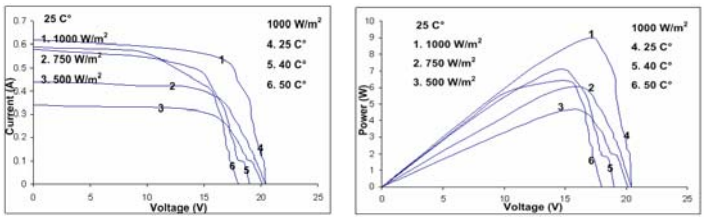

Figure 3. Characteristic of PV system with irradiation and temperature.

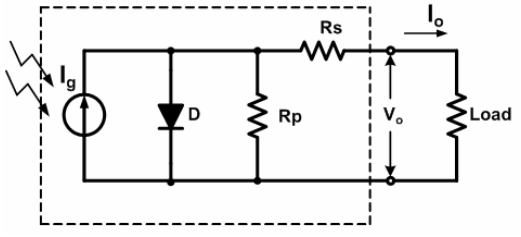

Figure 4. Equivalent circuit of the PV system.

III. BOOST CONVERTER

In a boost regulator the output voltage is greater than the input voltage, depicts a step-up or a PWM boost converter. It consists of dc input voltage source V_S, boost inductor L, controlled switch, diode D, filter capacitor C, and load resister R_L. The boost converter equivalent circuit diagram and its associated theoretical wave forms are show in Fig. 5 and 6, respectively. When the switch is turned on, the current in the boost inductor increases linearly and the diode D is off at that time. When switch turned off, the energy stored in the inductor is released through the diode to the output RC circuit, from which the dc voltage transfer function turns out to be.

$$V_O = \frac{V_S}{(1 - D)} \qquad (2)$$

Where V_O is maximum of the dc component of the output voltage. The output voltage is always greater than the input voltage. The boost converter operates in the continuous conduction mode where $L > L_{min}$

$$L_{min} = \frac{D(1-D)^2 R}{2fs} \qquad (3)$$

The filter capacitor must provide the output dc current to the load. When the diode D is off. The minimum value of the filter capacitance that results in the voltage ripple ΔV_O is give by.

$$\Delta V_O = \frac{V_O D}{RCfs} \qquad (4)$$

Where D is duty cycle at maximum converter output power, ΔV_O is the output voltage peak to peak ripple at maximum power, and fs is switching frequency.

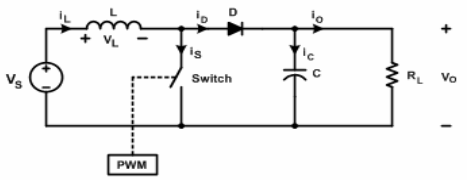

Figure 5. Equivalent circuit diagram of the boost converter.

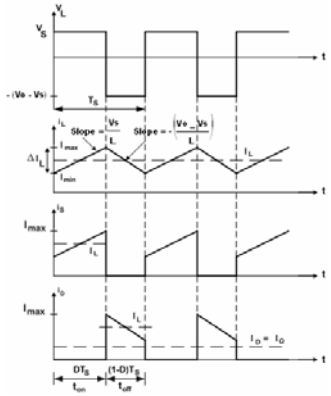

Figure 6. Voltage and current waveforms in a boost converter.

IV. GENETIC ALGORITHM

Genetic algorithms are a part of evolutionary computing, which is a rapidly growing area of artificial intelligence. As you can guess, genetic algorithms are inspired by Darwin's theory about evolution. Genetic algorithms are stochastic search techniques based on the mechanism of natural selection and natural genetics. Genetic algorithms, differing form conventional search techniques, start with an initial set of random solutions called population. Each individual in the population is called a chromosome, a binary bit string. The chromosomes evolve through successive iterations, called generations. During each generation, the chromosomes are evaluated, using some measures of fitness. To create the next generation, new chromosomes, called offspring, are formed by either merging two chromosomes from current generation using a crossover operator or modifying a chromosome using a mutation operator. A new generation is formed by selecting, according to the fitness values, some of the parents and of spring and rejecting others so as to keep the population size constant. Fitter chromosomes have higher probabilities of being selected. After several generations, the algorithm converge to the best chromosome, which hopefully represents the optimum or suboptimal solution to the problem. Structure of genetic algorithm is shown in Fig.7.

1) Generate random population of n chromosomes.
2) Evaluate the fitness f(x) of each chromosome x in the population.
3) Create a new population by repeating following steps until the new population is complete.
   3.1) Select parent chromosomes from a population according to their fitness (roulette wheel selection).
   3.2) With a crossover probability cross over the parents to form a new offspring. If no crossover was performed, offspring is an exact copy of parents.
   3.3) With a mutation probability mutate new offspring at each locus (position in chromosome).
4) Place new offspring in anew population.
5) If the end condition is satisfied, stop, and return the best solution in current population. Go to step 2

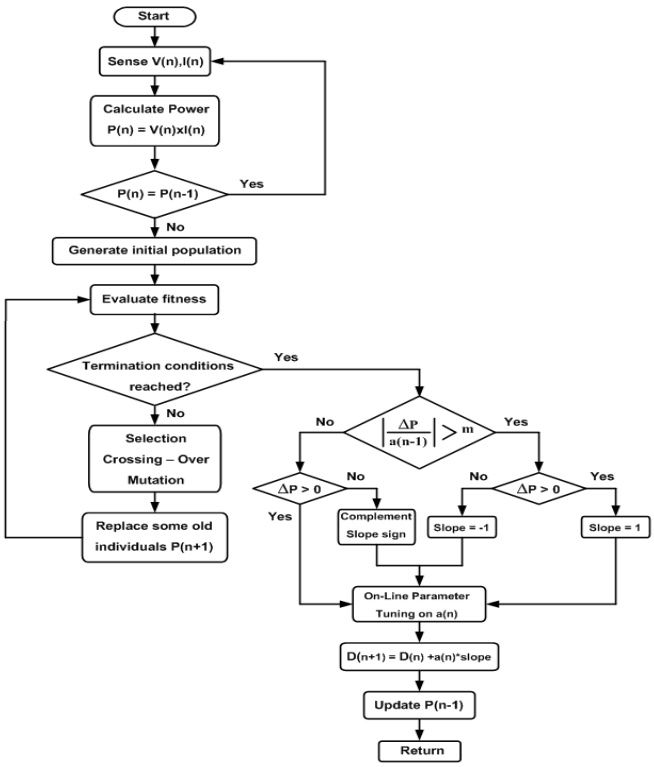

Figure 9. The flowchart of propose MPPT control method.

V. PROPOSED SYSTEM

A block diagram of proposed system is show in Fig. 8. The PV system which is to be used in this paper consists of Solartron Solar Module. Model SP10, P_{max} 10 w, V_{oc} = 21 V, I_{sc} = 0.62 A, V_{mp} = 17.24 V, and I_{mp} = 0.58 A. and DSP-based ADMC331, 26 MIPS, Fix-point 16-bit DSP core.

By using A/D converters, the voltage control which is between 0.3-3 V can be directly measured while current can be using the hall-effect sensor. The flowchart control program is show in Fig. 9, and fitness function for MPPT following in equation 5. Also, it features PWM output with program controlled duty cycle dc/dc boost converter 25 kHz maximum frequency.

$$f(x) = m_i \frac{\Delta P}{\Delta D(n-1)} \tag{5}$$

VI. EXPERIMENTAL RESULT

The MPP of PV system is compared between proposed method and INC method by varying the temperature from 25 °C, 40 °C, and 50 °C and the irradiation from 1000 W/m^2, 750 W/m^2, and 500 W/m^2. The INC used step-size ΔD = 0.02, experimental result, as show in Fig. 10-12, table 1, and 2.

VII. CONCLUSION

In this paper, the principle of genetic algorithm application has been used to deliver the highest possible power of the load from the PV system. The proposed control algorithm has been showed and compared with the conventional INC. method. The result from the experimental show that the proposed method has better performance of tracking maximum power than the conventional INC. method in term of efficiency.

***Abstract*-This paper presents an adaptive characteristic of mho distance relay for compensation of the phase to phase fault resistance. It has been shown an extend by insert parallelogram which the same as impedance angle of transmission line between *R-X* diagram of mho distance relay. The algolithm of propose system is verified by simulation and results.**

I. INTRODUCTION

Distance relays effectively measure the impedance between the relay location and the fault. If the impedance of the fault is low, the impedance is proportional to the distance from the relay to the fault. For a fault at the remote end of the line, the voltage at the local relay equals the current multiplied by impedance of the line, i.e. *IZ*. Therefore, the ratio of the voltage to the current measured at the relay equals the impedance of the line, *Z*. Since the ratio *V/I* is proportional to the line length between the relay and the fault, the ratio *V/I* is, therefore, a measure of the impedance to the fault. A distance relay is designed to only operate for faults occurring between the relay location and the selected reach point and remain stable for all faults outside this region or zone. In time stepped distance scheme this ensures adequate discrimination for faults that may occur between different line sections.

In this paper, we present an analysis of the adaptive characteristic of *R-X* diagram of mho relay for fault resistance compensation in the phase to phase fault.

II. MHO CHARACTERISTIC

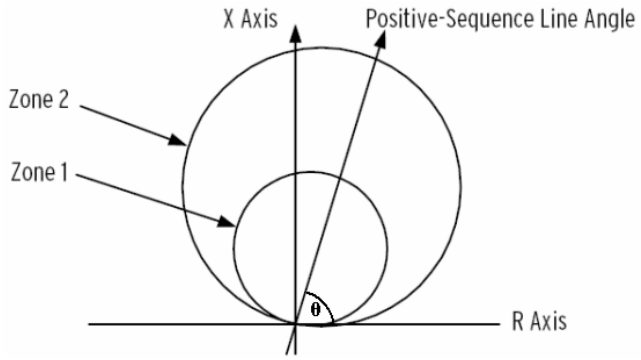

Figure 1. Mho Characteristic

Generally, mho distance relay is used widely in the present that have a circular impedance characteristic. The characteristic is suitable for the phase fault protection and in the case of a low fault resistance. But in the case of high value of fault resistance, the apparent of fault location is outside the zone circle and relay underreaches.

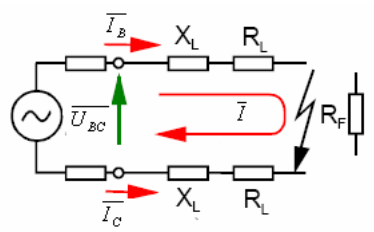

Figure 2. Phase *B-C* short-circuit with a fault resistance (single-ended infeed)

Consider the transmission system as shown in Figure 2, impedance is modified by inclusion of fault resistance, R_F. In the case of phase *B-C* short-circuit, the impedance seen by the faulted phase relay is

$$Z_{BC} = \frac{U_B - U_C}{I_B - I_C} \tag{1}$$

$$U_{BC} = U_B - U_C = 2\left(R_L \cdot I + jX_L \cdot I\right) + R_F I \tag{2}$$

$$I_C = -I_B = I \tag{3}$$

$$Z_{BC} = \frac{2\left(R_L \cdot I + jX_L \cdot I\right) + R_F \cdot I}{2I} = R_L + jX_L + \frac{R_F}{2} \tag{4}$$

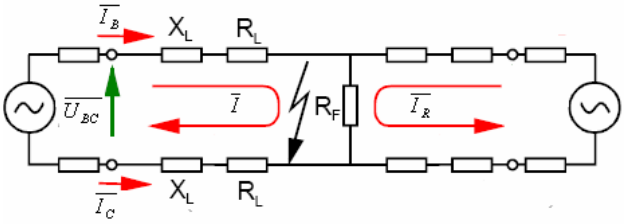

Figure 3. Phase *B-C* short-circuit with fault resistance (infeed from both sides)

Consider the transmission system show in Figure 3, and assume that the fault resistance is equal to R_F. If the contribution to the fault from the remote is I_R, the fault current $I_F=I+I_R$, and the voltage at the relay location is given by

$$U_{BC} = 2\left(R_L \cdot I + jX_L \cdot I\right) + R_F\left(I + I_R\right) \tag{5}$$

$$Z_{BC} = \frac{2\left(R_L \cdot I + jX_L \cdot I\right) + R_F \cdot \left(I + I_R\right)}{2I}$$

$$= R_L + jX_L + \frac{R_F}{2}\left(\frac{I_R}{I} + 1\right) \tag{6}$$

Since I_R may not be in phase with I, the fault resistance may contribute an error to the resistance as well as the reactance of the faulted line segment. This is illustrated in *R-X* diagram in Figure 4. In order to accommodate the resistance in the fault path, it is necessary to shape the trip zone of a distance relay in such a manner that region surrounding the apparent impedance is included inside the zone. It will be seen in this paper that different types of distance relays have different ability of accommodating the fault resistance. It should be remembered that a larger area for the protection zone in *R-X* plane accommodates greater fault path resistance.

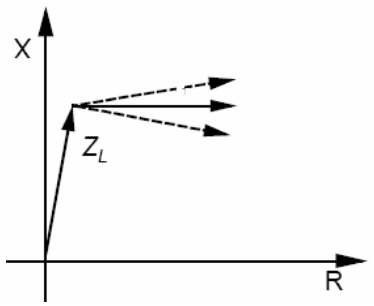

Figure 4. Its effect on the *R-X* diagram

III. Characteristic of Mho Distance Relay in The Case of Non-Adaptive *R-X* Diagram

The simulation of characteristic of mho relay simulate for phase *B-C* short-circuit of IEEE 14 Bus Test Case using the ATP-EMTP program as shown in Figure 5.

The simulation of phase-phase fault without fault resistance (R_F = 0 Ω), there is phase fault and fault location as shown in Figure 5. Assume phase *B-C* short-circuits at the location is about 10% of line length from busbar 1 to 2 or approximate 90% of line length from busbar 2 to 1. The characteristic of mho distance relay for non-adaptive *R-X* diagram is shown in Figure 6 and 7, respectively. All of distance relay setting is 85% of the line length in zone 1 and 120% in zone 2. The simulation result of the propose system with fault resistance 50 Ω (R_F = 50 Ω) is shown in Figure 8 and 9, respectively.

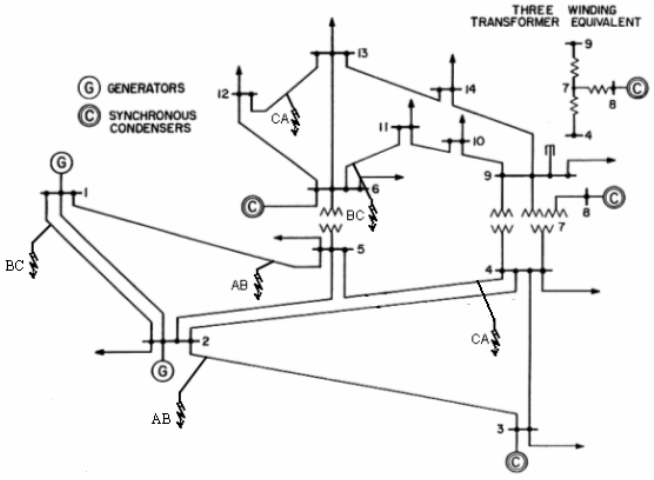

Figure 5. IEEE 14 Bus Test Case for simulation

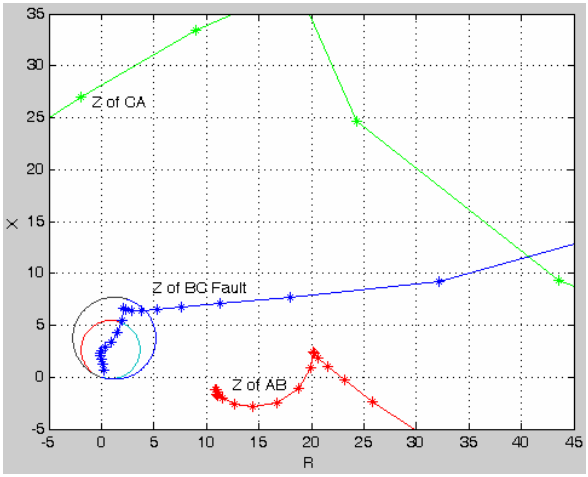

Figure 6. Impedance of fault between phase *B* and *C* (bus1 to bus2) in zone1

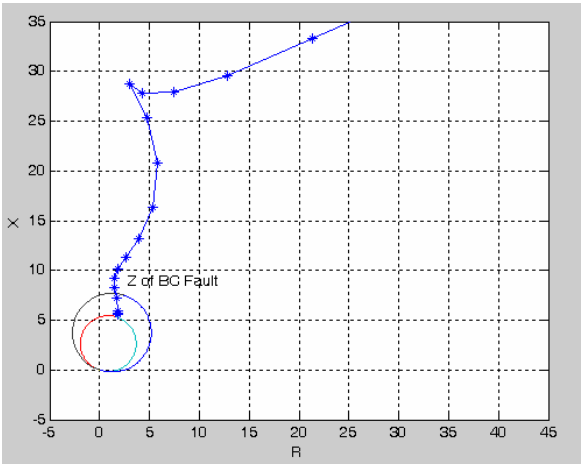

Figure 7. Impedance of fault between phase *B* and *C* (bus2 to bus1) in zone2

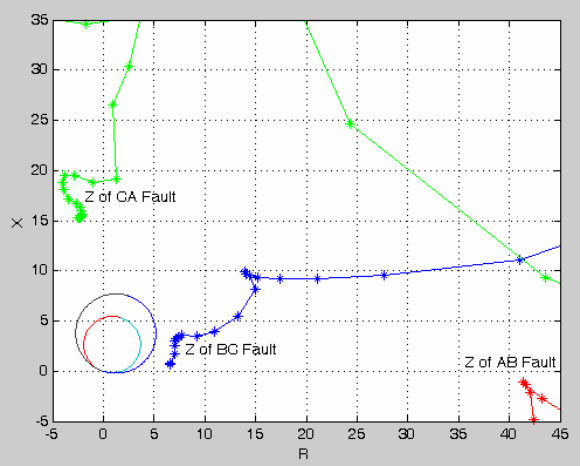

Figure 8. Impedance of fault between phase *B* and *C* (bus1 to bus2) without adaptive characteristic of mho distance relay

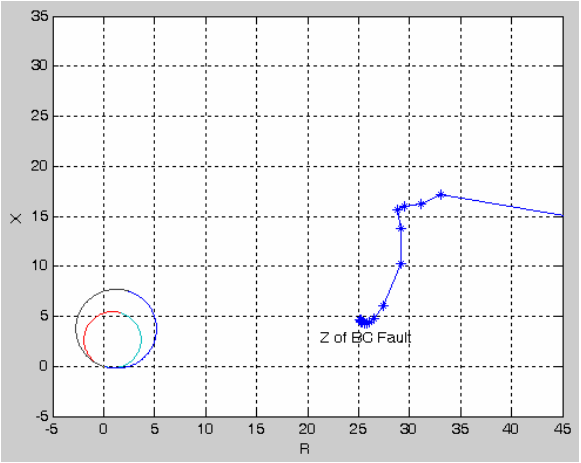

Figure 9. Impedance of fault between phase *B* and *C* (bus2 to bus1) without adaptive characteristic of mho distance relay

IV. Characteristic of Mho Distance Relay in the Case of Adaptive *R-X* Diagram

Fault component of the power system is an uncontrolled parameter which is influenced by many factors, and can be made up of fault arc resistance. The effect of fault resistance at the fault location is generally to reduce the effective reach of distance relay. In this paper presents adaptive characteristic of *R-X* diagram of mho relay for fault resistance compensation in the phase to phase fault. In order to accommodate the resistance in the fault path, it is necessary to shape the trip zone of a distance relay in such a manner that region surrounding the apparent impedance is included inside the zone. It will be seen in this paper that different types of distance relays have differing ability of accommodating the fault resistance. It should be remembered that a larger area for the protection zone in *R-X* plane accommodates greater fault path resistance.

Next, fault phase impedance can be calculated as in (6) with fault resistance of 50 ohms (R_F = 50 Ω) and setting relay for improving characteristic of the mho distance relay which shown in Figure 10 and 11.

The simulation results of all cases are shown in Table 1.

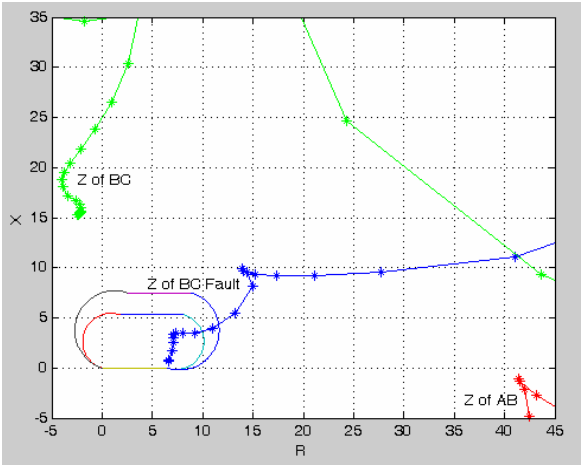

Figure 10. Impedance of fault between phase *B* and *C* (bus1 to bus2) with adaptive characteristic of mho distance relay (zone1)

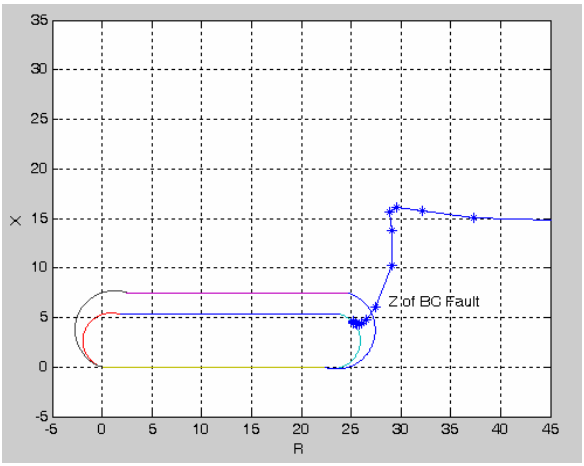

Figure 11. Impedance of fault between phase *B* and *C* (bus2 to bus1) with adaptive characteristic of mho distance relay (zone2)

V. Results

According to IEEE 14 Bus Test Case as shown in Figure 5, contains 31 relays. All the voltages and current at each location are extracted and feeding into the mho distance relay algorithm. In this test all distance relays operate in the conventional three-zone time stepped setting. When the Phase *B-C* short-circuit without fault resistance (R_F = 0 Ω) occurred 10% form busbar 1 on the line between busbus 1 and busbar 2 on circuit 1. Relay-12(circuit 1) operated in zone-one, relay-21(circuit 1), 21(circuit 2), 32, 51 in zone-

two and some in zone-three. At the same condition, when R_F = 50 ohms the mho distance relay does not detect fault between busbar 1 and busbar 2. However, after improve the characteristic of the mho distance relay, it able to correctly detect fault between busbar 1 and busbar 2 inside zone1 and 2, respectively. In another case of distance relay, the simulation results shown in Table 1.

VI. CONCLUSIONS

Adaptive characteristic of mho distance relay by using an extended parallelogram with the same as impedance angle of transmission line between *R-X* diagram of mho distance relay for Compensation of the Phase to Phase Fault Resistance is presented. The proposed system offers the mho distance can extend tripping of zone and correctly tripping circuit breaker.

***Abstract*— This paper presents a novel control method for a switched-capacitor (SC) AC-DC converter for small power applications. In the proposed method, the capacitors which are not used for electrical charge or discharge in the charge process are connected to an output terminal in parallel. Hence, the converter controlled by the proposed method can improve the properties such as power efficiency and ripple noise. Furthermore, to alleviate the stress to capacitors, the on-resistances of power-switches connected to the ground are controlled to keep a constant voltage in each capacitor. The validity of the proposed method is confirmed by theoretical analyses. The analyses show that the proposed method can improve power efficiency and ripple noise without changing the structure of the converter.**

I. Introduction

In the design of power converters, magnetic elements such as coils, transformers, etc. have been used in most converters. Being distinct from such converters, there is the switched-capacitor (SC) technique which can realize the power converters without magnetic elements. The SC technique has a possibility to implement the converters in an IC form though the power efficiency of SC power converters is inferior to that of the converters using magnetic elements. For this reason, several types of SC power converters have been proposed [1-4]. Among those, aiming at an IC implementation of an AC-DC converter, we focused on an SC AC-DC converter for small power applications.

In the previous studies, Oota realized a series-parallel type SC AC-DC converter [1]. The converter which performs only $1/N$ step-down conversion needs large capacitors, because the capacitors in the converter are charged only once in a half period of an AC input. To solve this problem, Hara et al. proposed a ring-type SC AC-DC converter [3]. Depending on the amplitude of an AC input, the converter controls the ratio of the step-down conversion, $1/P$ $(P \in \{2, 3, \ldots, N\})$, by changing the connections of power-switches at high speed. Thus the size of capacitors can be reduced. However, in the control method [3],[4] of the ring-type power converter, all the capacitors are not used for electrical charge or discharge when $P < N$.

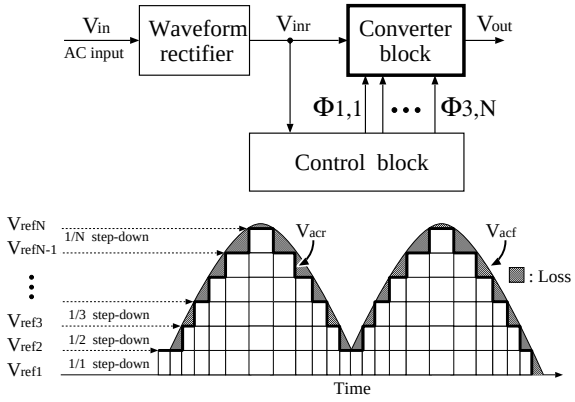

Fig. 1. Architecture of proposed AC-DC converter.

In this paper, a novel control method for an SC AC-DC converter is proposed to improve the properties such as power efficiency and ripple factor. In the proposed method, the capacitors which are not used for electrical charge or discharge in the charge process are connected to an output terminal in parallel. Hence, the converter controlled by the proposed method can improve the circuit properties. Furthermore, to alleviate the stress to capacitors, the on-resistances of power-switches connected to the ground are controlled to keep a constant voltage in each capacitor. The validity of the proposed method is confirmed through theoretical analyses.

II. Circuit Structure

Figure 1 shows the block diagram of the proposed SC AC-DC converter. In this paper, a family of the series-parallel type power converter [1] is used as a converter block [1] . Figure

[1]In the previous studies in [3] and [4], a ring-type power converter is used as the converter block. The ring-type converter needs many switches though it can provide stepped-up/stepped-down voltages. Aiming at the design of a step-down AC-DC converter, we employ a family of the series-parallel type converter. The number of switches for the series-parallel type converter is less than 75 % of that for the ring-type converter.

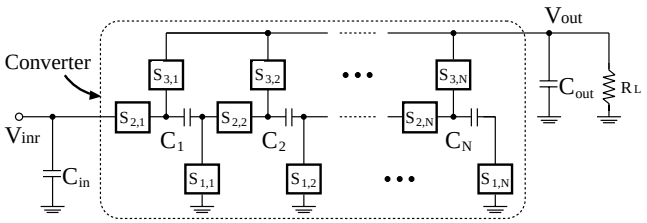

Fig. 2. Detail of converter block.

2 shows the converter block. The power-switches $S_{i,k}$ ($(i = 1, 2, 3)$ and $(k = 1, 2, \ldots, N)$) in Fig.2 are controlled by 2 phase clock pulses $\Phi_{i,k}$.

In the conventional method [3-4], the power-switches are controlled as shown in Fig.3 [2] . That is, all the capacitors are not used for electrical charge and discharge when $P < N$, where P is the number of series-connected capacitors to an input terminal in $State - T1$, N is the total number of capacitors in the converter block, and R_{on} [3] denotes an on-resistance of the power-switch. Figure 4 shows the proposed control method for SC converters. In Fig.4, the instantaneous equivalent circuit in $State - T2$ is omitted to save space, because the circuit in $State - T2$ is the same as Fig.3 (b). As Fig.4 shows, $C_{P+1} \sim C_N$ in Fig.3 (a) are connected to the output terminal. The operation of the converter block is as follows.

Firstly, the the input voltage V_{in} is rectified into a full waveform V_{inr}. In the converter block, V_{inr} is divided equally into N levels by comparators as shown in Fig.1. In the comparators, the reference voltages V_{refP}'s are set to satisfy $|V_{refP} - V_{refP-1}| =$ constant. During $V_{refP-1} < V_{inr} \leq V_{refP}$, the converter block changes the states of switches at the frequency of $1/T$, where the duty factor D of the converter satisfies that $T1 = DT$ and $T2 = (1 - D)T$.

In $State - T1$, depending on the amplitude of V_{inr}, P capacitors are connected in series, and $C_{P+1} \sim C_N$ are connected to the output terminal in parallel when $P < N$ (see Fig.4). In this timing, $S_{1,P} \sim S_{1,N}$, $S_{2,1} \sim S_{2,P}$, and $S_{3,P+1} \sim S_{3,N}$ are On and the other switches are Off, where the on-resistance of $S_{1,P}$, R_{onc} (see in Fig.4), is controlled to charge the voltage of each capacitor to V_{refN}/N. As for SC converters, it is known that the efficiency decreases when the voltage of each capacitor is not constant. Although the energy of the hatched area in Fig.1 becomes a loss, the proposed method enables the following: 1. the capacitors C_k's can be charged in spite of the amplitude of the input voltage, 2. the stress to the capacitors can be alleviated, and 3. the capacitors C_k don't have a dielectric loss.

Next, in $State - T2$, all the capacitors are connected in parallel (see Fig.3 (b)). In this timing, $S_{1,k}$'s and $S_{3,k}$'s are On and $S_{2,k}$'s are Off. By iterating these processes at high speed, the converter provides a DC voltage V_{out}.

[2]In Fig.3, to simplify the theoretical analysis in Sect.3, the resistance R_{on} is connected to the both sides of C_{out}.

[3]To simplify the analysis, the influence of fluctuation of switches is disregarded

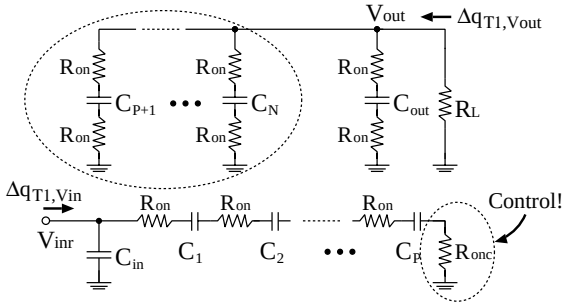

Fig. 4. Instantaneous equivalent circuit for converter using proposed method when $State - T1$.

III. Theoretical Analysis

A. Power Efficiency

Firstly, the equivalent circuit of the SC AC-DC converter by using the proposed method is analyzed. To simplify the theoretical analyses, we assume that the time constant is quite larger than T and parasitic elements are disregarded.

In the steady state, the differential values of the electric charges in C_k satisfy

$$\Delta q_{T1}^k + \Delta q_{T2}^k = 0, \quad (1)$$

where Δq_{T1}^k and Δq_{T2}^k denote the electric charges when $State - T1$ and $State - T2$, respectively. In the case of $T1$, the differential values of the electric charges in the input and the output terminals, $\Delta q_{T1,V_{inr}}$ and $\Delta q_{T1,V_{out}}$, are given by

$$\begin{aligned} \Delta q_{T1,V_{inr}} &= \Delta q_{T1}^{in} + \Delta q_{T1}^1 \\ &\cdots \\ &= \Delta q_{T1}^{in} + \Delta q_{T1}^P, \\ \Delta q_{T1}^1 &= \cdots = \Delta q_{T1}^P, \end{aligned}$$

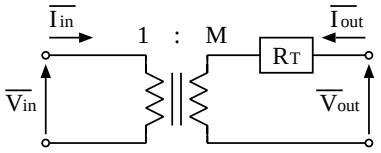

Fig. 5. General equivalent circuit of SC DC-DC converters.

and

$$\Delta q_{T1,V_{out}} = \begin{cases} \Delta q_{T1}^{out} + \sum_{k=P+1}^{N} \Delta q_{T1}^{k} & \text{if } P < N, \\ \Delta q_{T1}^{out} & \text{if } P = N, \end{cases} \quad (2)$$

where P (≥ 2) denotes the number of the series-connected capacitors via $S_{1,P}$ and $S_{2,k}$'s. According to the input V_{inr}, the parameter P is determined as follows:

$$P = \begin{cases} 1 & \text{if } V_{ref1} \leq V_{inr} < V_{ref2}, \\ 2 & \text{if } V_{ref2} \leq V_{inr} < V_{ref3}, \\ & \cdots \\ N & \text{if } V_{refN} \leq V_{inr}. \end{cases} \quad (3)$$

In $State - T1$, to alleviate the stress to capacitors, the on-resistance of $S_{1,P}$ connected to the ground is controlled to keep a constant voltage in each capacitor.

On the other hand, in the case of $State - T2$, $\Delta q_{T2,V_{inr}}$ and $\Delta q_{T2,V_{out}}$ are given by

$$\Delta q_{T2,V_{inr}} = q_{T2}^{in}$$
$$\text{and} \quad \Delta q_{T2,V_{out}} = \sum_{k=1}^{N} \Delta q_{T2}^{k} + \Delta q_{T2}^{out}. \quad (4)$$

During $V_{refP-1} < V_{inr} \leq V_{refP}$, the average currents of the input and the output, $\overline{I_{inr}}$ and $\overline{I_{out}}$, are given by

$$\overline{I_{acr}} = (\Delta q_{T1,V_{inr}} + \Delta q_{T2,V_{inr}})/T$$
$$\text{and} \quad \overline{I_{out}} = (\Delta q_{T1,V_{out}} + \Delta q_{T2,V_{out}})/T. \quad (5)$$

By substituting Eqs.(1), (2), and (4) into Eq.(5), the following equations are derived:

$$T \cdot \overline{I_{inr}} = \Delta q_{T1}^{1}$$
$$\text{and} \quad T \cdot \overline{I_{out}} = \sum_{k=P+1}^{N} \Delta q_{T1}^{k} - \sum_{k=1}^{N} \Delta q_{T1}^{k}. \quad (6)$$

From Eq.(6), the following equation is obtained:

$$\overline{I_{inr}} = -\frac{1}{P}\overline{I_{out}}. \quad (7)$$

As for SC converters, it is known that a general equivalent circuit of SC DC-DC converters [5-6] can be expressed by Fig.5, where M is a ratio of the ideal transformer, and $\overline{V_{in}}$ and $\overline{V_{out}}$ denote an averaged input voltage and an averaged output voltage, respectively. The equivalent circuit of the converter block in Fig.1 can be expressed by using Fig.5 though the circuit of Fig.5 is for the SC DC-DC converters. Because the converter block of Fig.2 can be used also as a DC-DC converter. In Fig.5, the consumed energy W_T is defined by

$$W_T = W_{T1} + W_{T2} \equiv (\frac{\Delta q_{V_{out}}}{T})^2 \cdot R_T \cdot T. \quad (8)$$

Hence, Eq.(8) can be rewritten as

$$W_T = \frac{R_T P^2}{T}(\Delta q_{T1}^{1})^2, \quad (9)$$

because $\Delta q_{V_{out}}$ is expressed by

$$\Delta q_{V_{out}} = \Delta q_{T1,V_{out}} + \Delta q_{T2,V_{out}} = -P\Delta q_{T1}^{1}.$$

Here, from Fig.4 and Fig.3 (b), the consumed energies in $State - T1$ and $State - T1$, W_{T1} and W_{T2}, are given by

$$W_{T1} = PR_{on}T1(\frac{\Delta q_{T1}^{1}}{T1})^2 + 2R_{on}T1\sum_{k=P+1}^{N+1}(\frac{\Delta q_{T1}^{k}}{T1})^2 + R_{onc}T1(\frac{\Delta q_{T1}^{1}}{T1})^2$$
and
$$W_{T2} = 2R_{on}T2\sum_{k=1}^{N+1}(\frac{\Delta q_{T2}^{k}}{T2})^2, \quad (10)$$

respectively. By substituting Eqs.(1), (2), (4),

$$\Delta q_{T1,V_{out}} = \frac{T1}{T}\Delta q_{V_{out}},$$
$$\text{and} \quad \Delta q_{T2,V_{out}} = \frac{T2}{T}\Delta q_{V_{out}}, \quad (11)$$

into Eq.(10), the consumed energy W_T can be derived by

$$W_T = \{\frac{R_{on}P(1+D) + R_{onc}(1-D)}{D(1-D)P^2} + \frac{2R_{on}D}{(N-P+1)(1-D)}\}\frac{P^2}{T}(\Delta q_{T1}^{1})^2. \quad (12)$$

Therefore, from Eqs.(9) and (12), the resistance R_T in Fig.3 can be given by

$$R_T = \frac{R_{on}P(1+D) + R_{onc}(1-D)}{D(1-D)P^2} + \frac{2R_{on}D}{(N-P+1)(1-D)}. \quad (13)$$

The equivalent circuit of Fig.5 can be expressed by the determinant using Kettenmatrix. From Eqs.(7) and (13), the following determinant is obtained:

$$\begin{bmatrix} \overline{V_{inr}} \\ \overline{I_{inr}} \end{bmatrix} = \begin{bmatrix} P & 0 \\ 0 & 1/P \end{bmatrix} \begin{bmatrix} 1 & R_T \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \overline{V_{out}} \\ -\overline{I_{out}} \end{bmatrix}. \quad (14)$$

Hence, the equivalent circuit of the proposed converter can be expressed by the circuit shown in Fig.6. From Fig.6, the

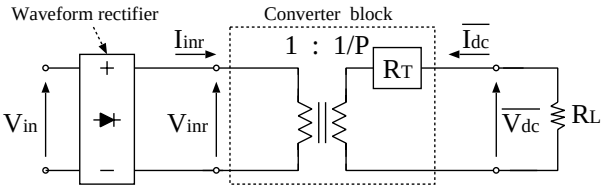

Fig. 6. Equivalent circuit of SC AC-DC converter using proposed control method.

power efficiency [4] is given by

$$\eta = \frac{(P\overline{I_{inr}})^2 R_L}{(P\overline{I_{inr}})^2 R_L + (P\overline{I_{inr}})^2 R_T} = \frac{P^2 R_L}{P^2 R_L + P^2 R_T}. \quad (15)$$

Here, the resistance R_T of the converter using the conventional control method is given by

$$R_T = \frac{R_{on}P(1+D) + R_{onc}(1-D)}{D(1-D)P^2} + \frac{2R_{on}D}{1-D}. \quad (16)$$

As Eqs.(13) and (16) show, the resistance R_T of the proposed method is smaller than that of the conventional method when $P \neq N$. This result means that the converter using the proposed method can improve the power efficiency.

B. Output Ripple Factor

Next, the ripple factor of the proposed converter is analysed. To simplify the analysis, the on-resistance of power-switches are disregarded. In the case of $State-T2$, the output voltage $V_{out,T2}(t)$ of Fig.3 (b) is given by

$$V_{out,T2}(t) = V_{max,T2} \cdot \exp(-\frac{t}{\tau_{T2}}), \quad (17)$$

where $V_{max,T2}$ denotes the output voltage when $V_{out,T2}(0)$ and τ_{T2} is a time constant $(N+1)CR_L$. On the other hand, in the case of $State-T1$, the output voltage $V_{out,T1}(t)$ of Fig.4 is given by

$$V_{out,T1}(t) = V_{out,T2}(T2) \cdot \exp(-\frac{t}{\tau_{T1}}) = V_{max,T2} \cdot \exp(-\frac{T2}{\tau_{T2}}) \cdot \exp(-\frac{t}{\tau_{T1}}), \quad (18)$$

where τ_{T1} is a time constant $(N-P+1)CR_L$. From Eqs.(17) and (18), the output voltage ripple ΔV_{out} and the average output voltage $\overline{V_{out}}$ are derived by

$$\Delta V_{out} = V_{out,T2}(0) - V_{out,T1}(T1) = V_{max,T2}\{1 - \exp(-\frac{T1}{\tau_{T1}} - \frac{T2}{\tau_{T2}})\} \quad (19)$$

[4]In Eq.(15), the energy loss caused by the waveform rectifier and the peripheral circuits such as the pulse generator is disregarded.

and

$$\overline{V_{out}} = \frac{1}{T1}\int_0^{T1} V_{out,T1}(t)dt + \frac{1}{T2}\int_0^{T2} V_{out,T2}(t)dt = V_{max,T2} \cdot [\frac{\tau_{T2}}{T2}\{1 - \exp(-\frac{T2}{\tau_{T2}})\} + \frac{\tau_{T1} \cdot \exp(-\frac{T2}{\tau_{T2}})}{T1}\{1 - \exp(-\frac{T1}{\tau_{T1}})\}], \quad (20)$$

respectively. Then, from Eqs.(19) and (20), the output ripple factor V_{rip} can be expressed by

$$V_{rip} = \frac{\Delta V_{out}}{\overline{V_{out}}} = \frac{1 - \exp(-\frac{T1}{\tau_{T1}} - \frac{T2}{\tau_{T2}})}{DM}, \quad (21)$$

where

$$DM = \frac{\tau_{T2}}{T2}\{1 - \exp(-\frac{T2}{\tau_{T2}})\} + \frac{\tau_{T1} \cdot \exp(-\frac{T2}{\tau_{T2}})}{T1}\{1 - \exp(-\frac{T1}{\tau_{T1}})\}.$$

Here, the difference between the proposed method and the conventional method in the ripple factor is the time constant in $State-T1$. The time constant τ_{T1} for the conventional method is CR_L. Therefore, the time constant τ_{T1} for the proposed method is larger than that for the conventional method when $P \neq N$. Hence, as you can see from Eq.(21), the ripple factor can be reduced by the proposed method.

IV. Conclusion

A novel control method for an SC AC-DC converter has been proposed in this paper. The validity of the proposed method was confirmed by theoretical analyses. The theoretical analyses showed that the proposed method can improve the properties such as power efficiency and ripple noise without changing the structure of the converter.

The IC implementation of the power converter using the proposed control method is left to the future study.

Abstract— **Robust DC-DC converter which can cover extensive load changes and also input voltage changes with one controller is needed. We proposed an aproximate 2DOF digital controller which which realizes the start-up response and dynamic load response independently. The controller makes the control bandwidth wider, and at the same time makes a variation of the output voltage small at sudden changes of loads and the input voltages. In this paper, a new approximate 2DOF digital controller using additinal zeros is proposed. The new controller makes a variation of the output voltage more small at sudden changes of loads and the input voltages. This controller is actually implemented on a DSP and is connected to a DC-DC converter. Experimental studies demonstrate that this type of digital controller can satisfy given severe specifications.**

I. Introduction

In many applications of DC-DC converters, loads cannot be specified in advance, i.e., their amplitudes are suddenly changed from the zero to the maximum rating. Generally, design conditions are changed for each load and then each controller is re-designed. Then, a so-called robust DC-DC converter which can cover such extensive load changes and also input voltage changes with one controller is needed. Then the demand to suppressing output voltage change becomes still severer. The application of the digital controller to DC-DC converter designed by the PID or root locus method etc. has been recently considered[1], [2]. However it is difficult to retain sufficient robustness of DC-DC converters by these techniques. The authors proposed the method of designing a approximate 2-degree-of-freedom (2DOF) controller of DC-DC converter[3]. This controller realized a first-order differential transfer characteristics between equivalent disturbances and an output voltage. In this paper, we propose a new approximate 2DOF digital controller which realise a second-order differential trasfer characteritics. The new controller makes a variation of the output voltage more small at sudden changes of resistive load and the input voltage. This characteristics is realized by introducing an additional zeros into a transfer function between equivalent disturbances and an output. A new DC-DC converter equipped the proposed controller in DSP is actually manufactured. Some simulations and experiments show that this new DC-DC converter can satisfy given severe specifications.

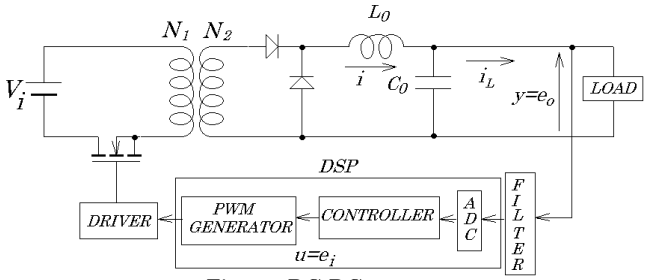

Fig. 1. DC-DC converter

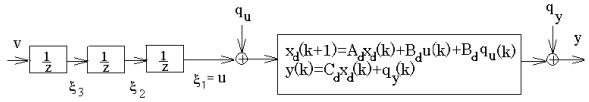

Fig. 2. Controlled object with input dead time $L_d(\leq T)$

II. DC-DC converter

The DC-DC converter as shown in **Fig.1** has been manufactured. We use the DSP(TI TMS320LF2801). This DSP has a built-in AD converter and a PWM switching signal generating part. The switching frequency is set at 400[KHz] and the peak-to-peak amplitude C_m is 125[V]. C_0 is 300[μF] and L_0 is 0.6[μH]. If the frequency of control signal u is smaller enough than that of the carrier, the state equation of the DC-DC converter in Fig.1 except for the controller in DSP can be expressed[**?**] as

$$\begin{cases} \dot{x} = A_c x + B_c u + B_c q_u \\ y = Cx + q_y \end{cases} \tag{1}$$

$$x = \begin{bmatrix} e_o \\ i \end{bmatrix} \quad A_c = \begin{bmatrix} -\frac{1}{C_0 R_L} & \frac{1}{C_0} \\ -\frac{1}{L_0} & -\frac{R_0}{L_0} \end{bmatrix} \quad B_c = \begin{bmatrix} 0 \\ \frac{K_p}{L_0} \end{bmatrix}$$

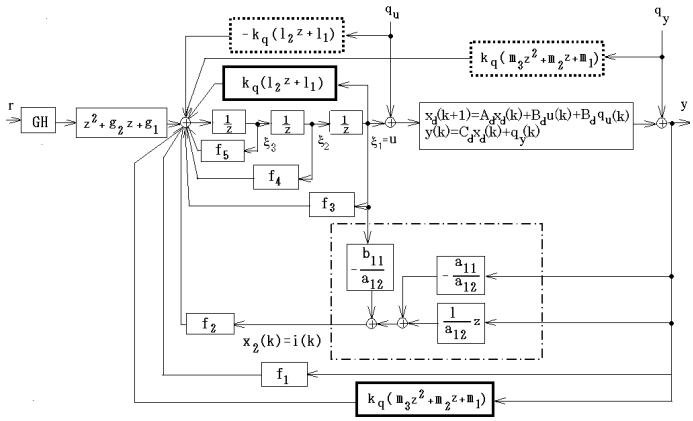

Fig. 3. Feedforward from equivalent disturbances q_u and q_y, and model matching with state feedback

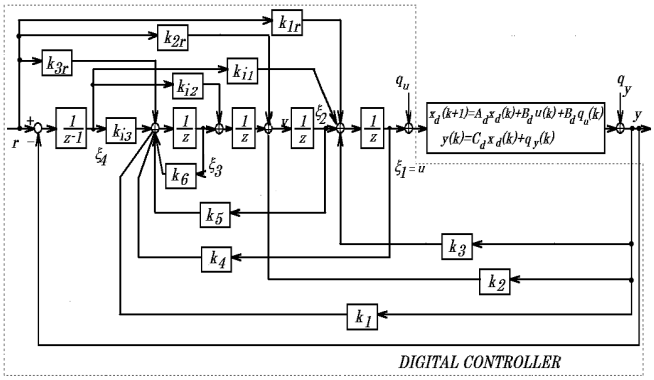

Fig. 4. Approximate 2DOF digital integral type control system

$$C = \begin{bmatrix} 1 & 0 \end{bmatrix} \quad u = e_i \quad y = e_0 \quad K_p = -\frac{V_i N_2}{C_m N_1}$$

and R_0 is the total resistance of coil and ON resistance of FET, etc., and the value is 0.015[Ω]. Then the discrete-time state equation of the system (1) with a zero order hold is expressed as follows :

$$\begin{cases} x_d(k+1) = A_d x_d(k) + B_d u(k) + B_d q_u(k) \\ y(k) = C x_d(k) + q_y(k) \end{cases} \quad (2)$$

$$A_d = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix} = e^{A_c T} \quad B_d = \begin{bmatrix} b_{11} \\ b_{21} \end{bmatrix} = \int_0^T e^{A_c \tau} B_c d\tau$$

The DC-DC converter with the following specifications 1-7 is designed and manufactured. Specs 5 and 7 are new ones. These specs are more severe than 50[mV] in references [3].

1. Input voltage V_i is 48[V] and output voltage e_o is 3.3[V].
2. Startup transient reponses are almost the same at resistive load and parallel load of resistance and capacity, where $0.165 \leq R_L < \infty$[Ω] and $0 \leq C_L \leq 200$[μF].
3. The rising time of the startup transient reponse is smaller than 100[μs].
4. Against all the loads of spec.1, an over-shoot is not allowable in the startup transient response.
5. The dynamic load response is smaller than 25[mV] against 10[A] change of load current.
6. The specs. 2, 3, 4 and 5 are satisfied also to change of input voltage of ±20%.
7. Regulation of output voltage is amaller than 25[mV] at the sudden change of input voltage within ±20%.

III. Design method with aditional zeros

A. Addional method of zeros

The following equation is obtained by repeating the difference of the output of eq.(2).

$$Y = O^* x_d(k) + U\bar{u}(k) + U\bar{q}_u + \bar{q}_y \quad (2)$$

$$Y = \begin{bmatrix} y(k) \\ y(k+1) \\ y(k+2) \end{bmatrix} \quad O^* = \begin{bmatrix} C \\ CA_d \\ CA_d^2 \end{bmatrix} \quad U = \begin{bmatrix} 0 & 0 \\ CB_d & 0 \\ CA_dB_d & CB_d \end{bmatrix}$$

$$\bar{u} = \begin{bmatrix} u(k) \\ u(k+1) \end{bmatrix} \quad \bar{q}_u = \begin{bmatrix} q_u(k) \\ q_u(k+1) \end{bmatrix} \quad \bar{q}_y = \begin{bmatrix} q_y(k) \\ q_y(k+1) \\ q_y(k+1) \end{bmatrix}$$

If both sides of eq.(4) are mulutiplied by $\bar{I}_2 = [I_2 \;\; 0]$(I_2 is a 2×2 unit matrix) from the left and solved about x_d, the following equation will be obtained.

$$\begin{aligned} x_d(k) &= (\bar{I}_2 O^*)^{-1} \bar{I}_2 Y - (\bar{I}_2 O^*)^{-1} \bar{I}_2 U \bar{u}(k) \\ &- (\bar{I}_2 O^*)^{-1} \bar{I}_2 U \bar{q}_u - (\bar{I}_2 O^*)^{-1} \bar{I}_2 \bar{q}_y \end{aligned} \quad (3)$$

From eqs.(4) and (5), the following relation is obtained.

$$\begin{aligned} &- (l_2 z + l_1) q_u(k) + (z^2 + m_2 z + m_1) q_y(k) \\ &= (l_2 z + l_1) u(k) + (z^2 + m_2 z + m_1) y(k) \end{aligned} \quad (4)$$

$$\begin{bmatrix} l_1 & l_2 \end{bmatrix} = -(I_3 - O^*(\bar{I}_2 O^*)^{-1} \bar{I}_2) U$$
$$\begin{bmatrix} m_1 & m_2 & m_3 \end{bmatrix} = (I_3 - O^*(\bar{I}_2 O^*)^{-1} \bar{I}_2)$$

The system of Fig.2 is constituted in consideration of a delay time for calculation etc., a estimation of current and a zeros addition. The state equation of Fig.2 can be expressed as

$$\begin{cases} x_{dw}(k+1) = A_{dw} x_{dw}(k) + B_{dw} v(k) \\ y(k) = C_{dw} x_{dw}(k) \end{cases} \quad (5)$$

$$x_{dw}(k) = \begin{bmatrix} x_d(k) \\ \xi_1(k) \\ \xi_2(k) \\ \xi_3(k) \end{bmatrix} \quad A_{dw} = \begin{bmatrix} A_d & B_d & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{bmatrix}$$

$$B_{dw} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix} \quad C_{dw} = \begin{bmatrix} C & 0 & 0 & 0 \end{bmatrix} \quad \xi_1(k) = u(k)$$

In Fig.3, the parts surrounded by dotted lines are the feedforward coefficients from q_u and q_y and the part surrounded by a chain line is the estimated part of current. From eq.(5), the feedforward of eq.(7) are changed as follws:

$$v(k) = k_q(l_2 z + l_1)u(k) + k_q(z^2 + m_2 z + m_1)y(k) + (z^2 + g_2 z + g_1)r(k) + [f_1\ f_2\ f_3\ f_4\ f_5\ f_6]x_{dw}(k) \quad (6)$$

That is, the parts surrounded by the dotted lines are replaced by the parts surrounded by solid lines from u and y. In Fig.3, the transfer functions between r and y, q_u and y, and q_y and y are as follows:

$$W_{ry}(z) = N_{ry}(z)/D(z) \quad (7)$$
$$W_{q_u y}(z) = N_{q_u y}(z)/D(z) \quad (8)$$
$$W_{q_y y}(z) = N_{q_y y}(z)/D(z) \quad (9)$$

$$\begin{aligned}
N_{ry}(z) &= GH(z^2 + g_1 z + g_0)(b_{11} z + b_{21}a_{12} - a_{22}b_{11}) \\
N_{q_u y}(z) &= N_{qz}N_p \qquad N_{q_y y}(z) = N_{qz}D_p \\
N_p(z) &= b_{11} z + b_{21}a_{12} - a_{22}b_{11} \\
D_p(z) &= z^2 - (a_{11} + a_{22})z + a_{11}a_{22} - a_{21}a_{12} \\
N_{qz} &= (a_{12}z^3 - a_{12}f_5 z^2 + (a_{12}b_{11}k_q - a_{12}f_4)z \\
&- f_3 a_{12} + f_2 b_{11} - a_{12}a_{22}b_{11}k_q + a_{12}^2 b_{21}k_q) \\
D(z) &= z^5 + (-f_5 - a_{22} - a_{11})z^4 + (a_{11}f_5 \\
&+ a_{11}a_{22} - a_{21}a_{12} + a_{22}f_5 - f_4)z^3 \\
&+ (a_{21}a_{12}f_5 - f_3 + a_{11}f_4 - a_{11}a_{22}f_5 \\
&+ a_{22}2f_4)z^2 + (a_{22}f_3 + a_{21}a_{12}f_4 + a_{11}f_3 \\
&- b_{11}f_1 - f_2 b_{21} - a_{11}a_{22}f_4)z + f_2 a_{11}b_{21} \\
&- a_{21}f_2 b_{11} + a_{21}a_{12}f_3 + f_1 a_{22}b_{11} \\
&- f_1 a_{12}b_{21}21 - a_{11}a_{22}f_3
\end{aligned}$$

From $D(z)$, the pole of the overall system can arrange arbitrarily by f_1, f_2, f_3, f_4 and f_5. From $N_{ry}(z)$, two zeros of r-y can arrange arbitrarily by g_0 and g_1. Moreover, from common N_{qz} in $N_{q_z}(s)$ and $N_{q_y y}(s)$, one zeros of $q_u - y$ and $q_y - y$ can be arbitrarily arranged at the same place by k_q. That is, one zeros can be arbitrarily added to W_{Qy}.

B. Design method

First, the transfer function between the reference input r and the output y is specified as follows:

$$W_{ry}(z) = N_H(z)/D_H(z) \quad (10)$$

$$\begin{aligned}
N_H(z) &= (1 + H_1)(1 + H_2)(1 + H_3)(z - n_1)(z - n_2) \\
&\times (z + H_4)(z + H_5) \\
D_H(z) &= (1 - n_1)(1 - n_2)(z + H_1)(z + H_2)(z + H_3) \\
&\times (z + H_4)(z + H_5)
\end{aligned}$$

$[f_1\ f_2\ f_3\ f_4\ f_5]$, $[g_1\ \ g_2]$ and GH are determined so that $W_{ry}(z)$ becomes eq.(16). And the transfer function among the disturbance input q_u, q_y and the output y is specified as follows:

$$W_{q_u y}(z)) = (z - 1)\bar{N}_{qz}N_p/D_H(z) \quad (11)$$
$$W_{q_y y}(z)) = (z - 1)\bar{N}_{qz}D_p/D_H(z) \quad (12)$$

Here the zeros are placed at 1 by setting k_q as the solution of $N_{qz}(1) = 0$. Then k_q becomes as

$$k_q = \frac{-a_{12} + a_{12}f_5 + a_{12}f_4 + f_3 a_{12} - f_2 b_{11}}{a_{12}(b_{11} - a_{22}b_{11} + b_{21}a_{12}} \quad (13)$$

$\bar{N}_{qz}$ is the remaining zeros of N_{qz} which cannot be placed arbitrarily. It shall be specified that the relation of H_1 and H_2, H_3 becomes $|H_1| \gg |Re(H_2)|$, $|H_1| \gg |Re(H_3)|$. Then $W_{ry}(z)$ can be approximated to the following first-order model:

$$W_{ry}(z) \approx W_m(z) = \frac{1 + H_1}{z + H_1} \quad (14)$$

This target characteristics $W_{ry}(z) \approx W_m(z)$ is specified so that it satisfies the specs.3 and 4.

The system added the inverse system and the filter to the system is constituted and an equivalent conversion of is carried out, the approximate 2DOF digital integral-type control systems will be obtained as shown in **Fig.4**. In Fig.4, the transfer function $K(z)$ becomes

$$K(z) = \frac{k_z}{z - 1 + k_z} \quad (15)$$

The transfer functions between $r - y$, $q_u - y$ and $q_y - y$ of the system in Fig.5 are approximated as

$$y \approx \frac{1 + H_1}{z + H_1} r \quad (16)$$
$$y \approx \frac{(z-1)^2}{z - 1 + k_z} \frac{\bar{N}_{qz}N_p}{D_H(z)} q_u y \quad (17)$$
$$y \approx \frac{(z-1)^2}{z - 1 + k_z} \frac{\bar{N}_{qz}D_p}{D_H(z)} q_y y \quad (18)$$

From eqs.(16), (17) and (18), it turns out that the characteristics from r to y can be specified with H_1, and the characteristics from q_u and $q_y y$ to y can be independently specified with k_z. That is, the system in Fig.5 is an approximate 2DOF, and its sensitivity against disturbance becomes lower with the increase of k_z.

In Fig.4, the parameters of the controller are as follows:

$$\begin{aligned}
k_1 &= (f_1 - f_2 a_{11}/a_{12} + k_q(-a_{11}^2 - a_{21}a_{12} + (a_{12}a_{11} \\
&+ a_{12}a_{22})a_{11}/a_{12}) + f_5(-k_q(a_{12}a_{11} \\
&+ a_{12}a_{22})/a_{12} + f_2/a_{12}) + f_5^2 k_q + (f_4 - k_q b_{11})k_) \\
&- GHk_z(g0 + (g1 + f_5)f_5 + f_4 - k_q b_{11})/(1 + H2)
\end{aligned}$$

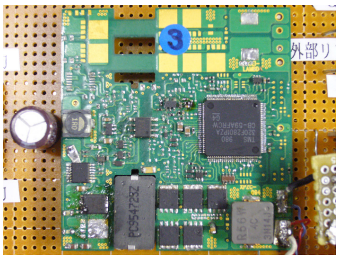

Fig. 5. The manufactured new quarter brick DC-DC converter

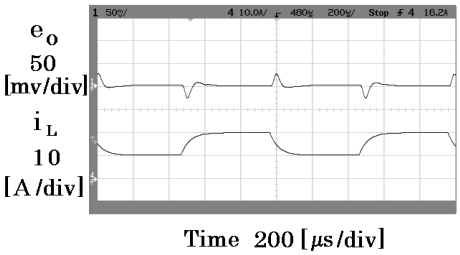

Fig. 6. Experimental result of dynamic load response at resistive load ($R_L = 0.33 \leftrightarrow 0.165[\Omega]$, $C_L = 200[\mu\mathrm{F}]$)

$$
\begin{aligned}
k_2 &= k_q - GHk_z/(1+H2) \quad k_5 = f_4 - k_q b_{11} \quad k_6 = f_5 \\
k_3 &= -k_q(a_{11}a_{12} + a_{12}a_{22})/a_{12} + f_2/a_{12} + f_5 k_q \\
&- (g1 + f_5)GHk_z/(1+H2) \quad k_2 r = (g1 + f_5)GH \\
k_4 &= f_3 - f_2 b_{11}/a_{12} + k_q((a_{12}a_{11} \\
&+ a_{12}a_{22})b_{11}/a_{12} - a_{11}b_{11} - b_{21}a_{12}) \\
k_i 1 &= (g0 + (g1 + f_5)f_5 + f_4 - k_q b_{11})GHk_z \\
k_i 2 &= (g1 + f_5)GHk_z \quad k_i 3 = GHk_z \quad k_1 r = GH \\
k_3 r &= (g0 + (g1 + f_5)f_5 + f_4 - k_{b11})GH \qquad (19)
\end{aligned}
$$

IV. Experimental studies

The sampling period T are set at 2.5[μs] and the input dead time L_d is about $0.999T$[μs]. The nominal value of R_L is 0.33[Ω]. We design a control system so that all the specifications are satisfied. First of all, in order to satisfy the specification on the rising time of startup transient reponse, H_1 and H_4 are specified as

$$
\begin{aligned}
H_1 &= -0.94 \quad H_2 = -0.18 + 0.2i \quad H_3 = -0.18 - 0.2i \\
H_4 &= -0.2 + 0.3i \quad H_5 = -0.2 - 0.3i
\end{aligned}
$$

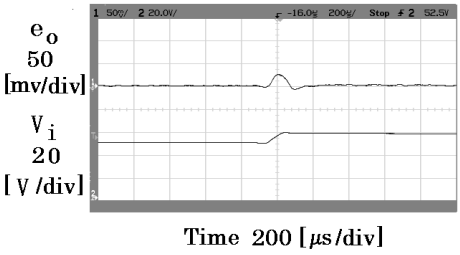

Fig. 7. Experimental result of output reponse at resistive load when input voltage changing suddenly from 48[V] to 58[V]

$$
k_z = 0.17 \quad k_q = -1 \qquad (20)
$$

Then the parameters of controller become as follows:

$$
\begin{aligned}
k_1 &= 1196.4 \quad k_2 = 787.37 \quad k_3 = -1446.4 \\
k_4 &= 0.74539 \; k_5 = 0.45538 \; k_6 = -0.20077 \\
k_{i1} &= -1.9948 \; k_{i2} = 1.6975 \quad k_{i3} = -2.8255 \qquad (21)
\end{aligned}
$$

The manufactured new DC-DC converter built-in DSP is shown in **Fig.5**. This fits in a quarter brick size (37mm x 58mm x 8mm) one. Experimental results when the digital controller with the parameters of eq.(21) is equipping in the DSP shown in **Figs.6** and **Figs.7**. Fig.6 shows the dynamic load response at the resistive load ($R_L = 0.33 \leftrightarrow 0.165[\Omega]$). It turns out that the specification us satisfied. It is checked that almost the same exprimental results as Fig.7 are obtained at the parallel load of resistance ($R_L = 0.33 \leftrightarrow 0.165[\Omega]$) and capacity ($C_L = 200[\mu\mathrm{F}]$). Although the load current changed suddenly from 20 [A] to 10 [A] or reverse, the output voltage change is very small and is suppressed within about 25[mV]. Fig.7 shows the output response at resistive load $R_L = 0.33[\Omega]$ when input voltage changed suddenly from 48[V] to 58[V]. It turns out that the specification us satisfied. It is checked that almost the same exprimental results as Fig.7 are obtained when input voltage changed suddenly from 38[V] to 48[V]. We checked by expriments that all other specifications are satisfied.

V. Conclusion

In this paper, the concept of controller of a DC-DC converter to attain good robustness against extensive load changes and input voltage change was given. The proposed digital controller was implemented on the DSP(TI TMS320LF2801). The new DC-DC converter built-in this DSP was manufactured. It was shown from experiments that a sufficiently robust digital controller is realizable. The characteristics of the dynamic load response and the output response against sudden input voltage change were improved by using the proposed method for approximate 2DOF digital controller with additional zeros. This fact demonstrates the usefulness and practicality of our method. The future work is to design a digital controller robust enough, when (LC+LC) circuits etc. are used as filters for removal of switching and carrier noises.

Abstract— **In this paper a multi-stage switching type digital controller is proposed for spreading capacitance load range more and improving transient characteristics for inductance load. In the previous proposed controller, the configuration of the controller is the same to all loads. At inductive load, there is a possibility that the transient characteristics may become bad and the specification may not be satisfied. Therefore, a load current is estimated at inductive load, and the controller which also uses load current for feedback is configured. A inductance is estimated and a controller is switched to this controller bumplessly. In order to extend the range of capacitance load, a controller is increased from two stage to three stage, and these are switched to each other bumplessly. A DSP is implemented to this digital controller. It is demonstrated from experiments that the multi-stage switching type digital controller is realizable and the given specifications are satisfied.**

I. Introduction

A Pulse Width Modulation (PWM) switching circuit is used for an electric-power conversion circuit, and a PWM power amplifier which constitutes feedback control systems so that the output voltage supplied to load might be proportional to a reference input is used as an amplifier itself or as a power supply. In many applications loads cannot be specified, i.e., its characteristics are changeable from capacitive to inductive. In addition, its amplitude is also sharply changed from the zero to the maximum rating. Then, a so-called robust PWM power amplifier which can cover such an extensive load change and also direct-current power supply voltage change is needed. We proposed previously the digital controller which uses the bumpless mode switching in order to extend the range of load wider[2]. In this paper a multi-stage switching type digital controller is proposed for spreading capacitance load range more and improving transient characteristics for inductance load. In the previous proposed controller[2], the configuration of the controller is the same to all loads. At inductive load, there is a possibility that the transient characteristics may become bad and the specification may not be satisfied. Therefore, a load current is estimated at inductive load, and the controller which also uses load current for feedback is configured. A inductance is estimated and a controller is switched to this controller bumplessly. In order to extend the range of capacitance load, a controller is increased from two stage to three stage, and these are switched to each other bumplessly. The digital controller with the muliti-stage bumpless mode switching function is actually realized by using DSP. It is demonstrated from experiments that the multi-stage switching type digital controller is realizable and the given larger specifications are satisfied smoothly.

II. PWM power amplifier

The power amplifier as shown in **Fig.1** is being manufactured. The triangular wave double carrier system is adopted as a PWM switching signal generating part. The carrier frequency of triangular waves are $10 - 100$[kHz], and the amplitude c_m is 10[V]. A power amplification part is a full-bridge type chopper circuit, and the voltage of direct-current power-supply E is 150[V]. The LC circuit is a filter for removing carrier and switching noises. The values L_0 and C_0 of LC circuit are determined so that control systems can make their sensitivity to load change low and reduce noise.

If the frequency of input u is smaller enough than that of the carrier, the state equation of the PWM power amplifier at no load and inductive load in **Fig.1** can be expressed from the state equalizing method[1] as follows:

$$\begin{cases} \dot{x} = A_c x + B_c u \\ y = Cx \end{cases} \tag{1}$$

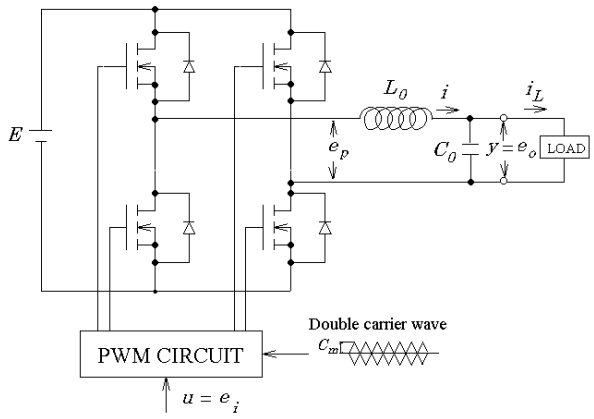

Fig. 1. PWM power amplifier

where at no load

$$x = \begin{bmatrix} e_o \\ i \end{bmatrix} \quad A_c = \begin{bmatrix} 0 & \frac{1}{C_0} \\ -\frac{1}{L_0} & -\frac{R_0}{L_0} \end{bmatrix} \quad B_c = \begin{bmatrix} 0 \\ \frac{K_p}{L_0} \end{bmatrix}$$

$$C = \begin{bmatrix} 1 & 0 \end{bmatrix} \quad u = e_i \quad y = e_0 \quad K_p = -\frac{E}{c_m}$$

and at inductive load

$$x = \begin{bmatrix} e_o \\ i \\ i_L \end{bmatrix} A_c = \begin{bmatrix} 0 & \frac{1}{C_0} & -\frac{1}{C_0} \\ -\frac{1}{L_0} & -\frac{R_0}{L_0} & 0 \\ \frac{1}{L_L} & 0 & \frac{R_{LL}}{L_L} \end{bmatrix} B_c = \begin{bmatrix} 0 \\ \frac{K_p}{L_0} \\ 0 \end{bmatrix}$$

$$C = \begin{bmatrix} 1 & 0 & 0 \end{bmatrix}$$

and R_0 is the total resistance of coil, ON resistance of FET, etc. and R_{LL} is a resistance of inductive load.

When realizing a digital controller by a DSP, a delay time exists between the start point of sampling operation and the output point of control input due to the input computing time and AD/DA conversion times. This delay time is considered to be equivalent to the input dead time which exists in the controlled object.
Then the discrete-state equation of the system with dead time is expressed as follows:

$$\begin{cases} x_d(k+1) = A_d x_d(k) + B_d v(k) \\ y(k) = C_d x_d(k) \end{cases} \tag{2}$$

where

$$x_d = \begin{bmatrix} x \\ \xi \end{bmatrix} \qquad \xi(k) = u(k) \quad C_d = \begin{bmatrix} C & 0 \end{bmatrix}$$

$$A_d = \begin{bmatrix} e^{A_c T} & e^{A_c(T-L_d)} \int_0^{L_d} e^{A_c \tau} B_c d\tau \\ 0 & 0 \end{bmatrix}$$

$$B_d = \begin{bmatrix} \int_0^{T-L_d} e^{A_c \tau} B_c d\tau \\ 1 \end{bmatrix}$$

Now, the power amplifier with the following specifications 1-3 is designed and manufactured by constituting

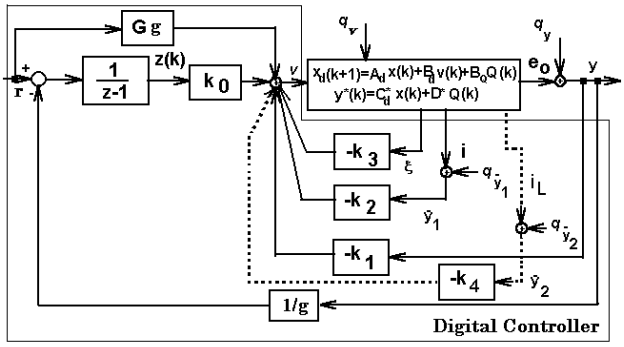

Fig. 2. Approximate 2-degree-of-freedom digital integral type control system

digital control systems to the PWM power amplifier (controlled object) at no load. The range of capacitive load in spec.1 has expanded more than those of our previous results[2].

1. The band-width of control systems is higher than 2[kHz] to each load , i.e., no load, resistance load, capacitive load, parallel load with resistance and capacitive load and inductive load, where $8.8 \leq R_L < \infty[\Omega]$, $0 \leq C_L \leq 100[\mu\text{F}]$, $5 \leq L_L < \infty[\text{mH}]$.
2. Against all the loads of spec.1, an over-shoot is not allowable in a step response.
3. The specs. 1 and 2 are satisfied also to change of the direct-current power supply of $\pm 10\%$.

The approximate 2-degree-of-freedom digital integral-type control systems will be obtained as shown in **Fig.2**. This control system satifies all specifications. In Fig.2, The dashed line including k_4 is a new feedback introduced for current i_L at inductive load.

III. Controller switching method

A. Load estimating method

From eq.(1), the capacitance is computed by the current in the coil and the derivative of output voltage such as

$$C_0 + C_L = \frac{i(t)}{\dot{e}_o(t)} \tag{3}$$

The capacitance can be estimated from eq.(11). In the case of the parallel load of capacitance and resistance, although the amount of feedbacks from $e_o(t)$ is added to $\dot{e}_o(t)$, if it is $\dot{e}_o(t) \gg e_o(t)$, the amount of addition can be ignored and the capacitance estimation can be carried out by eq.(11) even in this case. Eq.(3) can be expressed with discrete approximation as follows:

$$C_0 + C_L = \frac{T(i(k) + i(k-1))}{2(e_o(k) - e_o(k-1))} \tag{4}$$

Here, the current $i(k)$ uses the average value of $t = kT$ and $t = (k-1)T$. Noises, such as a carrier noise and a switching noise, are included in the output voltage of

PWM power amplifier. When the change of output voltage is small, the S/N deteriorates, and it becomes impossible to estimate the capacitance. Therefore, only when the change of output voltage is large, the capacitance can be estimated. When the change is small, the function of holding the previously estimated value is needed.

Next, from eq.(1), the inductance is computed by the output voltage and the derivative of the load current such as

$$L_L = \frac{e_o(t)}{\dot{i}_L(t)} \tag{5}$$

Eq.(5) can be expressed with discrete approximation as follows:

$$L_L = \frac{T(e_o(k) + e_o(k-1))}{2(i_L(k) - i_L(k-1))} \tag{6}$$

Here, the output voltage $e_o(k)$ uses the average value of $t = kT$ and $t = (k-1)T$. Now, the load current i_L is required to compute L_L. Moreover, this load current is required also for load current feedback. A method of estimating load current is used without using a sensor. From eq.(1), the load current is computed by the coil current and the derivative of output voltage such as

$$i_L(t) = i - C_0 \dot{e}_o(t) \tag{7}$$

Eq.(7) can be expressed with discrete approximation as follows:

$$\begin{aligned} i_L(k) &= (i(k) + i(k-1) \\ &- \frac{2C_0}{T}(e_o(k) - e_o(k-1)))/2 \end{aligned} \tag{8}$$

Here, the load current $i_L(k)$ uses the average value of $t = kT$ and $t = (k-1)T$.

Moreover, in order to use the derivatives of e_o and i_L, they have the gain characteristic of 20dB/dec, and have become sensitive to noise. In order to reduce thes influences, the following butterworth low-pass filters are inserted into the estimated values:

$$H(z) = \frac{a_0 z^2 + a_1 z + a_2}{z^2 + b_1 z + b_2} \tag{9}$$

The parameters a_0, a_1, a_2, b_1, b_2 are the suitable values determined that the cutoff frequency of the filters become as about 5[KHz]. Eqs.(4), eq.(6), eq.(8) and eq.(9) are all implemented by DSP.

B. Controller switching method

After estimating of the load current, inductance and capacitance, first it is judged whether there is inductance, next the size of capacitance is judged, and the mode is switched. The switching method using estimated inductance and capacitance is shown in **Fig.3**. About inductance load, it judges whether there is any inductance beyond a certain value, and if it is, it will only switch to mode 4. About capacitance load, when the estimated capacitance value is beyond a certain value , or when it is below, the mode is switched. If the estimated value is changed due to noise etc. when the load capacitance is close to threshold of change, the problem the the mode switches frequently will arise. Therefore, the hysteresis characteristic with mode switchingis established in Fig.3. The widths $TH_1 - TH2$ and $TH_3 - TH_4$ used for hysteresis are sets up so that a change does not arise beyond necessity by experiment. As for the controller, the mode 1 is chosen at the start of DSP execution program. Even when an estimated value exceeds TH_1, it does not switch to the mode 2. Only when it exceeds TH_2, it switches to the mode 2. In the time of being conversely less than TH_1 a switch from the mode 2 to the mode 1 is performed.

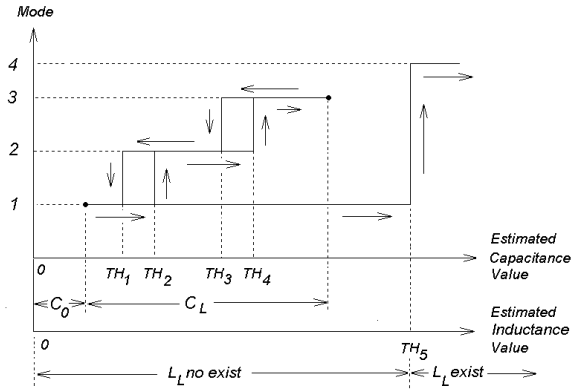

Fig. 3. Mode 1,2,3,4 switching method

C. Bumpless mode switching method

If the control variable is changed rapidly when the controller switches the mode, a bump will arise in an output. In order to suppress the bump, as shown in **Fig.4**, auxiliary feedback functions are implemented by a combination of mode i controller and mode j controller. Here $i = 1, 2, 3, 4$ and $j = 1, 2, 3, 4$ where $i \neq j$. In Fig.4, $X^\star$ is as in $X^\star = [y\ \bar{y_1}\ \xi]$, $k_{fi} = [k_{1i}\ k_{2i}\ k_{3i}]$ (at induccitive load $X^\star = [y\ \bar{y_1}\ \bar{y_2}\ \xi]$, $k_{fi} = [k_{1i}\ k_{2i}\ k_{3i}\ k_{4i}]$) and k_{0i} are the parameters of the mode i controller, $k_{fj} = [k_{1j}\ k_{2j}\ k_{3j}]$ (at induccitive load $k_{fj} = [k_{1j}\ k_{2j}\ k_{3j}\ k_{4j}]$) and k_{0j} is the parameters of the mode j controller. The parameter $k_{si} = 1/k_{0i}$ is the one for the bumpless switching function of the mode i controller and the parameter $k_{sj} = 1/k_{0j}$ is the one for the bumpless switching function of the mode j controller. According to these auxiliary function, at mode j, the control variable V_i of the mode i controller follows the control variable V_j of the controller j, and at mode i V_j follows V_i. Since V_j is mostly in agreement with V_j when

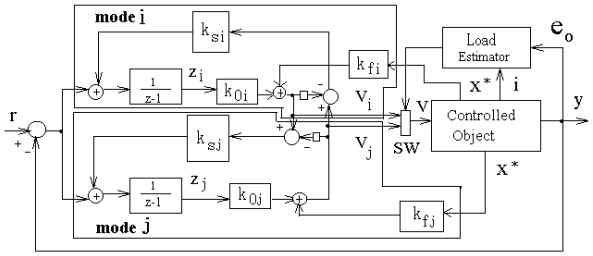

Fig. 4. Bumpless mode switching control system

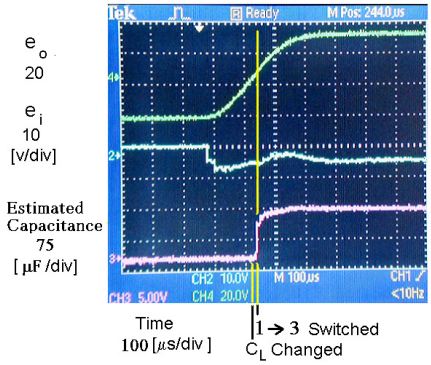

Fig. 5. Experimental result of step response using automatic bumpless switching from mode 1 to mode 2 and to mode 3 according to change of capacitance load from $C_0 + C_L = 0[\mu\text{F}]$ to $C_0 + C_L = 125[\mu\text{F}]$ ($C_0 = 25[\mu\text{F}]$)

the controllers are switched, they will be switched bumplessly. In addition, in Fig.4 the feedforward parameter Gg's are omitted.

IV. Experimental studies

A DSP(TMS320C6416) from Texas Imstruments(TI) is used, which realizes the digital controller in Fig.8. The sampling period T and the carrier frequency f_c are set as 12[μs] and 83.3[kHz], respectively. The input dead time L_d is about 11.9[μs]. At capacitive load the setting value of C_0 is changed. And three controllers which satisfy specifications in the following three kinds of range are designed.

mode 1: $C_0 = 25[\mu\text{F}]$ and $0 \leq C_L \leq 25[\mu\text{F}]$
mode 2: $C_0 = 40[\mu\text{F}]$ and $0 \leq C_L \leq 40[\mu\text{F}]$
mode 3: $C_0 = 60[\mu\text{F}]$ and $0 \leq C_L \leq 65[\mu\text{F}]$

The values of C_0 of mode 2 and 3 are temporary for the design, and the actually used C_0 is 25[μF] in the mode 1. According to actual load capacity, these three controllers are switched as shown in Fig.3. As a result, the capacitance range is as follows and satisfies specification.

$$0 \leq C_L \leq 100[\mu\text{F}] \tag{10}$$

At inductive load the controller (mode 4) using load current feedback is designed.

Experimental results when realizing the digital controller with switchable parameters of Table 2 by using the DSP, and connecting with the controlled object in Fig.1

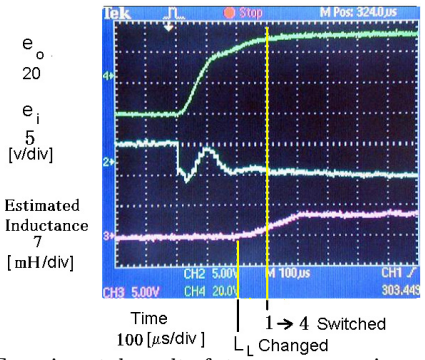

Fig. 6. Experimental result of step response using automatic bumpless switching from mode 1 to mode 4 according to change of inductance load from $L_L = 0[\text{mH}]$ to $L_L = 5[\text{mH}]$ ($C_0 = 25[\mu\text{F}]$)

are shown in **Fig.5** and **Fig.6**. Fig.5 shows the step responses of e_o and e_i and estimated capacitance using the automatic bumpless mode switching from mode 1 to mode 2 and mode 3 at $C_L = 100[\mu\text{F}]$. From Fig.5, it turns out that the parameters of the controller have switched from mode 1 to mode 2 and to mode 3 bumplessly during the transient response and all the specifications are satisfied. This experimental result shows that the bumpless mode switching can spread the range of the value of capacitive load. Fig.6 shows the step responses of e_o and e_i and the estimated inductance using the automatic bumpless mode switching from mode 1 to mode 4 at $L_L = 5[\text{mH}]$. From Fig.6, it turns out that the parameters of the controller have switched from mode 1 to mode 4 bumplessly and the specifications at incuctive load is satisfied.

V. Conclusion

In this paper, the concept of controller with multi-stage bumpless mode switching to attain the robustness to various loads and extensive load changes was given. The digital controller with multi-stage bumpless mode switching was realized by using a DSP implemented to the controlled object(PWM power amplifier which consists of a PWM signal generating part, an electric power conversion part and an LC filter). It is shown from an experiment that a sufficiently robust digital controller is realizable. The range of capacitive load colud be extended and the transient characteristics was improved by performing the multi-stage bumpless mode switching This fact demonstrated the usefulness of our method using the multi-stage bumpless mode switching.

***Abstract*-This paper presents the Quasi-Constant Frequency Hysteretic Current-Programmed Converters (CHCPC) with control of bifurcation. The simple proposed closed-loop control system is realized to regulate the output voltage which away from the first bifurcation. Moreover, by applying simple circuit, this system is maintained to operate at a constant frequency. In spite of nonlinear characteristics and instabilities of the converter, the performance of the closed-loop control system can be considerably improved. The proposed CHPCP can avoid bifurcation phenomena with constant switching frequency. Simulation results show that the technique introduced in this paper gives satisfactory results with the regulating modes in various operating conditions.**

I. INTRODUCTION

As an especially key part of a switching power supply a DC/DC converter is widely used because of the capabilities of chopping and filtering the input voltage through an appropriate switching action, mostly implemented by a Pulse Width Modulation (PWM) circuits, a conventional constant frequency with direct duty ratio control. A current-programmed converter becomes the regulating scheme of choice in DC/DC converter and offers significant improvement over a direct duty ratio control such as automatic overload protection and design flexibility in improving small-signal dynamics [1]. Due to nonlinear characteristics of switching devices employed in the converter, the design of a control scheme for such converter may be difficult because of a rich variety of bifurcation [2].

Recently, the main study of bifurcation and chaos has been observed and analyzed for various kinds of power electronic circuits. In order to guarantee for system stability in most practical situations, the key design problem is the control of bifurcation or chaos control [3] which required stable operation is a period-1. Several researches have focused on the control of bifurcation, especially a Constant clock Frequency Current-mode Boost Converter (CCFCMBC). The work presented in [4], for instance, that uses analog circuit for adjusting variable ramp compensation in a Current-mode Boost Converter (CMBC). Regardless, the technique is restricted to a fixed system component. In order to overcome the previous problem, the sophisticated artificial intelligence controller to optimize a ramp compensation signal has been presented in [5]. However, its structure is generally more complicated and requires relatively high performance processor. Although the gain feedback to control of bifurcation was proposed in [6], Nonetheless, this system was not guarantee the over compensation, lead system to the discontinuous-conduction mode (DCM).

In order to control of bifurcation without the ramp compensation signal, the complicated circuits for implementation of a sliding mode controller (SMC) or a Variable frequency Hysteretic Current-Programmed Converters (VHCPC) for a CMBC has been proposed in [7]. This system, however, is still lacking the unpredictable constant frequency for any given load and the design for automatic closed-loop operation has not been mentioned. Although the quasi-constant frequency with Hysteretic Current-Programmed Converters for CMBC is introduced [8], this system requires current controller not easy to implement in a cost-effectiveness system.

In this paper, in stead of a VHCPC, the proposed Quasi-Constant frequency Hysteretic Current-Programmed Converters (CHCPC) with control of bifurcation of is presented for a CMBC. A simple but very effective control of CMBC is introduced. The performances of the control system are verified using the simulations with various operating conditions. The paper is organized as follows. In Section II, the circuit configuration of a CCFCMBC is described, followed by the proposed control bifurcation using CHCPC in Section III. Simulation results from the control system are given in Section IV. Finally, conclusions are drawn in Section V.

II. THE CMBC CONFIGURATION

A. Circuit Configuration

The CCFCMBC circuit configuration is depicted in Fig. 1. The system consists of a constant DC voltage source, a CMBC and a load. The Proportional plus Integral (PI) current controller is used to regulate the output voltage (v_{out}), accordingly to the desired output voltage (v_{ref}), in spite of the fluctuations in the input voltage (v_{in}) and the changes in load levels (R_{Load}).

In this system, the inductor current, i_L, is chosen as the programming variable which, by comparing with reference current, I_{ref}, from current controller, generates the turning-output signal for switch S. The switch S is turned on by clock pulse signal at time equal to nT and turned off when i_L climbs up to the denoted value I_{ref} and remains in off position until the next cycle as shown in Fig. 2. Typically, the system state equation can be represented by [3]

$$\begin{bmatrix} \dot{v}_{out} \\ \dot{i}_L \end{bmatrix} = \begin{bmatrix} -1/R_{Load}C & q/C \\ -q/L & 0 \end{bmatrix} \begin{bmatrix} v_{out} \\ i_L \end{bmatrix} + \begin{bmatrix} 0 \\ 1/L \end{bmatrix} v_{in}, \quad (1)$$

where q is a switching function which is one during the switch off interval while zero during on interval. To regulate the v_{out}, the PI controller is realized.

B. Nonlinear dynamics of CCFCMBC

In a CCFCMBC, let us define $i_L(n)$ and $i_L(n+1)$ as the inductor current at a $t=nT$ and $t=(n+1)T$, respectively. In steady state condition, the inductor current can be derived from [3] as:

$$i_L(n+1) = I_{ref} + \frac{(v_{in} - v_{out})T}{L} t_n' \quad (2)$$

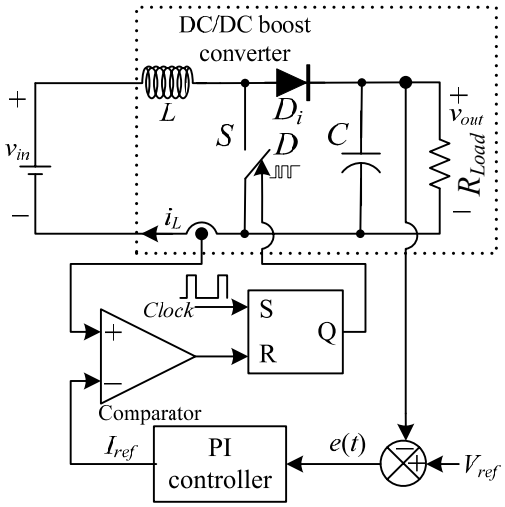

Figure 1. The closed-loop control of CCFCMBC.

and

$$t_n' = T - T\left[\frac{t_n}{T} \bmod 1\right], \tag{3}$$

where T is a clock pulse period and mod(.) is the modulus function. The slope of inductor current can be expressed by inspecting as:

$$\frac{I_{ref} - i_L(n+1)}{(1-D)T} = \frac{v_{out} - v_{in}}{L} \tag{4}$$

and

$$\frac{I_{ref} - i_L(n)}{DT} = \frac{v_{in}}{L} \tag{5}$$

The inductor current shown as solid line in Fig 2 under period-1 operation, which frequency of i_L equal f, can be expressed as:

$$\begin{aligned} i_L(n+1) = &\left(1 - \frac{v_{out}}{v_{in}}\right) i_L(n) \\ &+ \frac{I_{ref} v_{out}}{v_{in}}\left(\frac{v_{out} - v_{in}}{L}\right) T \end{aligned} \tag{6}$$

In order to maintain a stable period-1 operation [3], a CCFCMBC must operate with duty ratio D set below 0.5, so that the criterion of no bifurcation can be achieved. For the CCFCMBC, the equivalent criterion of no bifurcation in terms of I_{ref} using the steady-state equation relating R_{Load} and D is given by:

$$I_{ref} < \frac{v_{in}}{R_{Load}}\left[\frac{DR_{Load}T}{2L} + \frac{1}{(1-D)^2}\right]\Bigg|_{D=0.5} \tag{7}$$

When I_{ref} increases in CCFCMBC, i_L may operate in period-2 until submit the border collision as dot line, and then becomes chaotic as shown in Fig. 2.

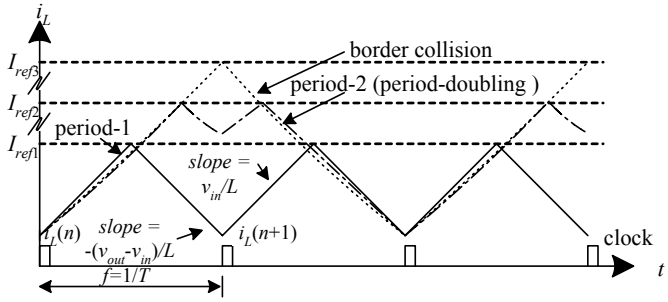

Figure 2. Typical waveform of inductor current i_L in CCFCMBC.

III. THE PROPOSED CHCPC

A. Voltage control loop

In this closed-loop control system I_{ref} is controlled via feedback loop which attempts to keep v_{out} fixed by adjusting I_{ref}. Let us defined the error function $e(t)$ is defined as:

$$e(t) = V_{ref} - v_{out}(t) \tag{8}$$

The output I_{ref} of PI controller can be calculated as:

$$I_{ref}(t) = K_p e(t) + K_i \int e(t)\,dt \tag{9}$$

, where K_p and K_i are PI controller parameters which chosen under system stability but play a role in determining the stability for dynamics response in a small-signal system model [9].

B. Adaptive of a quasi-constant frequency

Due to the disadvantages of a CCFCMBC as described in previous section, the proposed Quasi-Constant frequency Hysteretic Current-Programmed Converters (CHCPC) scheme is shown in Fig. 3, which applying from a variable frequency hysteretic current-programmed control (VHCPC) [7]. For VHCPC, the control signal to the switching converter tries directly to control the inductor current and to control the duty ratio indirectly. The switch S turns on and off by the gap of difference between reference current I_{ref} and inductor current i_L as:

$$\Delta i_L = I_{ref} - i_L(t) \tag{10}$$

The gap of hysteretic current-control ΔI_L is fixed. The switch S is turned off when i_L rises to its peak value determined

$$i_{L\max}(t) = I_{ref} \tag{11}$$

The switch S is turned on when i_L falls to its minimum given as

$$i_{L\min}(t) = I_{ref} - \Delta I_L, \tag{12}$$

where ΔI_L also denotes the ripple inductor current. Typical waveform of VHCPC control is shown in Fig. 4 as dot line. Thus, the switching frequency f for the switch S is given as:

$$f = \frac{v_{in}(t)\left(v_{out}(t) - v_{in}(t)\right)}{L\Delta I_L v_{out}(t)} \tag{13}$$

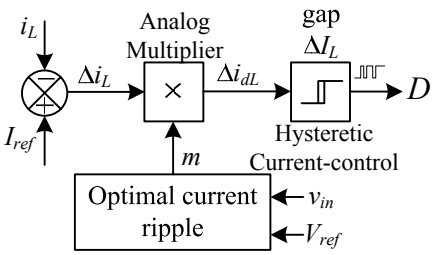

Figure 3. Control inductor current by the proposed CHCPC.

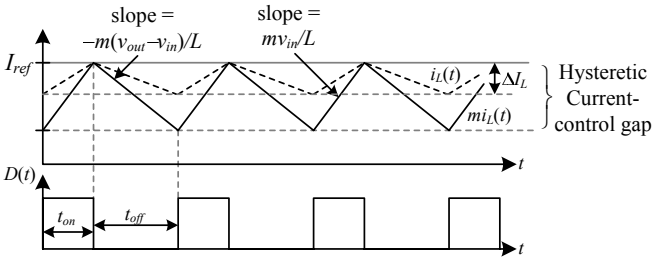

Figure 4. Typical wave forms of VHCPC and CHCPC.

From Fig. 4, it can be found that the switching frequency is varied in VHCPC depended on ΔI_L . Instead of control the switching frequency by adjusting the hysteretic current-control gap, the proposed CHCPC technique can limit the hysteretic current-control gap at the normalized value between 1 and 0 respectively. The control of switching frequency of CHCPC can be varied as shown in Fig.4 in solid-line. The constant switching frequency at steady state response can be obtained by adjusting the ripple current as: as

$$\Delta i_{dL}(t) = m\Delta i_L(t), \tag{14}$$

where m denotes the adjustable inductor current given by

$$m = \frac{V_{ref} L f_d}{v_{in}\left(V_{ref} - v_{in}\right)}, \tag{15}$$

where f_d is the desired switching frequency in this system.

IV. Simulation Results

To evaluate performances of the proposed system, computer simulations were conducted using MATLAB/SIMULINK® [10] as shown in Fig. 5. The CMBC model described in the previous section with the parameters given in Table I was invoked.

The bifurcation diagram [3] for the CCFCMBC is used to study system nonlinear behaviours with the bifurcation parameter I_{ref} (horizontal axis) and I_L (vertical axis). Corresponding to the variation of I_{ref} from 0 to 1A, the sampled i_L is observed and recorded. While R_{Load} is equal to 80Ω, the bifurcation diagram of this system is shown in Fig. 6 (a). In this figure, it can be seen that the period-1 is stable until I_{ref} is equal to 0.18A and 0.36A while v_{in} is fixed at constant values of 3V and 6V, respectively. When changing R_{Load} to 40Ω, this stable point is shifted to i_{ref} of 0.30A and 0.60A as shown in Fig. 6 (b).

The variations of supply voltages and load resistances have been fictitiously set as follows. The supply voltage are denoted constant at 6V and declined to 3V at 0.15s, and the values of load resistance are 80Ω and 40Ω from 0 to 0.4s and 0.4s onwards, respectively. The output voltage converges from the starting point to 10V as desired for all cases. The output voltage v_{out} and inductor current i_L for the CCFCMBC are depicted in Fig. 7.

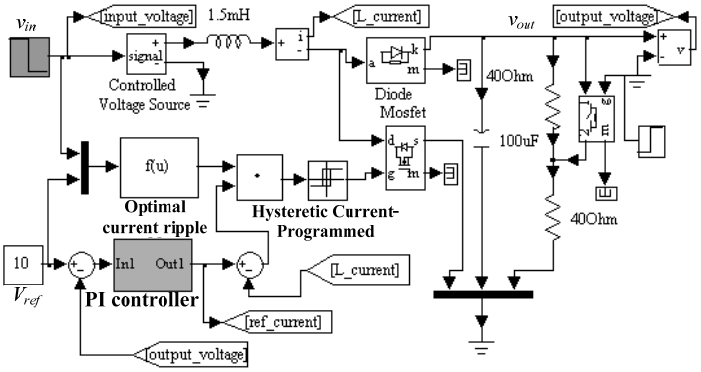

Figure 5. MATLAB/SIMULINK® model of the proposed CHCPC.

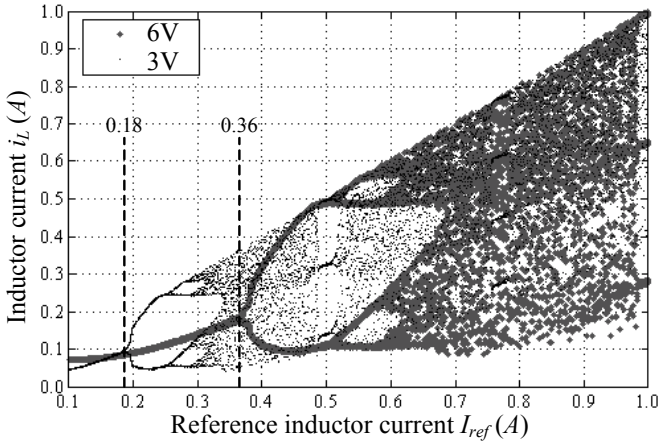
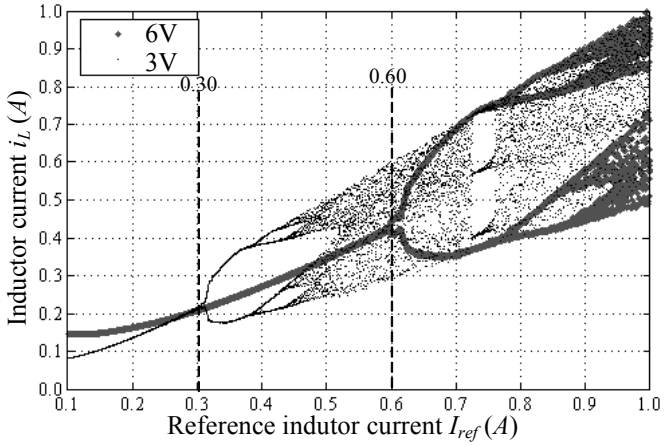
TABLE I.
THE CMBC PARAMETERS

Variable	***Definitions***
Inductor (L)	1.5mH
Capacitor (C)	100μF
The desired switching Freq (1/T).	10kHz
Output voltage (v_{out})	10V
Input voltage (v_{in})	3-6V



(a) 80Ω R_{Load}.



(b) 40Ω R_{Load}.

Figure 6. Bifurcation diagram in (I_{ref},i_L) plane with comparison of input voltage and load change.

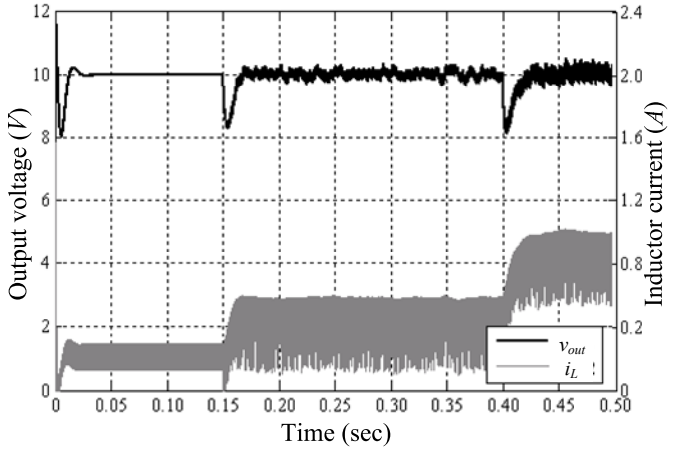


Figure 7. System responses of the CCFCMBC without bifurcation control.

After applying the VHCPC [7] with hysteretic current-control gap constant at 0.16A, the output voltage and inductor current are depicted in Fig 8. This result is confirmed that the VHCPC can compensate effects of the bifurcation phenomena. Generally speaking, the output voltage is not different between VHCPC and CHCPC. Fig 9 shows the result when applying the CMBC to the proposed CHCPC. It can be seen that the proposed CHCPC can maintain the output at period-1 operation for all cases.

In addition, the steady state inductor currents are compared in Fig. 10. The current ripples with R_{Load} of 40Ω, while v_{in} is kept constant at 3V, are 0.46, 0.16 and 0.14A for the CCFCMBC, VHCPC and the proposed CHCPC respectively. However, the frequency of inductor current of CHCPC is keep to control at the desired switching frequency 10kHz. In addition, it is noticeable that, the output voltage and current response between with and without CHCPC are clearly different from CCFCMBC.

V. CONCLUSIONS

In this paper, the Quasi-Constant frequency Hysteretic Current-Programmed Converters (CHPCP) with Control of Bifurcation has been presented. The proposed CHPCP is not only simple but also effective for control of nonlinear characteristics and instabilities of the power converter. The simulation results obviously show that the proposed CHPCP can avoid bifurcation phenomena and system operation at a desired constant switching frequency. Furthermore, the output voltage fluctuation in steady state condition is substantially mitigated. The proposed system is simple but more effective circuit which easy to implement in low cost power system.

***Abstract*-This paper presents the design of the adaptive Perturbation and Observation (P&O) algorithm with a Hysteretic Current-mode Converter (HCMC) of Maximum Power Point Tracking (MPPT) for a Solar-powered Battery Charger (SPBC). This unit captures solar energy by a solar array and delivers into battery through a boost converter. By slightly modifying the original algorithm, the proposed adaptive P&O algorithm is realized to improve MPPT speed. In addition, the HCMC is employed to improve the stability and dynamic response from a variation of system components. Simulation results with practical parameters show that our proposed MPPT using HCMC outperform the conventional variation of duty ratio for MPPT controller term of accuracy.**

I. INTRODUCTION

As the problem of fossil energy depletion becomes more severe, *photovoltaic* (PV) has received much interest to be used as a secondary energy source to produce the pollution-free energy. The term *photovoltaic* refers to the phenomenon involving the conversion of sunlight into electrical energy via a solar cell [1]. The solar energy is a strong candidate in many countries where a solar power density is relatively high. Under certain temperature and light intensity, there is only single maximum-power point (MPP) in a normal cell. Therefore, maximum power point tracking (MPPT) of the solar cell is essential as far as the system efficiency is concerned.

Several techniques have been proposed in the past decades. Many of them were implemented on digital processor, especially, with a solar-powered battery charging (SPBC) application. They range from conventional methods, such as the Hill-Climbing Method [2] and the Perturbation and Observation Method (P&O) [3], to much more sophisticated artificial intelligent methods, such as Artificial Neural Network (ANN) [2], Fuzzy Logic Control (FLC) [3], Adaptive Neural Fuzzy Inference System (ANFIS) [4]. Comparatively, conventional methods give poorer performances, but they are easier to implement. Artificial Intelligent methods, on the other hand, perform better, but their structures are generally more complicated and require relatively high performance processor. Most importantly, they generally lack the adaptability to deal with time varying environments. The adaptive P&O algorithm was presented and implemented [5] to improve MPPT speed.

Once MPP is determined via MPPT, hardware circuitry is required to move a current operating point of the system to MPP. To this end, DC/DC power converter, which connects PV to any load, is widely employed. The MPPT techniques based on a variation of duty ratio to control switch in a DC/DC boost converter for MPPT were employed [1-5]. The output voltage from the DC/DC converter is achieved by chopping and filtering the input voltage through an appropriate switching action. The variation of duty ratio for MPPT has several disadvantages to use with a DC/DC boost converter such as a variation of circuit parameters [6]. The nonlinear characteristics of the switching devices employed in the converter can lead to a rich variety of bifurcation [7] which compensated by variable ramp compensation. Another current-mode converter is the Hysteretic Current-mode Converter (HCMC) [8] which offers significant improvement over conventional direct duty ratio control such as automatic overload protection and especially design flexibility in improving small-signal dynamics [9].

In this paper, we propose an adaptive P&O Algorithm with a HCMC for an SPBC. Apart from the simplicity adaptive P&O algorithm, the MPPT time response is improved. Moreover, the HCMC merits include good stability suppressing the variation of system components and improving system dynamic response. The remainder of the paper is organized as follows. A typical SPBC system configuration is reviewed in Section II. The proposed MPPT system is addressed in Section III. In Section IV, the simulation results are shown in order to verify the capability of the system. Finally, conclusions are drawn in Section V.

II. SPBC SYSTEM CONFIGURATIONS

A. PV array Characteristic

The characteristic of a solar array can be comprehensively described by its operating curve known as an I-V curve, supplied by manufacturers to represent the solar array behaviors. It shows the relationship between output voltage and current of the solar array at certain light intensity and temperature as depicted in Fig. 1. It can be observed that under a certain light intensity and temperature there is a unique point located at the knee of the I-V curve, at which the maximum power can be generated from the solar array. Thus, a mechanism is required to track those underlying points so that the optimal operation of the overall system can be achieved.

The most commonly used equivalent circuit of a solar cell is shown in Fig. 2. The key equation to the relationship of each parameter, when internal series and shunt resistor are neglected [3], are given by

$$i_s = I_{LG} - I_{os}\left(\exp\left(\frac{v_s q}{AkT}\right) - 1\right), \tag{1}$$

where v_s denotes an output voltage of a solar array, i_s denotes a current of a solar array, A denotes the ideality factor, k is the Boltzman's constant (J/K), T is a cell temperature (K), q denotes an electron charge (C), I_{LG} denotes a light-generated current (A) and I_{os} denotes a cell reverse saturation current (A).

B. The MPPT for the SPBC

The configuration of the SPBC used in this research is shown in Fig. 2. The boost converter circuit used in the battery charging mechanism comprises of one inductor L with a switching device S. The power diode D_1 contributes to preventing the damage due to the reverse flowing current and not discharged from dark current leakage in a system from battery [3]. The capacitor C is large enough to filter

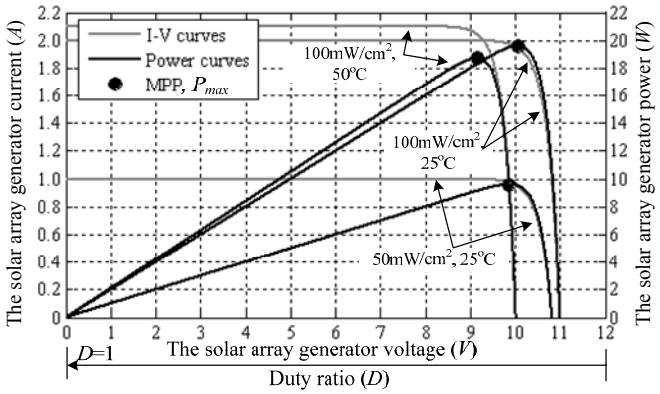

Figure 1. I-V and Power curves under light intensity and temperature.

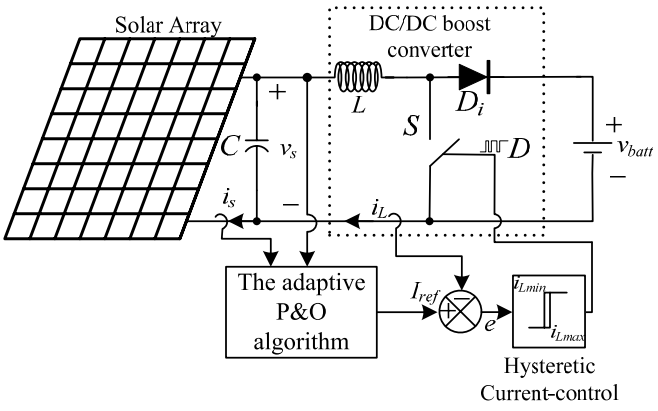

Figure 2. The proposed MPPT for SPBC system.

out the inductor current or to eliminate the pulsating power in this system.

In our design, the controller performs two main functions. First, it determines duty ratio D for the operation of switch S in such a way that the operating point of the solar array can be controlled toward the maximum power point. The controller also has to consistently detect the battery voltage to avoid battery overcharging. When the battery is fully charged, the controller will switch off the switch S. Instead of the direct duty ratio control for the operation of switch S, the HCMC is employed to improve small-signal dynamic response of MPPT system.

C. The SPBC's model

Generally, a power converter can be modeled with a circuit averaging technique [10]. The large-signal model of SPBC operating in continuous-conduction mode (CCM) is depicted in Fig. 3. The small-signal disturbance i_{dpv} and v_{dpv} denote as the output current and voltage of a solar array, v_{dbatt} and d is disturbance output voltage and PWM control signal, respectively. It notes that, I_{pv}, V_{pv}, I_L, D and V_{batt} are the DC components of an output current of a solar array, an output voltage of a solar array, inductor current, duty ratio and battery voltage. These components can be defined as zero in small-signal model. Using Kirchhoff's current and voltage low (KCL and KVL) the system state equations are obtained as:

$$i_{dpv} - C\frac{dv_{pv}}{dt} = i_{dL}\,, \tag{2}$$

$$v_{dpv} - L\frac{di_{dL}}{dt} = (1-D)v_{dbatt} - dV_{batt}\,, \tag{3}$$

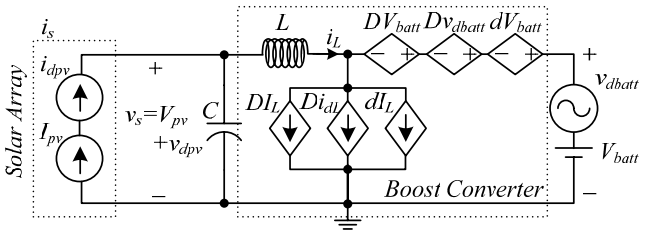

Figure 3. Large-signal model of boost converter operating in CCM.

and [6]

$$i_{dpv} = -Av_{dpv}\,, \tag{4}$$

where $A = (I_{os}q/kT)\exp(v_{dpv}q/kT)$. The duty ratio to output voltage of a solar array transfer function can be found as:

$$\frac{v_{dpv}(s)}{d(s)} = \frac{-V_{batt}/LC}{s^2 + A/C\,s + 1/LC}\,. \tag{5}$$

It can be found that in conversional direct duty ratio control, the capacitance C denotes the different damping or oscillation of v_{dpv} with a perturbation d.

III. The Proposed MPPT System

A. An adaptive P&O

As the name suggests, the P&O algorithm operates by periodically perturbing the control variable and comparing the instantaneous PV output power after perturbation with that before. In an original MPPT controller using P&O method the adjustment of the operating point is achieved by changing the reference voltage of the controller [5]. However, the adjustment can be made through the reference current I_{ref}. The algorithm is summarized in Table I.

Note that $v_s(k)$ and $P(k)$ are output voltage and the power of PV which is calculated from $v_s(k)\times i_s(k)$ at time k, respectively. Besides, $I_{ref.}$ and $\Delta I_{ref.}$ respectively denote reference current and change of reference current. To achieve faster MPPT response and more accurate MPP under dynamic environment, variable perturbation step-size, i.e. ΔI_{ref} can be employed. In fact, ΔI_{ref} can be selected as function of PV power as:

$$\Delta I_{ref}(k) = \alpha\cdot\beta\left|\frac{P(k)-P(k-1)}{v_s(k)-v_s(k-1)}\right|, \tag{6}$$

where α is the constant value to control the movement toward the MPP and the accuracy of convergence for MPPT, β is the sign of step dependent on perturbation direction.

B. Current Control

Due to the disadvantages of a constant variation of duty ratio in a power electronic converter, a Hysteretic Current-mode Control (HCMC) [4] is employed to improve the system dynamic response. In the HCMC, the control signal of the switching converter tries directly to control the inductor current and to control the duty ratio indirectly. The inductor current to input voltage of output voltage of a solar array transfer function can be found as

$$\frac{v_{dpv}(s)}{i_{dL}(s)} = \frac{-1/A}{C/A\,s+1} \tag{7}$$

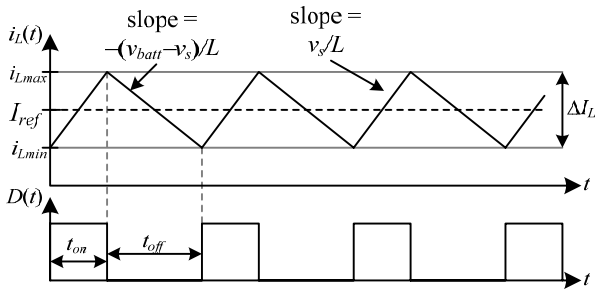

Figure 4. Typical wave forms of HCMC control.

It can be found that when applied the current-mode inductor control, the variation of capacitance C does not effect to the characteristic response of v_{dph}. In the HCMC, the switch S is turned off when i_L rises to its peak value determined by

$$i_{L\max}(t) = I_{ref} + \frac{\Delta I_L}{2}, \tag{8}$$

where I_{ref} is reference current. The switch S is turned on when i_L falls to its minimum given as

$$i_{L\min}(t) = I_{ref} - \frac{\Delta I_L}{2}. \tag{9}$$

The switching frequency f for the switch S is given by

$$\begin{aligned} f &= \frac{1}{t_{on}+t_{off}} \\ &= \frac{v_s(t)\left(v_{batt}(t)-v_s(t)\right)}{L\Delta I_L v_{batt}(t)} \end{aligned} \tag{10}$$

The maximum frequency $f_{\max}$ of the proposed MPPT system can be obtained as

$$f_{\max} = \frac{V_{batt}(t)}{4L\Delta I} \tag{11}$$

IV. Simulation Results

To evaluate performances of the proposed system, computer simulations were conducted using MATLAB/ SIMULINK®[11] with the solar array model described in the previous section as shown in Fig. 5. In addition, the boost converter circuit comprises one inductor (L=1.5mH) with two different capacitors C of 470μF and 4700μF were invoked. Using the solar array whose characteristics described above as shown in Fig. 1, the tracking performance of MPPT obtained from a variation of duty ratio D and the proposed HCMC for MPPT were examined. It should be noted that a sampling time for both algorithms was selected to be 5msec.

In the experiment, the light source was turned on at t = 0 sec under a light intensity of 50mW/cm^2 and temperature of 25^{o}C. The maximum power point at this environment is 9.66W. Fig 6 (a) and (b) show the power tracking results obtained from the variation of D by adaptive P&O algorithm with 470μF and 4700μF capacitors It can be seen that while both power results have the same settling time (t_s) at 0.02sec but the variation of duty ratio reach the steady state within 0.07sec. The performance of MPPT is degraded, however, when C is large. The output voltage of the solar array v_s tends to unstable with ripple (Δv_s) 5% from steady state as show in Fig. 6 (b)

Table I
MPPT Using Modified P&O Method

```
if((P(k) – P(k-1))>0)
    if((v_s(k) – v_s (k-1))>0
        I_ref = I_ref -ΔI_ref;
    else  I_ref = I_ref +Δ I_ref;
    end
 else
    if((v_s(k) – v_s(k-1))>0
        I_ref = I_ref +Δ I_ref;
    else I_ref = I_ref -ΔI_ref;
    end
 end
```

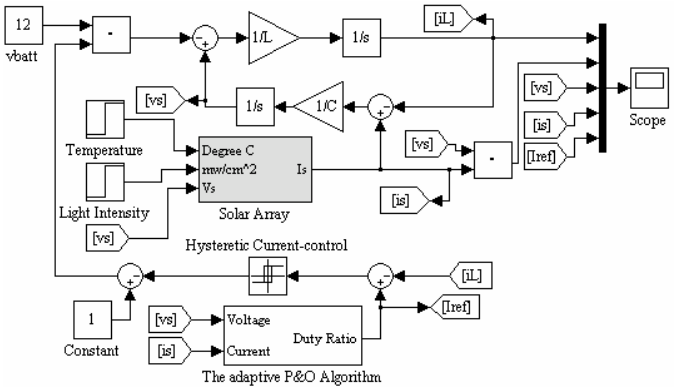

Figure 5. System simulation of MPPT
(Boost Converter, MPPT controller and Battery).

Fig. 7 (a) and (b) show the results of the obtained power from a variation of duty ratio and the proposed HCMC for MPPT. Comparing between Fig 6 (b) and Fig. 7 (b), we can obviously see that the performance of MPPT system is improved. Although the system has the large C, the fluctuated v_s can be mitigated and reached the steady state within 0.3sec.

Practical scenario where light intensity and temperature varies with time were assumed. That is, light intensity was 50 and 100mW/cm^2 from 0 to 0.75sec and 0.75sec onward, respectively. Furthermore, the temperature was 25^{o}C and 50^{o}C from 0 to 1.5sec and 1.5sec onward, respectively. The dynamic environment results in three maximum power points of 9.636W, 19.58W and 18.71W from 0 to 0.75sec, 0.75 to 1.5sec and beyond 1.5sec, respectively. The tracking results from the variation of duty ratio and the proposed HCMC when C is 4700μF are shown in Fig. 8 (a) and (b) respectively. It can be seen clearly that there are smaller power fluctuations in v_s and P during transient and steady state period when using HCMC for MPPT.

V. Conclusions

In this paper, the development an adaptive Perturbation and Observation (P&O) algorithm with a Hysteretic Current-mode Converter (HCMC) for a Solar-powered Battery Charger (SPBC) has been presented. The simulation results obviously show that the proposed adaptive P&O algorithm can give significantly faster tracking speed. Furthermore, the power fluctuation in steady state condition is substantially mitigated by using HCMC comparing with the conventional variation duty ratio control. The proposed system is simple but more effective circuit which is easy to implement in low cost power system.

***Abstract*—In this paper, we examine stabilizing simple repetitive controllers. The modified repetitive control system is a type of servomechanism for periodic reference input. Even if the plant does not include time-delay, the transfer function from the reference input to the output of the modified repetitive control system has generally an infinite number of poles. It is difficult to settle the input-output characteristics and the disturbance attenuation characteristics of the modified repetitive control system. From the practical point of view, the input-output characteristics and the disturbance attenuation characteristics of the control systems are required to be settled easily. In order to specify input-output characteristic and the disturbance attenuation characteristic easily, the transfer function from the reference input to the output and that from the disturbance to the output are desirable to have a finite number of poles. In order to specify input-output characteristic easily, we propose simple repetitive control systems such that the transfer function from the reference input to the output and that from the disturbance to the output have a finite number of poles. In addition, the parametrization of all stabilizing simple repetitive controllers is clarified.**

I. Introduction

In this paper, we examine stabilizing simple repetitive controllers. The repetitive control system is a type of servomechanism for periodic reference input. That is, the repetitive control system follows the periodic reference input without steady state error, even if a periodic disturbance or uncertainty exists in the plant [1–10]. It is difficult to design stabilizing controllers for the plant, because the repetitive control system follows any periodic reference input without steady state error is a neutral type of time-delay control system [8]. In order to design a repetitive control system that follows any periodic reference input without steady state error, the plant needs to be biproper [3–8]. However, in practice the plant is strictly proper. Many design methods of repetitive control systems for the strictly proper plants are given by [3–8]. These studies are divided into two types. One uses a low-pass filter [3–7] and the other uses an attenuator [8]. The latter is difficult to design because it uses a state variable time-delay in the repetitive controller [8]. The former has a simple structure and is easily designed. Therefore, the former type of repetitive control system is called the modified repetitive control systems [3–7].

However using the modified repetitive controllers in [3–7], even if the plants does not includes time-delay, the transfer function from the reference input to the output and that from the distrubance to the output have an infinite number of poles. When the transfer function from the reference input to the output and that from the disturbance to the output have an infinite number of poles, it is difficult to specify input-output characteristic and the disturbance attenuation characteristic. From the practical point of view, it is desirable that the input-output characteristic and the disturbance attenuation characteristic are easily specified. In order to specify input-output characteristic and the disturbance attenuation characteristic easily, the transfer function from the reference input to the output and that from the disturbance to the output are desirable to have a finite number of poles. However no paper examines a design method of modified repetitive control systems such that the transfer function from the reference input to the output and that from the disturbance to the output have a finite number of poles. In the following, we call the simple repetitive control systems if the controller works as a modified repetitive controller and the transfer function from the reference input to the output and that from the disturbance to the output have a finite number of poles.

In this paper, we propose simple repetitive control systems such that the controller works as a modified repetitive controller and the transfer function from the reference input to the output and that from the disturbance to the output have a finite number of poles. In addition, the parametrization of all stabilizing simple repetitive controllers is clarified.

II. Simple repetitive control systems and problem formulation

Consider the unity feedback control system given by

$$\begin{cases} y &= G(s)u + d \\ u &= C(s)(r-y) \end{cases}, \tag{1}$$

where $G(s) \in R(s)$ is the plant, $C(s)$ is the controller, $u \in R$ is the control input, $y \in R$ is the output, $d \in R$ is the disturbance and $r \in R$ is the periodic reference input with period $T > 0$ satisfying

$$r(t+T) = r(t) \ \ (\forall t \geq 0). \tag{2}$$

According to [3–7], when the plant $G(s)$ has a periodic disturbance d with period T and an uncertainty, in order for the output y to follow the periodic reference input r with period T with small steady state error, the controller $C(s)$ must be written by

$$C(s) = C_1(s) + C_2(s)C_r(s), \tag{3}$$

where $C_1(s) \in R(s)$, $C_2(s) \neq 0 \in R(s)$. $C_r(s)$ is an internal model for the periodic reference input r with period T and written by

$$C_r(s) = \frac{e^{-sT}}{1 - q(s)e^{-sT}}, \tag{4}$$

where $q(s)$ is a proper low-pass filter satisfying $q(0) = 1$. According to [3–7], if the low-pass filter $q(s)$ satisfy

$$1 - q(j\omega_i) \simeq 0 \quad (i = 0, \ldots, N_{max}), \tag{5}$$

where ω_i is the frequency component of the periodic reference input r written by

$$\omega_i = \frac{2\pi}{T} i \quad (i = 0, \ldots, N_{max}) \tag{6}$$

and N_{max} is the maximum frequency component of the periodic reference input r, then the output y in (1) follows the periodic reference input r with small steady state error. The controller written by (3) is called by the modified repetitive controller [3–7].

Using the modified repetitive controller $C(s)$ in (3), the transfer function from the periodic reference input r to the output y in (1) and that from the disturbance d to the output y in (1) are written as

$$\begin{aligned} \frac{y}{r} &= \frac{C(s)G(s)}{1 + C(s)G(s)} \\ &= \frac{\left\{C_1(s) - (C_1(s)q(s) - C_2(s))e^{-sT}\right\} G(s)}{[1 + C_1(s)G(s) - \{(1 + C_1(s)G(s))q(s) \\ &\qquad -C_2(s)G(s)\} e^{-sT}]} \end{aligned} \tag{7}$$

and

$$\begin{aligned} \frac{y}{d} &= \frac{1}{1 + C(s)G(s)} \\ &= \frac{1 - q(s)e^{-sT}}{[1 + C_1(s)G(s) - \{(1 + C_1(s)G(s))q(s) \\ &\qquad -C_2(s)G(s)\} e^{-sT}]}, \end{aligned} \tag{8}$$

respectively. Generally, the transfer function from the periodic reference input r to the output y in (7) and that from the disturbance d to the output y in (8) have an infinite number of poles. When the transfer function from the periodic reference input r to the output y and that from the disturbance d to the output y have an infinite number of poles, it is difficult to specify the input-output characteristic and the disturbance attenuation characteristic. From the practical point of view, it is desirable that the input-output characteristic and the disturbance attenuation characteristic are easily specified. In order to specify the input-output characteristic and the disturbance attenuation characteristic easily, the transfer function from the periodic reference input r to the output y and that from the disturbance d to the output y are desirable to have a finite number of poles.

From above practical requirement, we propose the concept of the simple repetitive controller as follows:

Definition 1: (simple repetitive controller)
We call the simple repetitive controller, if following expressions hold true:

1) The controller $C(s)$ works as a modified repetitive controller. That is, the controller $C(s)$ is written by (3), where $C_1(s) \in R(s)$, $C_2(s) \neq 0 \in R(s)$, $C_r(s)$ is written by (4) and $q(s) \in R(s)$ satisfies $q(0) = 1$.
2) The controller $C(s)$ makes the transfer function from the periodic reference input r to the output y in (1) and that from the disturbance d to the output y in (1) have a finite number of poles.

The problem considered in this paper is to propose the parametrization of all stabilizing simple repetitive controllers. That is, we find all controllers written by the form in (3) to make the transfer function from the periodic reference input r to the output y in (1) and that from the disturbance d to the output y in (1) be written as

$$y = \left(\bar{G}_{r1}(s) + \bar{G}_{r2}(s)e^{-sT}\right) r \tag{9}$$

and

$$y = \left(\bar{G}_{d1}(s) + \bar{G}_{d2}(s)e^{-sT}\right) d, \tag{10}$$

respectively, where $\bar{G}_{ri}(s) \in RH_\infty (i = 1, 2)$ and $\bar{G}_{di}(s) \in RH_\infty (i = 1, 2)$.

III. The parametrization

The parametrization of all stabilizing simple repetitive controllers is summarized in the following theorem.

Theorem 1: The controller $C(s)$ is a stabilizing simple repetitive controller if and only if $C(s)$ is written by

$$C(s) = \frac{X(s) + D(s)(Q(s) + \bar{Q}(s)e^{-sT})}{Y(s) - N(s)(Q(s) + \bar{Q}(s)e^{-sT})}, \tag{11}$$

where $N(s) \in RH_\infty$ and $D(s) \in RH_\infty$ are coprime factors of $G(s)$ on RH_∞ satisfying

$$G(s) = \frac{N(s)}{D(s)}, \tag{12}$$

$X(s) \in RH_\infty$ and $Y(s) \in RH_\infty$ are any functions satisfying

$$X(s)N(s) + Y(s)D(s) = 1, \tag{13}$$

$Q(s) \in RH_\infty$ and $\bar{Q}(s) \neq 0 \in RH_\infty$ are any functions satisfying

$$\frac{N(0)\bar{Q}(0)}{Y(0) - N(0)Q(0)} = 1. \tag{14}$$

Proof of this theorem requires following lemma.

Lemma 1: Unity feedback control system in (1) is internally stable if and only if $C(s)$ is written by

$$C(s) = \frac{X(s) + D(s)Q(s)}{Y(s) - N(s)Q(s)}, \tag{15}$$

where $N(s) \in RH_\infty$, $D(s) \in RH_\infty$ are coprime factors of $G(s)$ on RH_∞ satisfying (12), $X(s)$ and $Y(s)$ are RH_∞ functions satisfying (13) and $Q(s) \in RH_\infty$ is any function [11].

Using Lemma 1, we shall show the proof of Theorem 1.

Proof: First, the necessity is shown. That is, we show that if the controller $C(s)$ in (3) makes the control system in (1) stable and makes the transfer function from r to y of the control system in (1) have a finite number of poles, then $C(s)$ takes the form (11). From the assumption that the controller $C(s)$ in (3) makes the transfer function from r to y of the control system in (1) have a finite number of poles,

$$\begin{aligned}\frac{C(s)G(s)}{1+C(s)G(s)} \\ = \frac{\left\{C_1(s)-(C_1(s)q(s)-C_2(s))e^{-sT}\right\}G(s)}{\left[1+C_1(s)G(s)-\{(1+C_1(s)G(s))q(s)\right. \\ \left.-C_2(s)G(s)\}e^{-sT}\right]}\end{aligned} \tag{16}$$

has a finite number of poles. This implies that

$$C_2(s)=\frac{(1+C_1(s)G(s))q(s)}{G(s)} \tag{17}$$

is satisfied, that is, $C(s)$ is necessarily

$$C(s)=\frac{C_1(s)G(s)+q(s)e^{-sT}}{G(s)(1-q(s)e^{-sT})}. \tag{18}$$

From the assumption that $C(s)$ in (3) makes the control system in (1) stable, $C(s)G(s)/(1+C(s)G(s))$, $C(s)/(1+C(s)G(s))$, $G(s)/(1+C(s)G(s))$ and $1/(1+C(s)G(s))$ are stable. From simple manipulation and (18), we have

$$\frac{C(s)G(s)}{1+C(s)G(s)}=\frac{C_1(s)G(s)+q(s)e^{-sT}}{1+C_1(s)G(s)}, \tag{19}$$

$$\frac{C(s)}{1+C(s)G(s)}=\frac{C_1(s)G(s)+q(s)e^{-sT}}{(1+C_1(s)G(s))G(s)}, \tag{20}$$

$$\frac{G(s)}{1+C(s)G(s)}=\frac{(1-q(s)e^{-sT})G(s)}{1+C_1(s)G(s)} \tag{21}$$

and

$$\frac{1}{1+C(s)G(s)}=\frac{1-q(s)e^{-sT}}{1+C_1(s)G(s)}. \tag{22}$$

From the assumption that all the transfer functions in (19), (20), (21) and (22) are stable, $C_1(s)G(s)/(1+C_1(s)G(s))$, $C_1(s)/(1+C_1(s)G(s))$, $G(s)/(1+C_1(s)G(s))$ and $1/(1+C_1(s)G(s))$ are stable. This means that $C_1(s)$ is an internally stabilizing controller for $G(s)$. From Lemma 1, $C_1(s)$ must take the form

$$C_1(s)=\frac{X(s)+D(s)Q(s)}{Y(s)-N(s)Q(s)}, \tag{23}$$

where $Q(s)\in RH_\infty$.

From the assumption that the transfer functions in (19) and (22) are stable, $q(s)/(1+C_1(s)G(s))$ is stable. This implies that unstable poles of $q(s)$ is included in that of $C_1(s)$. That is, $q(s)$ is written by

$$q(s)=\frac{\hat{Q}(s)}{Y(s)-N(s)Q(s)}, \tag{24}$$

where $\hat{Q}(s)\neq 0\in RH_\infty$.

Since the transfer function in (20) is stable, $q(s)/\{(1+C_1(s)G(s))G(s)\}$ is stable. From (23) and (24), we have

$$\frac{q(s)}{(1+C_1(s)G(s))\,G(s)}=\frac{D^2(s)\hat{Q}(s)}{N(s)}. \tag{25}$$

From the assumption that $N(s)$ and $D(s)$ are coprime and the transfer function in (25) is stable, $\hat{Q}(s)$ is written by the form

$$\hat{Q}(s)=N(s)\bar{Q}(s), \tag{26}$$

where $\bar{Q}(s)\neq 0\in RH_\infty$. Substituting (17), (23), (24) and (26) for (3), we have (11). In this way, it is shown that if the controller $C(s)$ in (3) makes the control system in (1) stable and makes the transfer function from r to y of the control system in (1) have a finite number of poles, then $C(s)$ is written as (11). In addition, since $q(0)=1$ holds true, from (24) and (26), (14) is satisfied. Thus, the necessity has been shown.

Next, the sufficiency is shown. That is, if $C(s)$ takes the form (11), then the controller $C(s)$ makes the control system in (1) stable, makes the transfer function from r to y of the control system in (1) have a finite number of poles and works as a stabilizing modified repetitive controller. After simple manipulation, we have

$$\begin{aligned}\frac{C(s)G(s)}{1+C(s)G(s)} \\ = \left(X(s)+D(s)Q(s)+D(s)\bar{Q}(s)e^{-sT}\right)N(s),\end{aligned} \tag{27}$$

$$\begin{aligned}\frac{C(s)}{1+C(s)G(s)} \\ = \left(X(s)+D(s)Q(s)+D(s)\bar{Q}(s)e^{-sT}\right)D(s),\end{aligned} \tag{28}$$

$$\begin{aligned}\frac{G(s)}{1+C(s)G(s)} \\ = \left(Y(s)-N(s)Q(s)-N(s)\bar{Q}(s)e^{-sT}\right)N(s)\end{aligned} \tag{29}$$

and

$$\begin{aligned}\frac{1}{1+C(s)G(s)} \\ = \left(Y(s)-N(s)Q(s)-N(s)\bar{Q}(s)e^{-sT}\right)D(s).\end{aligned} \tag{30}$$

Since $X(s)\in RH_\infty$, $Y(s)\in RH_\infty$, $N(s)\in RH_\infty$, $D(s)\in RH_\infty$, $Q(s)\in RH_\infty$ and $\bar{Q}(s)\in RH_\infty$, the transfer functions in (27), (28), (29) and (30) are stable. In addition, from the same reason, the transfer function from r to y of the control system in (1) has a finite number of poles.

Next we show that the controller in (11) works as a modified repetitive controller. The controller in (11) is rewritten by the form in (3), where

$$C_1(s)=\frac{X(s)+D(s)Q(s)}{Y(s)-N(s)Q(s)}, \tag{31}$$

$$C_2(s) = \frac{\bar{Q}(s)}{\left(Y(s) - N(s)Q(s)\right)^2} \tag{32}$$

and

$$q(s) = \frac{N(s)\bar{Q}(s)}{Y(s) - N(s)Q(s)}. \tag{33}$$

From the assumption of $\bar{Q}(s) \neq 0$ and (32), $C_2(s) \neq 0$ holds true. In addition, from (33) and the assumption in (14), $q(0) = 1$ is satisfied. These expressions imply that the controller in (11) works as a modified repetitive controller. Thus, the sufficiency has been shown.

We have thus proved Theorem 1. ■

IV. Numerical example

Consider the problem to obtain the parametrization of all stabilizing simple repetitive controllers for the plant $G(s)$ written by

$$G(s) = \frac{s - 100}{(s+1)(s-1)} \tag{34}$$

that follows the periodic reference input r with period $T = 2[\mathrm{sec}]$.

A pair of coprime factors $N(s) \in RH_\infty$ and $D(s) \in RH_\infty$ of $G(s)$ in (34) satisfying (12) is given by

$$N(s) = \frac{s - 100}{(s+3)(s+2)},\ D(s) = \frac{(s+1)(s-1)}{(s+3)(s+2)}. \tag{35}$$

$X(s) \in RH_\infty$ and $Y(s) \in RH_\infty$ satisfying (13) are derived as

$$X(s) = -\frac{0.7075(s + 1.056)}{(s+3)(s+2)}, Y(s) = \frac{s^2 + 10s + 38.71}{(s+3)(s+2)}. \tag{36}$$

From Theorem 1, the parametrization of all stabilizing simple repetitive controllers for $G(s)$ in (34) is given by (11), where $Q(s) \in RH_\infty$ and $\bar{Q}(s) \in RH_\infty$ are any functions satisfying (14).

In order for the output y to follow the periodic reference input $r = \sin(\pi t)$ with small steady state error, $Q(s)$ and $\bar{Q}(s)$ are settled by

$$Q(s) = \frac{Y(s)}{N_o(s)}\bar{q}_d(s) \tag{37}$$

and

$$\bar{Q}(s) = \frac{Y(s) - N(s)Q(s)}{N_o(s)}\bar{q}_r(s), \tag{38}$$

respectively, where

$$\bar{q}_d(s) = \frac{1}{0.0001s + 1}, \bar{q}_r(s) = \frac{1}{0.0001s + 1}, \tag{39}$$

$$N_i(s) = -\frac{s - 100}{s + 100}, N_o(s) = -\frac{s + 100}{(s+3)(s+2)}. \tag{40}$$

Using above-mentioned parameters, we have the simple repetitive controller. When the designed simple repetitive controller $C(s)$ is used, the response of the output y in (1) for the periodic reference input $r = \sin(\pi t)$ is shown in Fig. 1. Here, the dotted line shows the response of the periodic reference input r and the solid line shows that of the output y. Figure 1 shows that the output y follows the periodic reference input r with small steady state error.

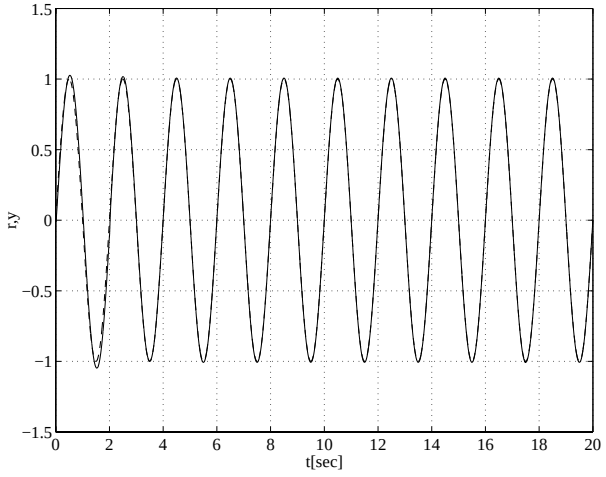

Figure 1. The response of the output y for the periodic reference input $r = \sin(\pi t)$

V. Conclusion

In this paper, we proposed the simple repetitive control systems and the parametrization of all stabilizing simple repetitive controllers.

***Abstract*-The dielectric properties over the frequency range from 20 kHz to 1.5GHz at room temperature approximately 27ºC were measured for liquid sample cut from pineapple, lemon and orange. The dielectric constant and loss-factor data were obtained from the laboratory test for pineapple, lemon and orange. Not only the dielectric loss-factor decreased consistently with the increasing frequency up to 1.5GHz but the aging of fruits also depends on the frequency. The suitable range of frequency for the suitable discrimination is between 50 kHz and 80 kHz.**

Keywords: Dielectric Investigation, Dielectric Spectroscopy, High Frequency, Dielectric, Loss Tangent Factor

I. INTRODUCTION

The dielectric constant is essential information used in the designing capacitors and in other electrical apparatus where a material might be expected to have the capacitance in a circuit. If a material that have high dielectric constant placed into an electric field, the magnitude of that field will reduced the volume of the dielectric. This fact is commonly used to increase the capacitance of a particular capacitor design. The dielectric properties of moist materials can be determined by the electrical methods because of the correlation between molecular structure of material and water content on dielectric permittivity. A method that is used to determine the dielectric properties of fresh material is the use of electromagnetic field. The dielectric properties depends on water content, the frequency of the applied electromagnetic field, the temperature of the material, salts or dissolved iron of water, and the structure of the material[1-5]. The charge particle in the material which differs in molecule structure and composition acts differently in the electromagnetic field. The permittivity measurement determination of agriculture material can be use to determined the stage of freshness of fruits, grain, and seed be fore they are transfer to the customer. The frequency range of 20 MHz to 1.0 GHz is studied due to the ability of the RF analyzer the nondestructive frequency used by most research for RF radio wave to Microwave.

Thailand is one of the agricultural countries that has exported fresh fruits world wide. Nondestructive and destructive methods have been used for an inspection of the quality of fruits. In 1997, permittivity of homogenized macaroni, cheese, and wheat has been measured by S.O. Nelson et al. [6]. In 2001: W. Kongrattanaprasert et al. used force vibration and ultrasonic to classify the maturity of fruits[7]. In 2004, mango and durian inspection have been studied using inverse scattering technique by M.Krairiksh et al. [8]. In this paper, the study concerns with the behavior of dielectric constant, dielectric loss factor and loss tangent of three juices; pineapple, lemon and orange is presented.

II. DIELECTRIC PARAMETERS

A. Dielectric Constant

The dielectric constant is represented as ε_r. It is defined as (1) [9].

$$\varepsilon_r = \frac{\varepsilon_s}{\varepsilon_0} \tag{1}$$

Where

ε_s is the static permittivity of the material

ε_0 is vacuum permittivity

Vacuum permittivity is derived from Maxwell's equations by relating the electric field intensity E to the electric flux density D. In vacuum (free space), The permittivity ε_s is just ε_0, so the dielectric constant is 1.

The relative dielectric constant ε_r can be measured for any static electric fields and described as follows:

First, the capacitance of a test capacitor C_0 is measured with vacuum between its plates. Then, using the same capacitor and distance between its plates, the capacitance C_x with a dielectric between the plates is measured.

The relative dielectric constant can be then calculated as (2)

$$\varepsilon_r = \frac{C_x}{C_0} \tag{2}$$

For time-varying electromagnetic fields, the dielectric constant of materials becomes frequency-dependent and in general it is called permittivity.

B. Permittivity:

Generally, ε is a complex number whose real and imaginary parts depend on frequency as (3).

$$\varepsilon(f) = \varepsilon'(f) - j\varepsilon''(f) \tag{3}$$

Where

ε′(f) = real part (implies electromagnetic stored energy)

ε″(f) = imaginary part (implies electromagnetic loss energy)

If we divide (3) by permittivity of free space (εo = 8.854×10^{-12} F/m), the relative complex permittivity can be written as follows;

$$\varepsilon_r(f) = \varepsilon_r^{/}(f) - j\varepsilon_r^{//}(f) \tag{4}$$

Where

$\varepsilon_r'(f)$ = dielectric constant,

$\varepsilon_r''(f)$ = dielectric loss factor or loss conductivity

$$\varepsilon_r''(f) = \frac{\sigma}{2\pi f \varepsilon_0} \quad (5)$$

Or

$$\sigma = 2\pi f \varepsilon_0 \varepsilon_r''(f) \quad (6)$$

Where

σ = conductivity (S/m),

f = operating electromagnetic frequency (Hz).

The loss tangent of material can be defined as (7):

$$\tan\delta = \frac{\varepsilon''}{\varepsilon'} \quad (7)$$

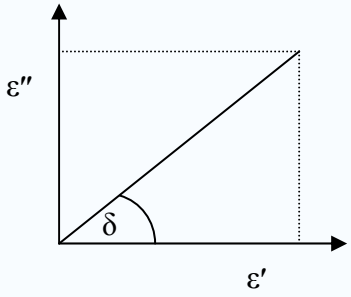

Figure 1.The relative of the loss tangent factor, ε′ and ε″

III. MECHANISMS OF ELECTRICAL POLARIZATION

There are 3 major mechanisms of the electric polarization:

A. Electronic or Optical polarization: the external electric field causes deformation or translation of the electron clouds of atom or molecules within certain media.

B. Atomic or ionic polarization: the electric field causes the atoms or ions of poly-atomic molecules to be displaced relative to each other.

C. Orientational polarization: the electric field causes the reorientation of the permanent dipoles in materials toward the direction of the field.

The peak of absorption loss will occur at resonant frequency, ω_c, that is;

$$\omega_c \tau = 1. \quad (8)$$

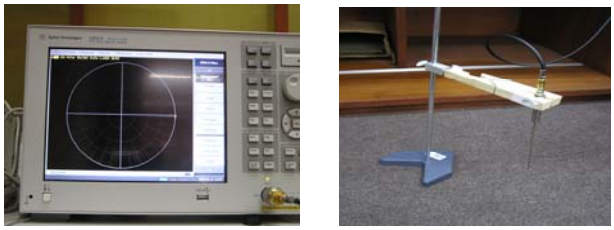
Where τ is relaxation time (s).

IV. EXPERIMENTAL LABORATORY

Samples of three different fresh fruit; pineapple, lemon, orange from a local agriculture farm are prepared for the measurements and investigation of the electrical dielectric. The sample fruits are cut in to small pieces of 2*2 cm^2 after picking up from the nearby farm. The sample cuts then are process into liquid form by electric processor. The liquid sample of 150 cm^3 in volume is then kept in a refrigerator at 2 degree Celsius. The liquid samples have water contents greater than 70%.

The electrical equipments are set up in the laboratory. The processes to measure the electrical dielectric of fruits are as follows;

A.The equipment are prepared for the experiment. A Hewlett-Packard network analyzer (model E5061A), a coaxial line cable (RG-58A/U) and a open-ended dielectric probe are used



a) b)

Figure 2. Shows the measurement equipments
a) Hewlett-Packard network analyzer model E5061A

B.The calibration procedure is performed under open-circuit and short circuit test using distilled water at temperature of 25 degree Celsius as standard reference.

a) b)

Figure 3. Shows the probe and glass vessel
a) The calibration probe using distilled water at temperature of 25 degree Celsius as standard reference.
b) The measurement probe for different fruits in a glass vessel

C. Measure the permittivity properties of three different fruits; pineapple ,lemon, and orange on the 1st, 2nd, 3rd, 4th, 5th, 6th and 7th day after picking up from fruit trees at the local agriculture farm.

D. Calculate the permittivity (dielectric constant and loss factor) by using an appropriate 8085 dielectric probe kit software version E100 designed by Agilent technology, USA.

E. Two measurements are obtained from the experiment.

i) The dielectric, loss factor are obtained for three samples of fruits: pineapple, lemon and orange with frequency range from 20 kHz to 1.5GHz at room temperature 27 degree Celsius

ii) The dielectric, loss factor, conductivity of fruit samples are obtained for watermelon with frequency range from 20 kHz to 1.5GHz at temperature 30,50,70,90 degree Celsius.

V. EXPERIMENTAL RESULTS

The results obtained from the experiment conducted in the laboratory are as follows;

A. The dielectric properties of samples from three fruits on the **1st** day with frequency range as table1 are shown in Fig. 4.

TABLE I.

The Data for the Permittivity of All Three Fruits at Temperature of 20 Degree Celsius for Frequencies between 20 kHz,790 MHz and 1.5GHz

f / Fruits	20 MHz		790 MHz		1.5 GHz	
	$\varepsilon_r^{/}$	$\varepsilon_r^{//}$	$\varepsilon_r^{/}$	$\varepsilon_r^{//}$	$\varepsilon_r^{/}$	$\varepsilon_r^{//}$
Pineapple	127.0	225.2	76.3	10.8	74.4	11.3
Lemon	147.1	324.8	76.0	12.5	74.7	11.3
Orange	134.3	253.2	74.4	11.8	72.4	11.7

B. The dielectric properties of samples from three fruits on the **2nd** day with various frequencies are shown in Fig. 5.

C. The conductivity properties of samples from the watermelon with frequency range from 20 kHz to 1.5 kHz at temperature of 30, 50, 70, 90 degree Celsius is shown in Fig. 6.

D. The dielectric constant of watermelon at various frequencies and different temperature is shown in Fig. 7.

E. The dielectric loss factor of watermelon at various frequencies and different temperature is shown in Fig. 8.

VI. CONCLUSIONS

The major conclusions can be drawn from the experimental results as follows;

- The loss tangent, dielectric constant, dielectric loss factor of fruits depend greatly on an electromagnetic frequency. However, these parameters tend to decrease as the frequency of fruits is increased over the interval of 20 MHz-1.5 GHz.
- Over the frequency range 20 – 600 MHz, the dielectric loss factor can be approximated as linear equation.
- The conductivity tends to increase as the frequency and the temperature of fruits is increased.
- The most suitable frequency for the investigation is in the range of 20-100 MHz
- The quality or the degree of freshness of fruits can be determined by the method presented in this paper.

***Abstract*-This paper represents the design and construction of the 100 kV capacitive voltage divider for alternative voltage measurement. Metallized Polypropylene film capacitors were connected in series circuit as high voltage arm of the voltage divider which was in PVC insulating cylinder. Besides, the same kinds of capacitors were connected in parallel in the brass tube as the low voltage arm. The scale factor of the designed voltage divider is 2000:1. The voltage output of the voltage divider was compared with that obtained from sphere gap calibration in IEC 60-1 [1]. Furthermore, this divider passed the withstand test at 110 kV.**

Key word: Voltage divider, Measuring AC high voltage, High voltage capacitor.

I. INTRODUCTION

At present, production of devices for high voltage in Thailand is quickly developed. Quality examination is necessary for electrical apparatus. The processes followed the processes in national standard. Each examination must use accurate equipment following the standard. In the past, these equipments were ordered from foreign which was more expensive. However, now, electrical high voltage technology in Thailand is high enough to design and construct some equipment using materials in our country which reduces the price a lot. Equipment produced in Thailand has similar quality to the one ordered from foreign. The necessary equipment for high voltage laboratory is voltage divider.

This paper reported the design and construction of capacitive voltage divider, used for measuring AC high voltage up to 100 kV, 50 Hz. The materials used to construct this voltage divider were available in Thailand which had lower price than those ordered from abroad.

II. RELEVANT PRINCIPLES

A High voltage measuring system with voltage divider

High voltage measurement technique uses voltage divider reduced the high voltage to low magnitude as shown in Fig.1. Impedance (Z_1, Z_2) may be resistors or capacitors. Generally, resistive divider is suitable for measuring DC high voltage and capacitive divider is suitable for measuring AC high voltage.

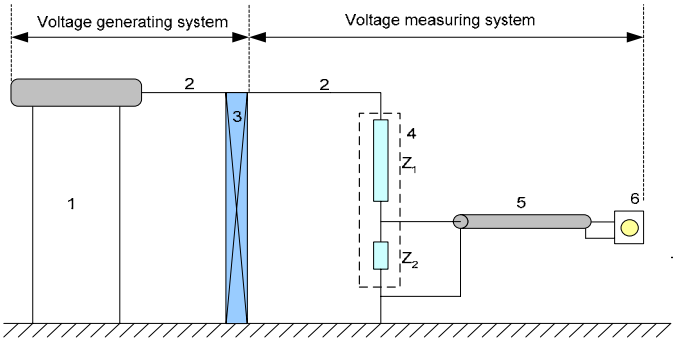

Figure 1. Voltage divider for AC high-voltage measurements

Where

1 = High voltage AC supply
2 = High voltage conductor
3 = Test object
4 = Voltage divider
5 = Measuring cable
6 = Measuring instrument
Z_1 = High voltage arm of voltage divider
Z_2 = Low voltage arm of voltage divider

B. Capacitive voltage divider

Capacitive voltage divider is favorite measurement for AC high voltage. The ratio of V to V2 depended on the values of C_1 and C_2 as expressed in Eq.1.

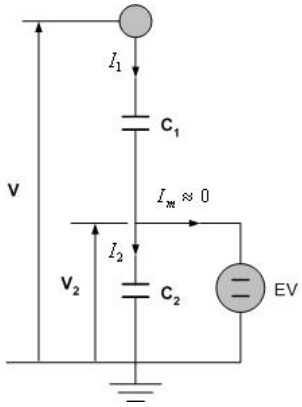

Figure 2. Capacitive voltage divider

$$V = \frac{C_1 + C_2}{C_1} \times V_2 \qquad (1)$$

where

V = High voltage input
V_2 = Low voltage output
C_1 = High voltage capacitance
C_2 = Low voltage capacitance

III. DESIGN OF VOLTAGE DIVIDER

This paper presents the design of 100 kV voltage divider. The designed scale factor is 2,000:1. Detail of design is summarized as follows.

A. Design and construction of 100 kV voltage divider

- High voltage arm

The high voltage arm consists of 100 Metallized Polypropylence Film capacitors, 10 nF/ 2 kV_{DC}, connected in series on acrylic with replace overlap 25 layer, 4 pieces per layer show in Figure 3. The diameter and the length of each capacitor are 10 mm and 32 mm as shown in Figure 4. This high voltage arm can withstand the voltage up to 100 kV with the safety factor of 40%. According to IEC 60-2 [2], the voltage divider must be able to withstand voltage at least 110% of rate for 1 minute. This withstand test is also considered in this present work. The divider is contained in PVC tube which used air insulation, Figure 5.

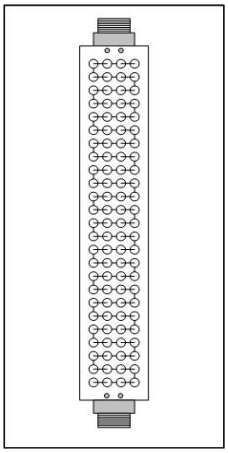

Figure 3. Dimension configuration of high voltage capacitance

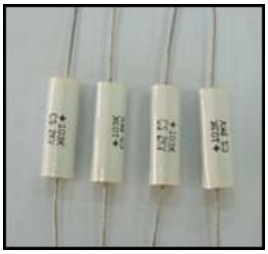

Figure 4. Metallized Polypropylence Film capacitors

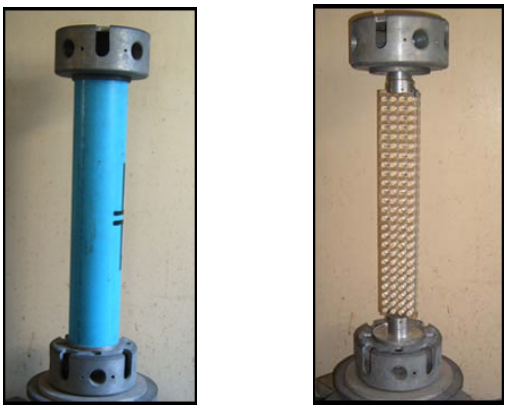

Figure 5. High voltage capacitive configuration

- Low voltage arm

The ratio of voltage at 2,000:1 gives the output voltage (V_2) about 50 V. This low voltage can be measured by the available measuring equipment. Therefore, the low voltage arm consists of two of 100 nF/2 kV_{DC} capacitors connected in parallel as shown in Figure 6. This low voltage arm is contained in brass shield case as seen in Figure 7. The whole set of the capacitive voltage divider is shown in Figure 8.

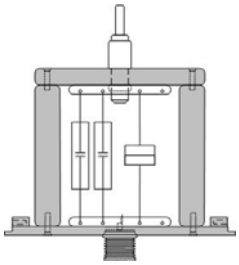

Figure 6. Dimension configuration of low voltage

Figure 7. Low voltage capacitive configuration

Figure 8. Voltage divider rate 100 kV

IV. EXPERIMENTAL RESULTS AND EVALUATION

A. Experimental circuit

The test circuit is shown in Figure 9. It consists of AC voltage source 220 V, variac 0-240 V, transformer 220/100 kV, water resistor (R_W) 1.44 $M\Omega$, Standard sphere diameter 12.5 cm and the designed capacitive voltage divider. 'UP & Down' method is used to find the breakdown voltage (U_{50}) by applying 20 times of AC voltage. The test gap lengths are 0.5, 2, 3.5, 5 cm

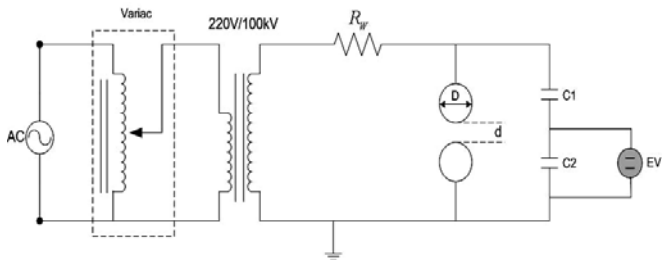

Figure 9. Experimental circuit

B. Comparison with sphere gap calibration

The measuring device needs accuracy and consistency. Therefore, the breakdown voltage (U_{50}) measured from this voltage divider is compared with the voltage obtained by sphere gap calibration following IEC 60-1. Experimental result is shown in Table I.

TABLE I

BREAKDOWN VOLTAGE (U50) OBTAINED FROM DESIGNED VOLTAGE DIVIDER AND SPHERE GAP CALIBRATION.

Gap length (cm)	$U_{50,kd}$ from voltage divider (kVp)	U_{50} from sphere gap calibration (kVp)	%Error
0.5	17.14	16.8	-2.05
2	59.40	59	-0.69
3.5	97.34	97	-0.35
5	128.82	129	0.14

C. Voltage wave shape obtained from voltage divider

Measured output signal of voltage divider may slightly off from sine wave. If wave shape is slightly off sine wave, it may affect the measurement. It may cause higher error. This experimental is referred to IEC 60-1 which assigned $V_P/V_{rms}=\sqrt{2}\pm5\%$ with a frequency in a range 45 to 65 Hz . The output waveform is shown in Fig.10 and Fig 11 which is sinewave with error of -1.12% and frequency of 50.4 Hz. This output waveform is accepted following IEC 60-1.

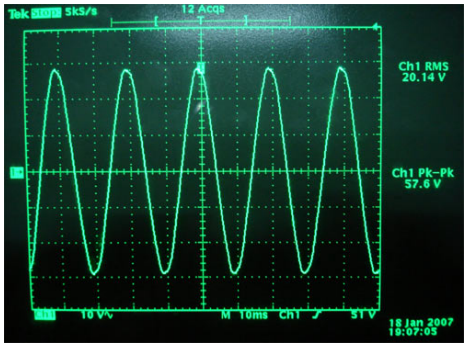

Figure 10. Voltage wave shape of voltage divider

D. AC Withstand voltage test

According to IEC 60-2, the voltage divider must withstand the voltage of 110% of its rating for 1 minute. Therefore, in this present work, the voltage of 111 kV 50 Hz is applied to the voltage divider for 1 minute and then, the divider can withstand this voltage without breakdown. Results are shown in Table 2. This assures that this designed voltage divider is suitable to use at the level of 100 kV.

TABLE II

RESULT OF AC WITHSTAND VOLTAGE TEST.

Rated (kV)	Voltage test (kV)	Time (s)	Voltage with voltage divider correct with k_d (kV)	Error %	Result
100	111.11	60	111.40	0.26	Withstand

V. DISCUSSION

In voltage divider calibration, the instrument used for measuring voltage was multimeter (Amprobe No. 330T). The value measured was RMS value. From results in Table I found that in gap lengths of 2, 3.5, 5 cm, %error was less than 1%, but with the gap length of 0.5 cm, %error was 2.05%. This indicated that this voltage divider can work with a very good accuracy as the breakdown voltage was above 59 kV. While the accuracy of the voltage divider was less as the breakdown voltage was below 20 kV though its error was less than 3% which is the error accepted for sphere gap calibration. This might be due to very low voltage at this gap distance compared to its rating with safety factor of 40%.

VI. CONCLUSION

Design and construction of 100 kV capacitive voltage divider was used for measuring AC high voltage. Materials used in this construction were available in Thailand which its price is much lower than that of materials imported from foreign. The characteristics of the designed voltage divider can be summarized as follows:

1. The maximum error compared to the sphere gap calibration is only 2.05% at the gap distance of 0.5 cm.
2. This voltage divider is tested with AC withstand by applying the 110 kV for 1 minute according to IEC 60-2. The voltage divider can withstand voltage without damage.
3. Output signal of voltage divider is sine wave with the ratio of V_p/V_{rms} less than 5%. This follows IEC 60-1.

Finally, it can be said that this constructed capacitive voltage divider is suitable for use at the level of 100 kV.

The Hydrophobic of Polymeric Insulator under Dust Pollution and A Comparison with Artificial Pollution

Apisit Chaisaengsukkul**, Norasage Pattanadech, Siriwat Potivejkul
Electrical Engineering Dept., Faculty of Engineering, King Mongkut's Institute of Technology Ladkrabang
Bangkok, 10520 Thailand ; E-mail : apisit@cpf.co.th, norasage@yahoo.com

Astract- **This paper presents results of properties of polymeric insulation study, e.g. hydrophobic , ageing which operate influence the electrical characteristic of polymeric insulator etc. when they are subjected by artificial polluted condition compared with natural pollution in Thailand.**

The test results show that hydrophobic property of polymeric insulator under various salinities, i.e. small salinity, medium salinity and high salinity are still relatively remain its property while hydrophobic property under flour dust is partially maintain except the area covered with flour dust. However, hydrophobic property will be lost when it exposed with feed dust and cement dust. It is also found that the insulation resistance of polymeric insulator decreases when it was exposed to polluted condition such as saline solution no matter of any level of salinity, flour dust, animal feed dust or cement dust. When the duration of ageing is prolonged, the insulation resistance trends to be reduced. In addition, the insulation resistance of polymeric insulator under 50 ^{o} C atmospheric is slightly lower than that of 30 ^{o} C.

Keywords: Hydrophobic, polymeric insulator, dust pollution

I. INTRODUCTION

The polymeric insulators are found in many countries in distribution system especially polluted condition such as industrial area where there are many factories generate polluted dust, e.g. cement plant , flour mill etc. In Thailand, they have been used in some areas to solve the problem of flashover which are easily cause to porcelain insulators. Since it is the early stage of using of polymeric insulators and its characteristic needs to be studied to verify whether it is suitable for use or not. The purpose of this paper is to study properties of polymeric insulator such as hydrophobic, ageing under industrial dust pollution generated from factories. As it is known, polymeric insulator has main advantage on its hydrophobic property which can reduce the path of current leakage, in other words, reduce flashover.

II. SAMPLES AND PROCESS OF HYDROPHOBIC VERIFICATION

** The author would like to express thankfulness to Provincial Electricity Authority (PEA); Department of Chemistry, Faculty of Science and High Voltage Engineering Laboratory, Faculty of Engineering , KMITL for their kind support of relevant instrument and equipment.

The pollution process for hydrophobic study can be carried out by preparing twelve specimens from polymeric insulator, then gradually flowing on all specimens with prepared solutions (saline solutions with small salinity, medium salinity and high salinity and solutions with flour dust , animal feed dust and cement dust respectively) two specimens for each type of solutions , let them naturally dry and then sprayed water all over the surface of all specimens to verify hydrophobic property. After that, separated into two group, one to be kept at 30 ◦ C while the other kept at 50 ◦ C. The duration of these specimens under temperature control lasted 8 hour a day and took for five days. After the fifth day, all specimens were sprayed with water to verify hydrophobic and compare with the first day.

Fig. 1. Samples of pollution dusts (from left to right : flour; ,animal feed and cement dust)

III. SAMPLES AND AGEING PROCESS

For ageing study, thirty six specimens from polymeric insulator were prepared, six specimens for each case, there are six cases to be studied : saline solutions (artificial polluted condition) with three salinities : small salinity, medium salinity and high salinity respectively; flour dust, animal feed dust and cement dust collected from factories (natural pollution) . The pollution process for all specimens for ageing study are the same as for hydrophobic study. The specimens for ageing are separated into two group, one group is kept at 30 ◦ C while the other group kept at 50◦ C The duration of specimens to be under temperature

control lasted 8 hours a day and this experiment took place for five days. The insulation resistance of all specimens are measured after completion of temperature control of each day.

To prepare specimens under polluted conditions is referred Solid Layer Method from IEC 507 Standard.

During ageing process, Scanned Electron Microscope (SEM) is also used to monitor insulator surface under various polluted conditions.

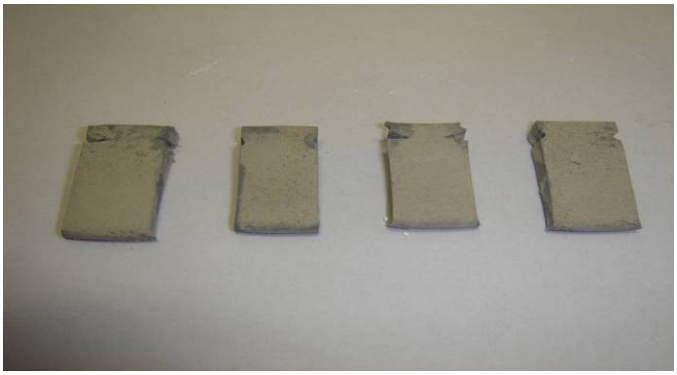

Fig. 2. Specimens for ageing study after pollution process with cement dust

TABLE 1
DATA OF VARIOUS POLLUTED DUST AND SALINE SOLUTIONS

Type of pollution	ESDD (mg /cm^2)	Remark
Saline solutions	0.028	small salinity
Saline solutions	0.102	medium salinity
Saline solutions	0.250	high salinity
Flour	0.041	
Feed	0.662	
Cement	0.106	

IV. TEST RESULTS

From the test results in Fig 3 (a) to (g), it is obvious that hydrophobic property of polymeric insulator under various salinities, i.e. small salinity, medium salinity and high salinity are still relatively remain its property while hydrophobic property under flour dust is partially maintain except the area covered with flour dust. However, hydrophobic property will be totally lost when it exposed with feed dust and cement dust.

In addition, from Fig 4 (a) and (b) it is found that the insulation resistance of polymeric insulator decreases when it was exposed to polluted condition such as saline solutions no matter of any level of salinity, flour dust, animal feed dust or cement dust. When the duration of ageing is prolonged, the insulation resistance trends to be reduced. In addition, the insulation resistance of polymeric insulator at 50 ° C is slightly lower than that of 30 ° C.

Fig. 5. Illustration of polymeric insulator surface of various Pollutions with magnification of 500 X

V. CONCLUSIONS

Since hydrophobic property of polymeric insulator still relatively maintain when it is under saline solutions and it is partially remain for flour dust except the area that is covered with flour dust. The hydrophobic property of polymeric insulator will be lost when it is under cement dust and animal feed dust. Polymeric insulator is suitable to use for coastal environment while it is unsuitable to use under polluted condition such as cement plant, animal feed factory including flour factory.

When polymeric insulator is under polluted condition, its insulation resistance will be gradually decreased, in such condition, it has the chance to cause flashover to insulator.

ACKNOWLEDGMENT

The author would like to express thankfulness to Provincial Electricity Authority (PEA); Department of Chemistry, Faculty of Science and High Voltage Laboratory, Faculty of Engineering, KMITL for their kind support of relevant instrument and equipment.

Astract- **Porcelain insulators are generally used in distribution system , in some polluted area such as industrial area where there are many factories generated polluted dust, e.g. flour mill , cement plant , animal feed factories etc., polymeric insulators are used to replace porcelain insulators. However, in such polluted condition, it sometimes cause flashover of insulators in power system and as a result, it would impact power system stability. This paper presents results of corona phenomena study on 33 kV system AC insulators under industrially polluted dust , e.g. flour dust, cement dust and animal feed dust collected from factories and compared with kaolin which is artificial pollution.**

The results show that corona inception voltage of porcelain insulators under flour dust, kaolin, feed dust and cement dust are relatively constant when tested pollution levels are increased and corona inception voltage of flour dust and cement dust are higher than that of kaolin and animal feed dust with the increasing of pollution levels.

The corona inception voltage of polymeric insulators under kaolin and feed dust conditions decrease when tested pollution levels are increased while corona inception voltage of polymeric insulator under flour dust and cement dust conditions are relatively constant with the increasing of tested pollution levels.

In addition, corona inception voltage of polymeric insulators under industrial dust, i.e. kaolin, flour dust , animal feed dust and cement dust are higher than that of porcelain insulators.

The leakage current of porcelain insulators under animal feed dust increase when tested pollution levels are increased while leakage current of porcelain insulators under kaolin, flour and cement dust as well as polymeric insulator under various kinds of dust are relatively constant with the increasing of tested pollution levels.

Keywords: polymeric insulator , dust pollution, corona

I. INTRODUCTION

In electrical system particularly distribution system, porcelain insulators are generally used. In some polluted area such as industrial area where there are many factories produced polluted dust, e.g. flour mill , cement plant , animal feed factories etc. , polymeric insulators are widely used to replace porcelain insulators in many countries. However, in such polluted condition, it sometimes cause flashover of insulators in power system and as a result, it would cause power interruption in power system and on the other hands, impact to power system stability.

** The author would like to express thankfulness to Data Entry Co.,Ltd, Faculty of Sceince , KMITL including relevant factories for supporting of equipment and polluted dust.

II. SOLID LAYER METHOD

The simulation of industrial polluted condition can be referred IEC507 standard , this standard recommends Solid Layer Method to verify the insulator being suitable to use under polluted condition. Three porcelain insulators and three polymeric insulators with alternating sheds were provided to carry out the test.

A.. Solid Layer Chamber

Solid layer chamber is fabricated as according to standard requirements. The dimension of chamber is width x length x height = 4.2 x 4.2 x 4.5 m^3 Electric steam generator produces steam from ground level to upwards direction with the rate of approximately 50 g / hr / m^3 The object test is suspended approximately 2.0 m above ground.

(a) Polluted porcelain insulators

(b) Polluted polymeric insulators

Fig. 1. Test objects

B. Solid Layer Preparation

The preparation of solid layer can be done by providing 40 g. Kaolin and 3 g. salt. Then dissolve in the container with 1000 g. water, stir together and fill in jet spray. Spray test objects (porcelain and polymeric insulators) with this solution and let it dry. After test objects naturally dry, carefully collect suspended dust from test objects by using wet brush and dissolve suspended dust in the known quantity water in another container, stir for approximately 2 minutes and then measure its conductivity with conductivity meter and record. The ESDD (Equivalent Salt Deposit Density) can be determined by referring IEC 507 standard. After first ESDD is obtained, the other values of ESDD can be obtained by the procedure mentioned above with appropriate amount of salt as according to tested pollution levels, i.e. 13 and 60 g. etc. The consideration of ESDD in this study focus on three pollution levels , i.e. small contamination, medium contamination and high contamination respectively.

The solid layer including ESDD for other kinds of dust, i.e. flour dust, cement and feed dust can be obtained by repeating steps mentioned in previous paragraph.

Fig. 2 Samples of dust (upper : Kaolin , flour ; lower : cement and feed)

TABLE I
ESDD OF VARIOUS KINDS OF DUST

Pollution level s	ESDD (mg / cm^2)			
	Kaolin	Flour	Feed	Cement
Low	0.033	0.045	0.034	0.037
Medium	0.057	0.13	0.037	0.056
High	0.13	0.36	0.193	0.20

III. TEST PROCEDURE

The test arrangement for solid layer method was set up as shown in Fig. 3. After all equipment including test object (porcelain insulator) with low pollution level of kaolin are set up, the test begins. Test voltage is gradually applied to test object until 19 kV (phase voltage) and then maintain , after that open valve to let steam from steam generator slowly distributes from ground level and flow in upward direction and detect corona phenomena by corona camera. In case no corona occurred, gradually increase voltage level and still detect corona phenomena , the maximum voltage is limited not exceed 55 kV. Then the second specimen of porcelain insulator is taken place. After three specimens of porcelain insulator with low pollution level are tested. The consequential test of three polymeric insulators with low pollution level are carried out. After completion of test for low pollution level of both porcelain and polymeric insulators. Then, porcelain and polymeric insulators with medium pollution level and high pollution level are then provided for the test.

The test is carried out with the same test procedure mentioned above for flour dust, animal feed dust and cement dust respectively. During each test, leakage current is measured and recorded at all applied voltage when corona phenomena occurred. Leakage current can be measured by current transformer with ration 1: 40 and signal is transmitted to digital oscilloscope.

V. CONCLUSIONS

The corona inception voltage of porcelain insulators under flour dust, kaolin, feed dust and cement are relatively constant when tested pollution levels are increased and corona inception voltage of flour dust and cement dust are higher than that of kaolin and animal feed dust with the increasing of pollution levels.

The corona inception voltage of polymeric insulators under kaolin and feed dust conditions decrease when tested pollution levels are increased while corona inception voltage of polymeric insulator under flour dust and cement dust conditions are relatively constant with the increasing of tested pollution levels.

In addition, corona inception voltage of polymeric insulators under industrial dust, i.e. kaolin, flour dust, animal feed dust and cement dust are higher than that of porcelain insulators.

The leakage current of porcelain insulators under animal feed dust increase when tested pollution levels are increased while leakage current of porcelain insulators under kaolin, flour and cement dust as well as polymeric insulator under various kinds of dust are relatively constant with the increasing of tested pollution levels.

***Abstract*-This paper describes a modulation at 0.1 Hz for very low frequency (VLF) transformer. This transformer is used for testing field aged cable. This paper shows a new modulation circuit for VLF transformer by modulation sinusoidal signal with frequency 0.1 Hz and triangular signal frequency 1 kHz. This VLF transformer gives many advantages. First of all, it is not only saves transformer weight but also reduces cost. Secondly, it can be used in diagnostic tests such as partial discharge detection. Thirdly, it is easy to be used at site location. This modulation circuit will be used to construct a VLF transformer to be used in non-destructive testing.**

I. INTRODUCTION

The problem associated with testing field aged cable using DC and AC high voltage test equipment has some disadvantages. The AC high voltage transformer is large, heavy and expensive even with resonant test sets [1]. While testing by DC high voltage needs a very high voltage so it causes some damage on the insulation of the cable. Therefore, the VLF transformer is represented to solve these problems. Typically this equipment produced 0.1 Hz voltage having a sinusoidal waveform. This is not only saves weight and reduces cost but also simplifies its use in diagnostic tests such as partial discharge detection.

TABLE **I**

Suitability of selected waveform in voltage withstand tests

Wave form	Scale of equipment	Water-tree detection capability	Soundness
AC	×	☻	☺
DC	☻	×	×
VLF	☺	☺	☻
SOW	☺	☺	×

☻ : Suitable;

☺ : OK;

×: Unsuitable;

Table 1 shows the results. AC provides high water – tree detection capability. DC test equipment is the most lightweight. In the case of VLF the test equipment can be made lighter and more compact than for AC. Finally, OSW is the equal of VLF in terms of the size of the test equipment and water – tree detection capability.

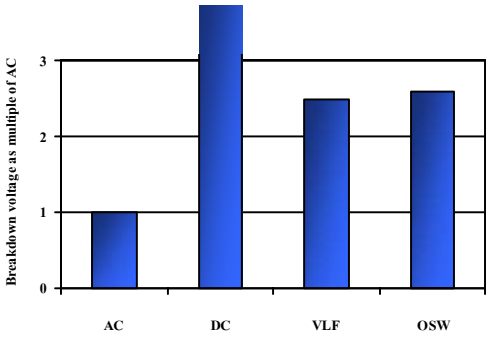

Figure 1. Comparison of AC, DC, VLF and OSW breakdown Voltage during water-tree detection.

Fig.1 shows that comparison of breakdown voltage of cable under AC, DC, very-low frequency (VLF) and oscillating wave (OSW) voltages. This indicates that OSW is the equal of VLF in terms of the size of the test equipment and water-tree detection capability. However. VLF has a better soundness capability. It is therefore concluded that VLF is the most suitable waveform for use in voltage withstands testing of water-tree cable [2].

This paper covers a new modulation circuit for VLF transformer to modulate sinusoidal signal with frequency 0.1 Hz and triangular signal with frequency 1 kHz for VLF transformer.

II. THEORY

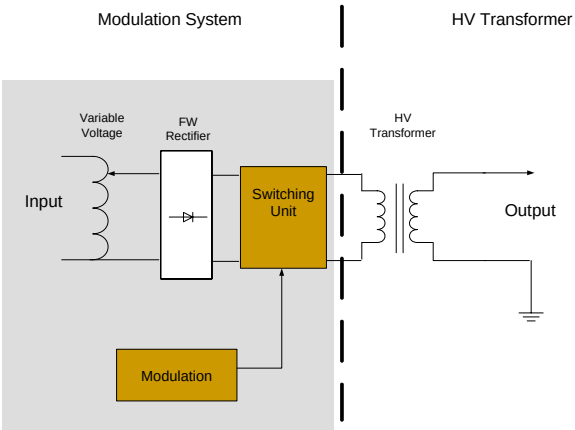

Figure 2. Block Diagram of VLF transformer.

The input power for the system is obtained from a normal 220V 50 Hz source. The input voltage for the rectifier is varied by an autotransformer, then the DC voltage from the rectifier is supplied to the switching unit. The output of this full-wave rectifier is modulated with the desired VLF frequency, 0.1 Hz in this present work. The schematic diagram is shown in Fig.2. Finally, the output voltage from switching unit, which is already AC, is stepped up through the transformer.

The principle of the pulse-width modulation (PWM) circuit. It is the signal lead reference signal (V_{sine}= 0.1 Hz) compared with a carrier of carrier signal (V_{tri}= 1 kHz).

The modulation used full-bridge circuit as a dc-to-ac inverter. One of the full-bridge inverter (square-wave) is unipolar switching scheme [3]. This unipolar switching is chosen for this work to get sinusoid output voltage. Also, it is easy to find the power circuit to drive this inverter.

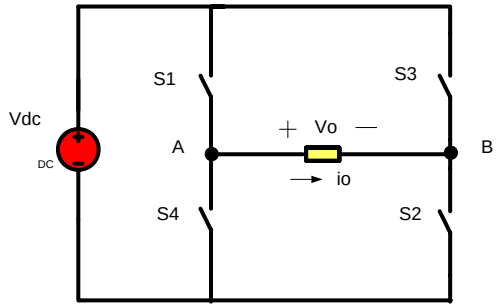

Figure 3. Full-bridge inverter.

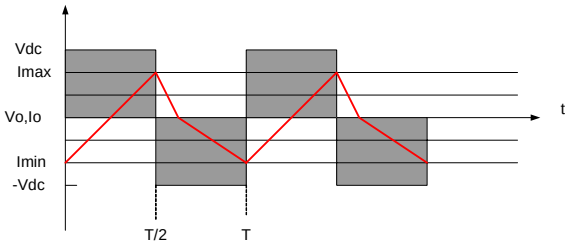

Figure 4. Output voltage and current waveform for PWM operation.

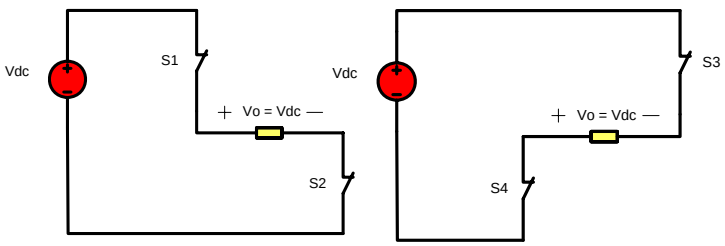
The full-bride inverter circuit is shown in Fig.3. Its output and current waveform are shown in Fig.4. During the first half-cycle, S1, S2 is closed while S3 and S4 is opened. The circuit as shown in Fig.5 (A) will get V_O=V_{dc}. In the next half-cycle, S3, S4 is closed while S1 and S2 is opened. The circuit as shown in Fig. 5(B) will get V_O= -V_{dc}



(A) (B)

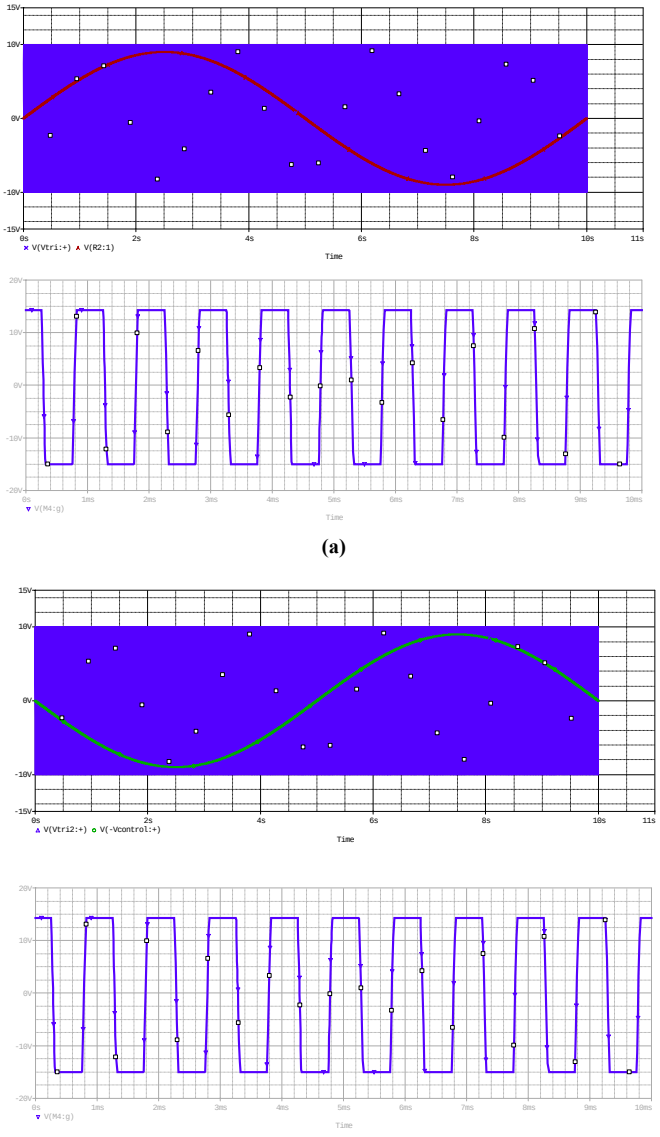
Figure 5. (A) The first half cycle, (B) The second half cycle.

From in Fig.3 point A and B of the full-bridge inverter are controlled by comparing V_{tri} carrier signal (V_{tri} = 1kHz) with V_{ref} reference signal (V_{sine} = 0.1 Hz) and V_{tri} with - V_{ref}. The waveforms are used to control the switch as follows:

At point A: $V_{ref} > V_{tri}$: S1 on and
$V_{ref} < V_{tri}$: S4 on

At point B: - $V_{ref} > V_{tri}$: S3 on and
- $V_{ref} < V_{tri}$: S2

The PWM signal obtained simulations are showing Fig.6.



(a)

(b)

Figure 6. PWM signals (a) at point A (b) at point B.

III. EXPERIMENT

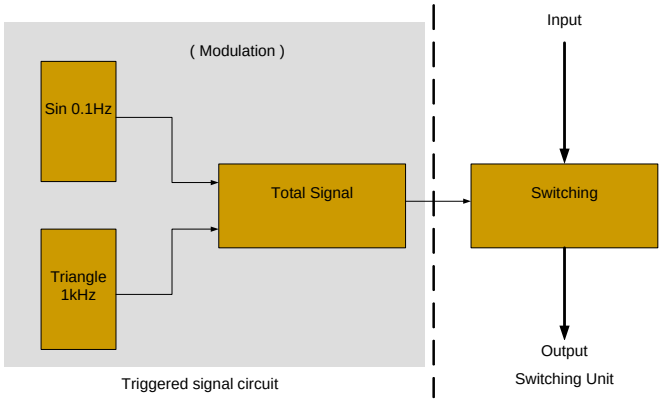


Figure 7. Block Diagram of the Modulation System.

The basic idea of the new modulation circuit is shown in Fig 7. It is used to generate sine wave signal at frequency 0.1 Hz and triangle wave signal at frequency 1 kHz. These two signals, then, are modulated to combine these signals into the total signal. This total signal is used to trig the switching unit

Triggered signal circuit

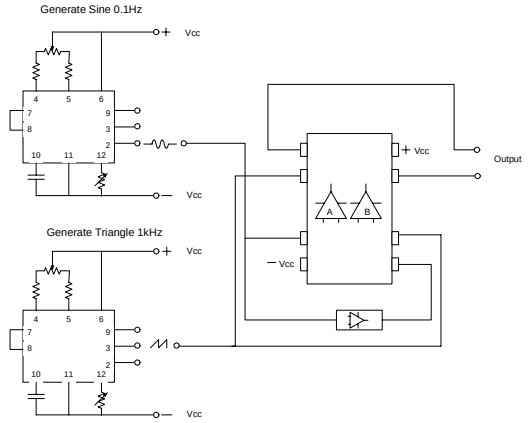

Figure 8. Triggered signal circuit.

The modulation system in Fig. 7 is schematically shown in Fig.8. The output signal is shown in Fig.9.

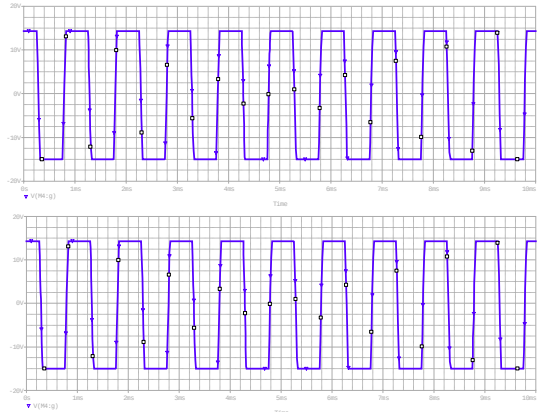

Figure 9. The actual triggered signal.

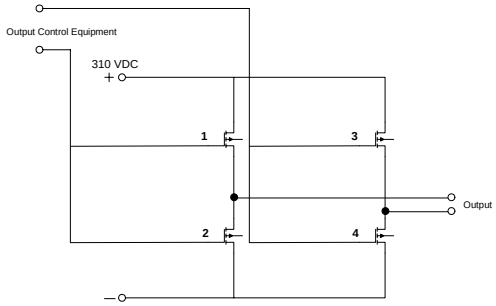
Switching unit



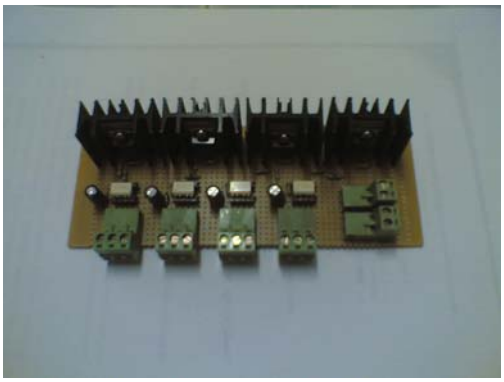


Figure 10. Switching circuit.

The input voltage for the switching circuit is obtained form rectifier which is 310 V_{dc}. The output of this switching circuit is a modulation of a 0.1Hz and 1 kHz carrier waveform at the magnitude of 310Vac. The simulation result is shown in Fig.11. Then, this signal is filtered by the LP filter as shown in Fig. 12.

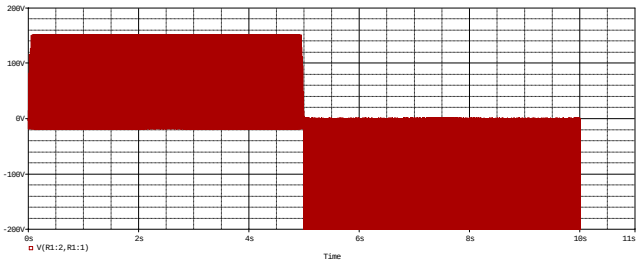

Figure 11. The simulated modulation signal in switching unit.

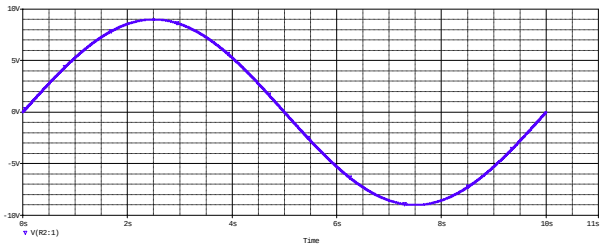

Figure 12. The filtered modulation signal

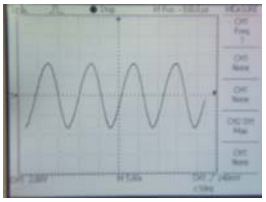
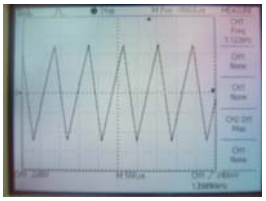
IV. IC System

Generate Sine 0.1Hz and Triangle 1 kHz

The waveform generator IC in Fig. 8 is capable of producing high accuracy sine, triangular waveform. The frequency can be selected externally from 0.1 Hz to more than 1 kHz.



Generated Sine wave 0.1 Hz



Generate Triangle wave 1 kHz

Total Signal

To combine two signals generated from wave generator IC in Fig.8, two independent, high gains, internality frequency compensated operational amplifiers which a signal power supply over a wide range of voltage are needed. These two Op-Amps should be easily implemented in single power supply systems.

V. Discussion

The utility of the idea discussed above can be shown by illustrating systems that have been designed using these techniques.

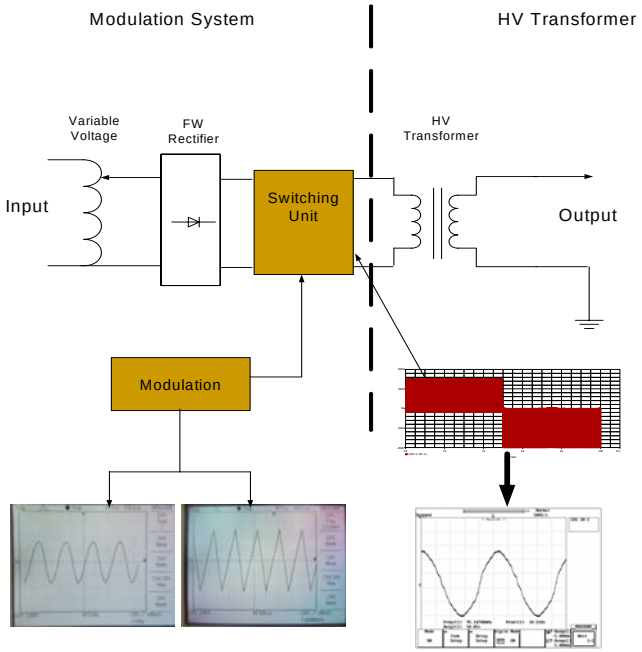


Figure 13. VLF System

When the output signal of the switching unit is filtered by the LP filter, the signal will be 0.1 Hz sine wave signal as shown in Fig.14. The signal can be looked as a sine wave with a frequency of 0.095 Hz.

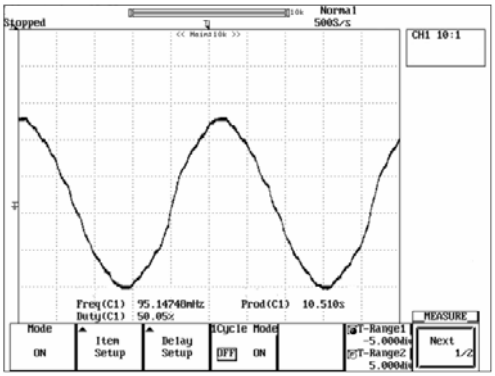

Figure 14. Waveform Produced by Power Equipment after transfer LP filter

VI. Conclusions

The modulation system described in this paper will be used for VLF transformer. This modulation circuit decreases the size of the transformer and reduces cost of the equipment used for withstand test of cables.

The Challenges of Near-Future EMC Facility

Vichate Ungvichian
EMI Lab., Florida Atlantic University, Boca Raton, Florida, email: ungvich@fau.edu

Abstract -This paper presents the upcoming Electromagnetic compatibility (EMC) requirements and its ripple effect to the EMC evaluation companies. The upper frequency during the EMC evaluation has to cover up to 10 harmonics of the highest operating frequency or 40 GHz, whichever is the lower of the two [1]. Most EMC compliance laboratories are capable of measuring the emissions up to about 5 GHz, which is sufficient for compliance verification for most commercial devices. With the upcoming high-speed digital devices such as Bluetooth, the upper frequency needs to be increased to at least 26 GHz. A challenge lies in the performance of a test site and the sensitivity of a receiving system. A new VSWR technique is proposed to quantify the site. This site validation is very similar to the full-anechoic chamber [2] used in the antenna characterizations [3]. Further discussion will be on the conducted and radiated emissions, the measurement setup and the difficulty in obtaining repeatability.

Keywords: EMC, site evaluation, OATS, Semi-anechoic room, VSWR

I. INTRODUCTION

In the early seventies, Federal Communications Commission (FCC) received many consumers' complaints that the digital devices degraded the sound and picture qualities of their radios and televisions. Performance of amateur radios was also affected. Subsequently, limits at a fixed distance (3, 10, or 30 meters) were introduced to combat the unwanted emissions from several types of devices. According to the FCC Part 15, Subpart B ruling (unintentional emissions), any electronic device employing digital technology and operating 9 kHz clock or higher, must comply with this requirement [4].

In the modern world, digital technology has played a significant part of our daily lives. For example, cell phones, palm tops or PDAs, which use such technology, are present everywhere. The devices have been improved in the past two decades with immense sophistications. Laptop computer operating clock speed has reached 3 GHz and is expected to be even higher. Consumers demand that devices operate longer requiring either better efficiency batteries or lowering system operating voltages. Lithium-ion or Metal Hydride technology has been used in computer or electronic consumer products. However, battery research continues to push for higher performance in terms of storage and recharging time. Fuel cell technology has received more attention in the past decade. The current goal is to use fuel cells as sources of high power supply. But for low consuming power computing devices, Lithium-ion battery is sufficient to supply the power to the units. The computer charger based on the switching power supply (SPS) converts the AC to DC to replenish its energy. The SPS is very noisy in terms of emissions due to the conversion process and it can be used as a conducted noise reference [5].

A commercial product like an SPS must undergo conducted emission evaluations in the typical 150 kHz to 30 MHz frequency range [1, 6-8]. This is an emission generated from the device that directly feeds the unintentional current back to the power grid. If it is strong enough, the emission can interfere with the sensitive devices sharing the same circuit.

A transducer used to monitor the conducted emissions, known as a line-impedance-stabilization network (LISN), provides known load impedance [1] to the device under test (DUT), also filters utility-line noise. The LISN used in this paper operates from 150 kHz to 30 MHz. The LISN has the impedance at 150 kHz around 30 Ω and increases to about 47 Ω from 1 MHz to 30 MHz.

For radiated emissions, normally, the measurements were performed on either an open area test site (OATS) [9] or inside a semi-anechoic chamber. The digital device was placed on an 80-cm wooden table situated above an OATS, and over the metallic ground plane. The minimum conductive ground plane dimensions suitable for selected distance are described in [1]. There should be no large scattering objects or buildings in the vicinity of OATS. For the Semi-anechoic chamber, the absorbing materials are installed on all four walls and the ceiling.

The unintentional radiated emission assessment is another evaluation that the devices have to comply. The emission limits described in the FCC Code of Federal Regulations (CFR) Part 15, Subpart B, are based upon the location of the device to be used, either at a residential or commercial venue. The limit applicable to device for residential use is more stringent than those for a commercial application.

For a low power-transmitting source, the device must comply with the FCC CFR Part 15 Subpart C, Intentional radiator requirements [4]. The discussion of this paper will only be limited to devices operating in the 88-108 MHz FM band. The advertising industry and entertainment industry have low power accessories that allow the consumer to retrofit newly available devices to vehicle. The

modifications stems from direct connect or coupling to the existing aerial antenna. This new category for measurement setup for compliance assessment will be discussed in the subsequent section.

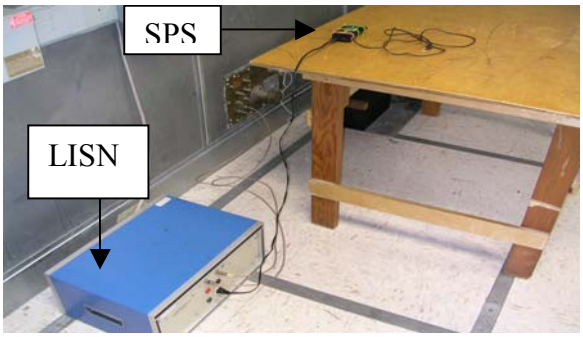
II. CHANGLLENGES

A. *CONDUCTED EMISSIONS*

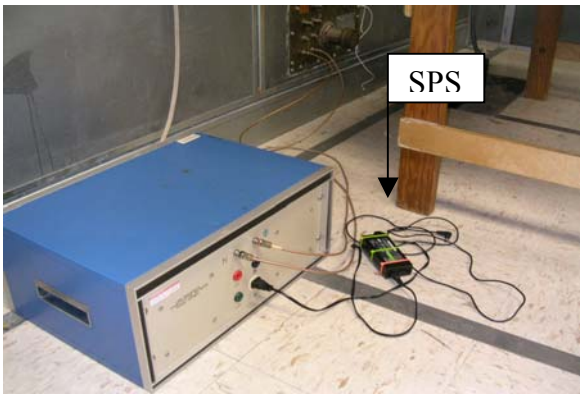
This aspect of measurement is to determine the voltage level of emission generated by DUT during operation that is transmitted back to the main power utility. As a minimum requirement, the site must have a 2X2 m^2 horizontal ground plane. This is suitable for a floor type of device. An additional 2X2 m^2 vertical ground plane, which is electrically connected with the ground plane along the line where both plates meet, is needed for tabletop device [1, 6]. The LISN bonded to the ground plane is the monitoring junction in which its output port is connected to a receiver, such as a spectrum analyzer.

In most cases, the DUT is easily classified as either floor or tabletop operating device. However, there are many DUTs with unclear classifications. The worse case emission scenario should be the goal of the assessment. But the problem would be how to search for the configuration that will produce the strongest emission and at the same time the results can be reproduced elsewhere, such as at another test laboratory. The conducted evaluation throughout this study has been performed in the shielded enclosure, which has satisfied the site requirements.

As demonstrated, the emissions generated by a SPS used with the laptop computer are setup and measured as tabletop floor. Picture 1 is the tabletop setup and the emission result is depicted in Figure 1. Picture 2 is the floor setup. After moving the cable and the SPS, the emission reading became worse. It can be seen from Figure 2 that very different results are obtained by as much as 10 dB at some frequencies. With the floor setup, stronger emissions on an average can be obtained. The phenomena are due to the mutual coupling between cable and the SPS with the conducting ground plane.



Photograph 1: Laptop SPS on the Table



Photograph 2: Laptop SPS on the Floor

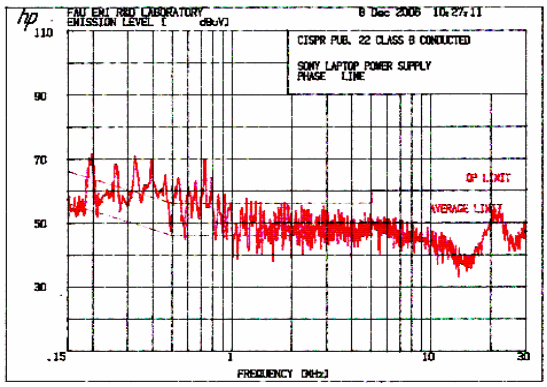


Figure 1: Laptop SPS on the Table

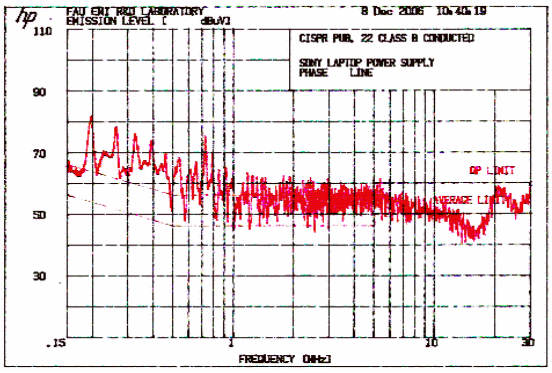

Figure 2: Laptop SPS on the Floor

B. *RADIATED EMISSIONS*

In an attempt to validate the EMC test site beyond the operating frequency of 1 GHz, CISPR has developed a draft CISPR 16-1-4 entitled "Site Evaluation above 1 GHz" [10], which is expected to get an approval sometime this year. The document applies for the site assessment from 1 GHz to 18 GHz. Similar to the current standards, test volume that the DUT occupied is defined as a cylindrical volumetric with radius and the height. The voltage standing wave ratio

(VSWR) is used as a figure of merit in the site performance evaluation. Actually, this approach has been used to assess the classical full-anechoic chamber suitable for antenna pattern and gain measurements. The quieted zone is a common terminology for the RF engineer, which is defined in terms of the amount of amplitude and phase of electric-field ripple on a plane perpendicular to the income wave within a specific area [2-3]. The spherical coordinate system is used in the antenna research. To modify OATS and Semi-anechoic chamber to perform similar to full-anechoic room, the ground plane must be lined with RF absorbing material, to reduce the reflection from the conductive ground. The differences are that the phase information has been ignored and the cylindrical coordinate system is used in the latter. Also the amplitude fluctuation is more relaxed than the full-anechoic room. The lowest height of both transmitting antenna and receiving antenna are 1 meter above the floor. Figures 3-4 depict the cylindrical volume in top view and side view with designated 6 positions at each location [10].

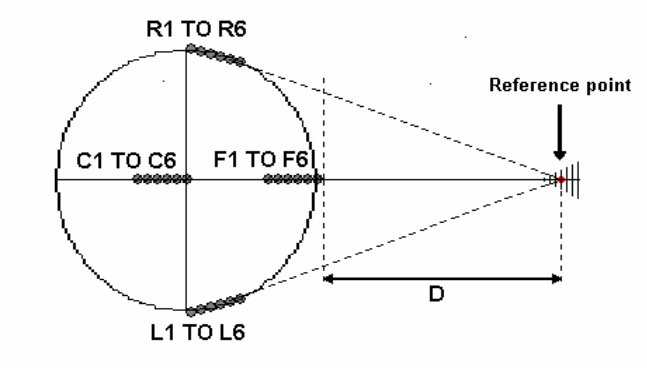

Figure 3: The Volumetric Top View

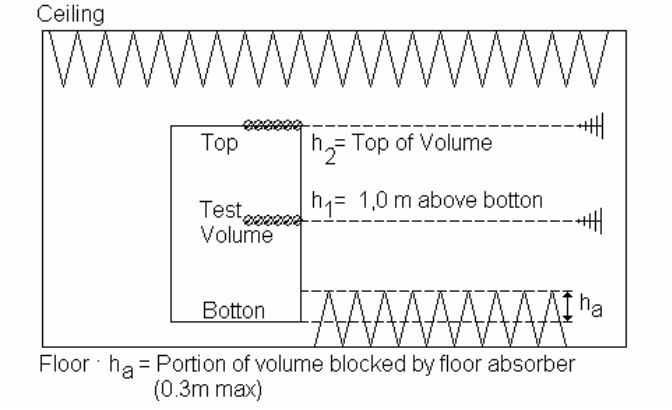

Figure 4: The Side View of VSWR Measuring Positions (Different Height)

There are two VSWR procedures, which are the Standard Site VSWR and Reciprocal Site VSWR. The former is used for OATS and the latter is for Semi-anechoic chamber. The main difference between both procedures is the reversed position between the transmitting antenna and receiving probe. At each location on OATS volume, the measurements will be performed for six predetermined points. The first location (F6, R6, L6 and C6) is the nearest distance, defined in the specification, from the antenna (reference point), see Figures 3-4. The transmitting antenna, which will be subsequently used for normal radiated emissions, is placed at those locations. The distances of 5 locations are the first location (closest to the antenna) plus 2, 10, 18, 30 and 40 cm away from the probe for the subsequent locations. It is important to keep the receiving probe location fixed. The voltage readings are corrected using the distance factor, which is in dB as 20xlog ($D_{actual}/D_{reference}$). After the readings have been corrected for all of the 6 locations and all positions (left, right, front), the site will be acceptable, if the maximum VSWR is ≤ 6 dB across the frequency band. If the top of the volume is ≥ 0.5 m, then the process has to be repeated at this height. However, if the top of the test volume is > 1.5 m, not only will the process have to be repeated, but the additional center position must be included in the assessment. Finally, both horizontal and vertical polarizations must be measured to complete the data set.

The challenges are two folds: 1) the accuracy of distance and six movements along the position as shown in Figures 3 and 4, 2) the receiving signal to process a linear characteristic and maintain 20 dB above the receiver display noise floor.

1) The smallest movement in the order of 2 cm and the broadside aiming of the antenna toward the probe are called for. This may need a laser measuring distance device having ±2 mm accuracy to reduce the measuring uncertainty.
2) The typical probe sensitivity is around 1 V/m. This seems manageable for low GHz. Even with a good amplifier, the transmitting antenna performance and cable loss are stacked up against the required 20 dB signal above the noise floor. The amplifier gain of 30-40 dB can be achieved with current technology. The low-loss cable (TFlex 401) can provide the cable loss of 50 dB/100 ft at 18 GHz. For GHz frequency application, the cable resonance due to the diameter has to be considered. When the operating frequency is above the resonance, the cable no longer possesses only the transverse electromagnetic (TEM) mode, but the multi-modes as well. Hence, the cable loss is quite complicated to determine. The connector is another point of concern. A high quality type N connector without corner bend can handle up to 18 GHz. The 2.9 mm connector may have to be used instead, to extend the upper frequency to 40 GHz. To reduce the distance between the receiving antenna and hence, the cable loss, the

receiving system may have to be placed on a movable cart lined with absorbing material.

C. SEMI-ANECHOIC CHAMBER SHIELDING EFFECTIVENESS

OATS is the simplest site to construct [9]. In the GHz range, the ground plane may not reflect as well, but due to the antenna characteristic, less electric field will illuminate the ground. In addition to having an absorbing material in the area between the receiving antenna and test volume, the ground plays very little role at this frequency range due to the antenna beamwidth. However, for a sweep frequency technique normally employed in EMC test procedure, the ambient has become a major factor in assessing the emissions. But, for a semi-anechoic chamber, the ambient signals will be attenuated from the shielding walls and absorbing materials inside the room. If the existing EMC semi-anechoic room is upgraded to operate beyond 1 GHz, the shielding effectiveness as well as power-line filters must be evaluated. A specification of commonly used EMC filter covers up to 10 GHz. The filters must be either replaced or retrofitted with higher frequency units. Further concern is the room shielding effectiveness in the high GHz frequency. The gaps or slits around the corners or connections between plates may be large in terms of electrical wavelength, and hence they act like apertures. It is recommend that the shielding effectiveness of the room be quantified beyond 1 GHz.

D. SETUP EXPLORATORY

To keep up with new technology, many companies design digital electronic accessories that are retrofitted to the commonly found devices with minimum efforts. The discussion focuses on the radio entertainment industry. For example, the CD player becomes a standard device on late model luxury vehicles. But this is not true for early models; only the AM/FM radio with cassette tape is available in the standard models. When the consumer demands an upgrade, many companies currently offer an external CD player having the coupling mechanism connected to the existing radio antenna as a mean to feed the CD signal directly to the radio RF input. Hence, the original vehicle antenna behaves either in the receiving or transmitting mode. As when the CD signal presents, the vehicle antenna operates in the transmitting mode. The RF leakage may interfere with the proximal vehicles. This RF emission must also comply with the unintentional limit (FCC Part 15 Subpart B) except for the CD intentional frequency (normally in the FM band) where the 250μV/m field strength at 3 m is the limit. Currently, there is no description in the EMC documents [1, 6-8] on how to setup this type of accessory for compliance assessment.

E. EQUIPMENT

An early version of a residential cordless phone, analogue technology operating in the 43-49 MHz with 25channels is used. Later, digital phones operating at 900 MHz, 2.4 GHz and currently 5.8 GHz bands are available. One observation is that for the 2.4 GHz cordless phones, the 10^{th} harmonic (24.0 GHz) is already beyond the intent of the draft CISPR 16-1-4. This is a void at this juncture. For the 5.8 GHz phones, the 10^{th} harmonic is 58.0 GHz, which is over the 40 GHz limits [1]. Hence, only the emission will be evaluated to 40 GHz. Similar to 3.5 GHz phones, the upper limit for compliance testing is 40 GHz. To validate the device compliance, the receiving system [11], including amplifier, cable, connector, antenna, and receiver must be sensitive enough to measure the average electric field of 54 dBμV/m (500 μV/m) at a 3 m distance. This is a challenging task. The system noise floor including noises from the amplifier and receiver is an important factor in determining the system sensitivity. In addition, the receiver noise will increase when the required receiver resolution bandwidth setting is at least 1 MHz [4]. If the amplifier gain is insufficient, then the limit value may be below the noise floor. Obviously, the compliance condition is undetermined.

In the classical antenna characterizations, such as gain or beamwidth, the operating bandwidth is normally in the order of 1 decade. The data collection is done by focusing on a particular frequency at a time. Hence, the resolution can be drastically reduced and the transmitting signal will be higher than the EMC emissions. Therefore, the sensitivity of the receiving system for the antenna area is not an important issue. But for the EMC, the radiated emission covers from 30 MHz to 40 GHz, which is over 3 decades of frequency spans. Several receiving antennas as well as amplifiers must be used in the efforts. One option to overcome the loss is the use of the waveguide system. There is a trade off in the data collecting time due to the waveguide narrow band behavior.

III. CONCLUSIONS

The progress in digital electronics in the last five years has been tremendous. The EMI community must be prepared to upgrade their equipment for the commonly found GHz devices. The EMI test facilities are facing tough challenges in the receiving system sensitivity and bandwidth. Even with the use of the average detector and with preamplifier and the best cable, the compliance limit may be only a few dB above the display noise floor, for the MHz receiver resolution setting. Furthermore, the test site assessment in the GHz range is also a challenge. Very limited documentation suggests the VSWR method can be used for the site evaluation beyond 1 GHz. The interference from other unwanted RF sources are everywhere for OATS; whereas a semi-anechoic chamber with sufficient shielding will eliminate those signals. However, the chamber may be

more difficult to pass the VSWR technique, due to the reflection from chamber walls as well as the floor lined with imperfect absorbing materials.

In the case where the measurement setup does not explicitly describe the setup for a particular device, engineering judgment plays an important decision. Depending upon the conducted emission setup for SPS, either tabletop or floor placement, the reading can be different as much as 10 dB. To be conservative, the worse case value and scenario should be used. Finally, the in situ measurement may still be needed and data should be acceptable if it is impractical to bring the device into the chamber area.

I. INTRODUCTION

Recently, demand for high power converters for adjustable speed drive for industry, and electric railway system as well as power electronics-based power system devices such as FACT and Custom Power Devices has been increased. These high power converters must capable of handling both high voltage and high current. Connecting several power semiconductor switches in series to increase withstanding voltage level of a composite switch in conventional two-level inverter is not practical due to voltage sharing problem and limited performance. Multilevel inverter technology has emerged as the solution for working with higher voltage level.

Multilevel inverters include an array of power semiconductors and capacitor voltage sources. The output voltage is generated in stepped waveforms. The commutation of the switches permits the addition of the capacitor voltages, which reach high voltage at the output, while the power semiconductors must withstand only reduced voltages [1]. The advantages of multilevel inverter include better electromagnetic compatibility, lower output voltage THD, and higher efficiency due to lower average device switching frequency [2].

Three different topologies have been proposed for multilevel inverters: diode-clamped (neutral-clamped); capacitor-clamped (flying capacitors); and cascaded multicell with separate dc sources. In addition, several modulation and control strategies have been developed or adopted for multilevel inverters including the following: multilevel sinusoidal pulsewidth modulation (PWM), multilevel selective harmonic elimination, and space-vector modulation (SVM) [1].

Sinusoidal pulsewidth modulation (SPWM) technique is commonly used in the two-level inverter and can be applied to multilevel inverter as well. In multilevel sinusoidal puslewidth modulation, multiple carrier signals are used. There are two techniques developed for multicarrier SPWM; phase-shifting carrier and level-shift carrier method [1].

Currently, pulsewidth modulation circuits are included in some of high performance microcontrollers or digital signal processors (DSP). These modulation circuits, however, are designed for use extensively with two-level 6-switch inverters. Multilevel inverters, on the other hand, require larger number of gate signals than those provided with the DPS. If the DPS is used for generating gate signals for multilevel inverter, which can be done by software approach, the burden of the DSP computation increased and results in delay time of the control loop.

This paper proposes application of field programmable gate array (FPGA) for gate signal generation for a five-level flying-capacitor multilevel inverter, which requires 24 gate signals. The design and programming of the FPGA are based on the Quartus II program. The design makes use of Mega Function block diagram already included in Quartus II. This can reduce error and required no VHDL programming skill. The designed circuit is implemented with Altera ACEX1K FPGA and can interface with microprocessor system via 3-bit address bus and 10-bit data bus.

In the following section structure of flying capacitor inverter and multilevel pulsewidth modulation are firstly reviewed. Then the implementation of FPGA for pulsewidth modulation is explained. Finally, the experiment and experimental results are reported.

II. CONFIGURATION OF FIVE-LEVEL FLYING CAPACITOR INVERTER

Fig. 1 illustrates the fundamental building block of a phase–leg of a five-level flying-capacitor inverter. The outermost capacitor is called common DC link capacitor and the other capacitors are called flying capacitors.

The output voltage between point A and 0, i.e. V_{A0} is the result of the summation of the capacitor voltages in series, which can be expresses by

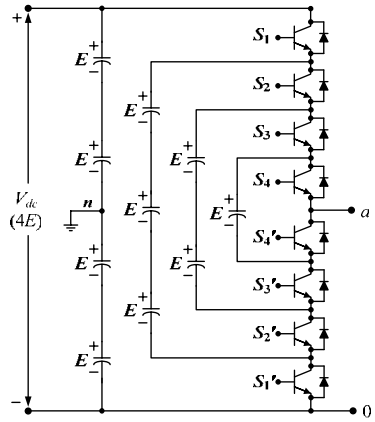

Figure 1. Fundamental building block of a phase-leg of five-level flying-capacitor inverter.

$$V_{A0} = \sum_{i=1}^{m-1} S_i E, \tag{1}$$

$$\text{where, } S_i = \begin{cases} 0 & \text{when switch } i \text{ is "OFF"} \\ 1 & \text{when switch } i \text{ is "ON"} \end{cases}, \tag{2}$$

TABLE I
POSSIBLE SWITCHING STATES OF A FIVE-LEVEL FLYING CAPACITOR INVERTER

Switching states				Output voltage related of capacitor	Inverter phase voltage v_{AN}	C_1	C_2	C_3	C_4
S_1	S_2	S_3	S_4						
1	1	1	1	4*E*	V_{dc}(4*E*)	-	N	N	N

Index: 1-sw on, 0-sw off, N-none, + charging mode, - discharging mode

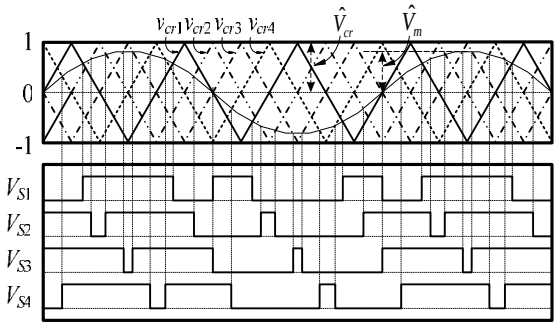

Figure 2. Method for phase-shift carrier pulsewidth modulation.

m is the number of voltage level, S_i is the switching state of the i^{th} switch, and *E* is the voltage across each capacitors, which are assumed to be constant and equal.

In Fig. 1, the voltage across each switch is *E*, and the output voltage could be produced from 0 with the entire switch turning off to 4*E* with the entire switch turning on. Table I summarizes the possible switching state and its corresponding output voltage for the inverter in Fig. 1. In Table I, there are redundant switching states that produce the same output voltage. These redundant states can be utilized for balancing the flying capacitor voltages.

III. MULTILEVEL PULSEWIDTH MODULATION FOR FLYING CAPACITOR MULTILEVEL INVERTER

Two types of multilevel pulsewidth modulation have been developed for multilevel inverter; phase-shifted carrier; and level-shifted carrier technique [3]. Only phase-shifted carrier technique is adopted in this paper. Fig. 2 illustrates the method of phase-shifted carrier pulsewidth modulation. For five-level flying capacitor inverter, four triangular carrier signals with 90-degree phase shifted between each signal are used.

The amplitude modulation index is defined by

$$m_a = \frac{V_m}{V_c}, \ 0 \le m_a \le 1, \tag{3}$$

where, V_m is the amplitude of the modulated signal and V_C is the amplitude of the carrier signal.

The frequency modulation index of the output voltage is given by

$$m_f = \frac{f_c}{f_m} \tag{4}$$

where, f_c is the frequency of the carrier signal and f_m is the frequency of the modulated signal.

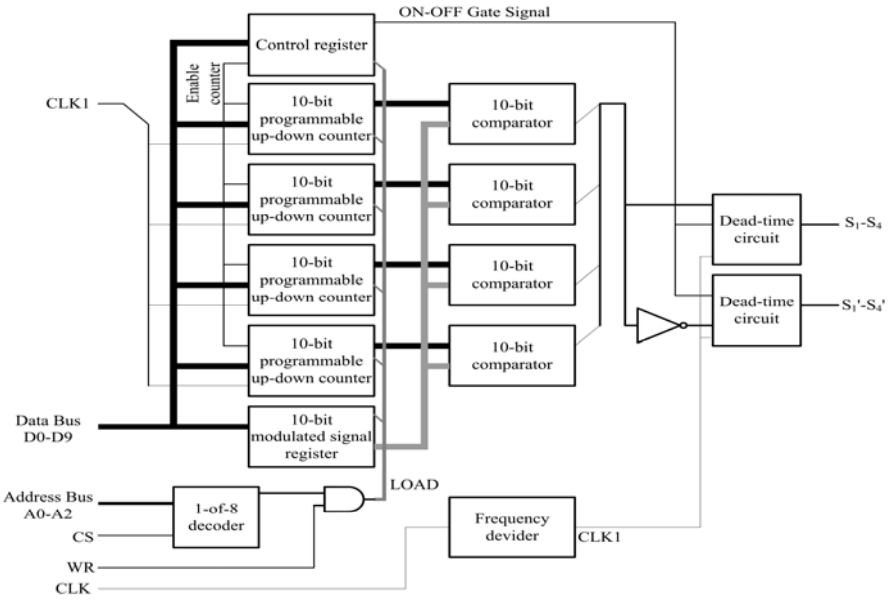

Figure 3. Block diagram of the designed FPGA-based gate signal generator

The device switching frequency is equal to the carrier frequency and the inverter frequency or the output voltage frequency is equal to $(m-1) f_c$.

IV. Implementation of FPGA for Pulsewidth Modulation

A. Block Diagram of Gate Signal Generator

The design and verification of the circuit was done on Quartus II Web Edition. The design makes use of Mega Function block diagram already included in Quartus II. This helps reduce error and requires no VHDL programming skill.

Fig. 3 illustrates block diagram of the modulator for one leg of the inverter. The overall circuit for the inverter generating the total of 24 gate signals includes four up-down counters, three 10-bit modulated signal registers, and twelve 10-bit comparators.

An 18.432 MHz external clock is divided by 12 to make 1.5636 MHz CLK1 signal for the counters and dead-time circuits. Four independent 10-bit up-down counters are used for triangular carrier signal generation. The phase shift between each carrier signal can be programmed by its initial value. In this paper the phase shift between these signals is set to 90 degrees. The frequency of the carrier signal is set to 750Hz. In each sampling, the value of modulated signal will be loaded into the modulated signal register and compared to the carrier signals by 10-bit comparators. The outputs of the comparators are subjected to the dead-time circuit before sending out to the external gate-drive circuits. The dead-time circuit includes four set of D flip-flop in cascade connection. The dead time is equal to four clock signal periods or 2.558 microseconds. The control register controls the operation of the counters and dead-time circuits. To enable or disable the operation of the counter and the dead-time circuit, pre-defined value must be written to this register. Each counter and register has its own address. Access of these devices is controlled by the 1-of-8 decoder.

Figure 4. Picture of FPGA development board

B. FPGA Board

The Altera ACEX1K FPGA is adopted in this paper. Fig. 4 shows the development board. The FPGA features 30,000 typical gates, 1728 logic element, up to 24,576 bit of memory, and independent 171 input-output pins [4]. A blank socket on the top-right of the board is for configuration device storing the design circuit. The stored content will be automatically loaded into the FPGA during power up.

V. Experiment and Results

A prototype three-phase five-level flying capacitor inverter as shown in Fig. 5 has been constructed for experiment. The details of the inverter are given in Table II. A PC equipped

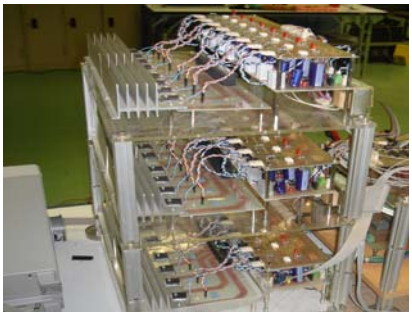

Figure 5. Picture of the prototype five-level flying-capacitor inverter

TABLE II
Parameters of the Prototype Five-Level Flying-Capacitor

DC link capacitor	2.2 mF 450VDC
Flying capacitor	2.2mF 450VDC
DC link voltage	200 V
IGBT	G2BN60B3D (1200V,40 A)
Load	500 W resistive

with a PCI-to-8255 PIO board is used for modulated signal computing. The modulated signals are sent to the FPGA via the PCI-to-8255 PIO board. The modulated signal is computed at a rate of 10,000 samplings per second. The fundamental frequency of the modulated signal is 50Hz.

Fig. 6 shows captured signals during the loading of modulated signals into the modulated signal registers. The figure shows sequentially sending of phase-a, phase-b, and phase-c modulated signals, respectively.

Fig. 7 illustrates captured signals demonstrating the result of the dead-time circuit. The designed value of the dead time is attained.

Fig. 8 shows the captured waveform of the output line-to line voltage. The line-to-line voltage results in 11 voltage levels and agrees well with theoretical results.

VI. Conclusions

For multilevel inverter a larger number of gate signals are required and the software-based gate signal generation is not efficient as it increases computation burden to the DSP or microcontroller. FPGAs are more suitable for this task because all the computations are performed by the dedicated hardware. The application of FPGA for gate signal generation for a five-level flying-capacitor multilevel inverter has been proposed and explained. The experiment has been carried out using prototype laboratory-built inverter and the FPGA-based gate signal generator functioned as designed.

***Abstract*-This paper presents the study and comparison of PWM schemes for five-level flying capacitor inverter. The PWM schemes. Included in this study are phase-shifted and level-shifted multi-carrier sinusoidal modulation. The comparison focuses on output voltage THD, capacitor voltage balancing and effect of the dead time. The results of the comparison will be used to aid the design of five-level flying capacitor inverter in the future.**

***Keywords* - Flying-capacitor multilevel inverter, SPWM, total harmonic distortion, energy balance.**

INTRODUCTION

In recent years, industry has begun to demand higher power equipment, which now reaches the megawatt level. Controlled ac drives in the megawatt range are usually connected to the medium-voltage network. Today, it is hard to connect a single power semiconductor switch directly to medium-voltage grids (2.3, 3.3 or 6.9kV). For these reasons, a new family of multilevel inverters has emerged as the solution for working with higher voltage levels [1]-[2].

Today, multilevel inverters are extensively used in high-power applications with medium voltage levels. The field applications include use in motor drive, harmonic elimination and improvement power factor in system and static VAR compensations to system.

Three different topologies have been proposed for multilevel inverters: diode-clamed (neutral-clamped); capacitor-clamed (flying capacitors); and cascaded multi-cell with separated sources. In addition, several modulation and control strategies have been developed or adopted for multilevel inverters including the following: multilevel sinusoidal pulse width modulation (SPWM), multilevel selective harmonic elimination, and space-vector (SVM) [2].

The most attractive features of multilevel inverters are as follows.

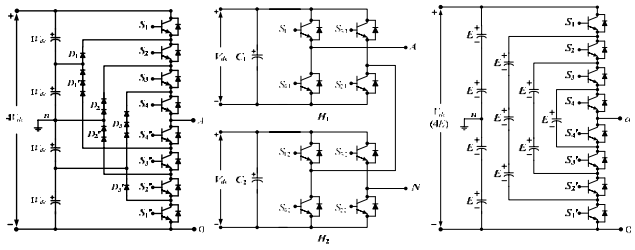
- They can generate output voltages with extremely low distortion and lower *dv/dt*.
- They draw input current with very low distortion.
- They can operate with a lower switching frequency.

Table I shows the comparison of the multilevel inverter topologies. In the application that requires energy source, such as adjustable speed drive of ac machines, the dc link energy is normally fed from the ac source via rectifier or converter circuit. Having only single dc link is the benefit in term of reliability and ease of control. Another issue concerning with multilevel inverter is balancing of voltage across each capacitor. Having capability of balancing the capacitor voltage without additional dedicated hardware is preferable. The flying-capacitor and cascade multi-cell inverter utilize the redundant switching states to solve this problem. Owning to the single dc source constraint, the flying-capacitor inverter is selected for this study.

Multilevel sinusoidal pulse-width modulation (SPWM) is investigated in this study. The PWM schemes included in this study are phase-shifted and level-shifted multi-carrier sinusoidal modulation. The investigation focuses on output voltage THD, capacitor voltage balancing and effect of the dead time. The results of the comparison will be used to aid the design of five-level flying-capacitor inverter in the future.

FLYING CAPACITOR INVERTER CIRCUIT

The flying-capacitor inverter Fig. 2 can produce an inverter phase voltage with five voltage levels. When switches S_1, S_2, S_3, and S_4 conduct, the inverter phase voltage v_{AN} is $4E$, which is the voltage at the inverter terminal A with respect to the negative dc bus N. Similarly, with S_1, S_2, and S_3 switched on, $v_{AN} = 3E$. Table II lists all the voltage levels that can be obtained by the six sets of different switching states.



(a) (b) (c)

Figure 1. Multi-level inverter topology. (a) diode-clamped. (b) cascaded-multicell. (c) capacitor-clamped (flying-capacitor).

TABLE I
COMPARISON OF MULTILEVEL INVERTER CIRCUITS TOPOLOGIES

Comparison	Diode-clamped	Cascaded-multicell	Flying capacitor
Common DC link	✓	×	✓
Redundant of switching state.	×	✓	✓
Number of dc capacitors	Few	Few	Many
Isolated voltage dc source	Single	Many	Single

The switching state redundant is a common phenomenon in multilevel converters, which provides a great flexibility for the switching pattern design.

SINUSOIDAL MULTI-CARRIER PULSE-WIDTH MODULATION

Several multi-carrier techniques have been developed to reduce the distortion in multilevel inverters, based on the classical SPWM with triangular carriers [1]. Some methods use carrier disposition and others use phase shifting of multiple carrier signals [3].

A. Phase-shifted Multi-carrier PWM Scheme

Fig. 3 illustrates typical gating signal using phase-shifted multi-carrier PWM for one phase leg of the inverter shown in Fig. 2. In this paper, we choose a number of *m*-voltage levels requires (*m*-1) triangular carriers in one phase with their carriers shifted by an angle given by

$$\theta_{cr} = 360°/(m-1), \quad (1)$$

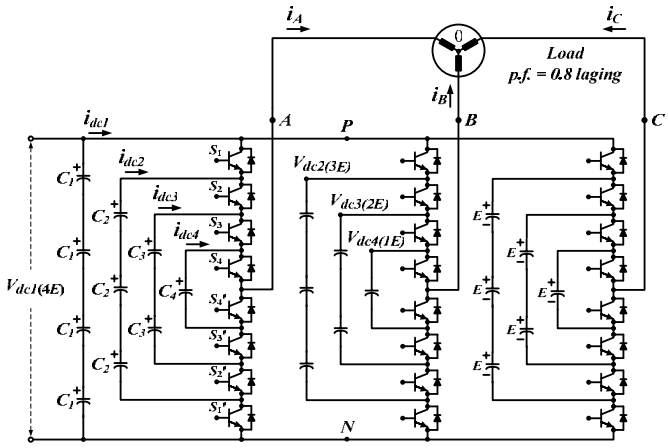


Figure 2. Five-level flying-capacitor inverter.

TABLE II
VOLTAGE LEVEL AND SWITCHING STATE OF A FIVE-LEVEL FLYING-CAPACITOR INVERTER

Switching states				Output voltage related of capacitor	Inverter phase voltage v_{AN}	C_1	C_2	C_3	C_4
S_1	S_2	S_3	S_4						
1	1	1	1	4*E*	V_{dc}(4*E*)	-	N	N	N
1	1	1	0	4*E* - 1*E*	3*E*	-	N	N	+
1	1	0	1	4*E* - 2*E* + 1*E*		-	N	+	-

B.Level-shifted Multi-carrier PWM Scheme

Fig. 4 illustrates three variation of the level-shifted multi-carrier PWM named (a) in-phase disposition (IPD) where all carriers are in phase, (b) alternative phase opposite disposition (APOD) where all carriers are alternatively in opposite disposition and (c) phase opposite disposition (POD) where all carriers above the zero reference are in phase but in opposition with those below the zero reference. In what follows, only IPD modulation scheme is discussed in detail due to page limitation.

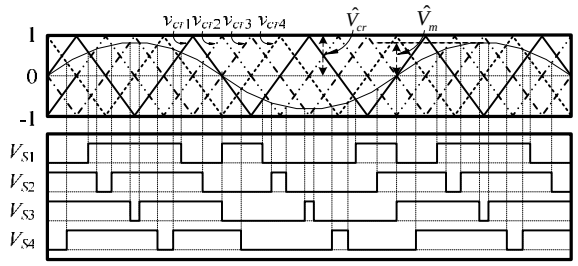

Figure 3. Modified phase-shifted modulation for five-level inverter of one phase-leg.

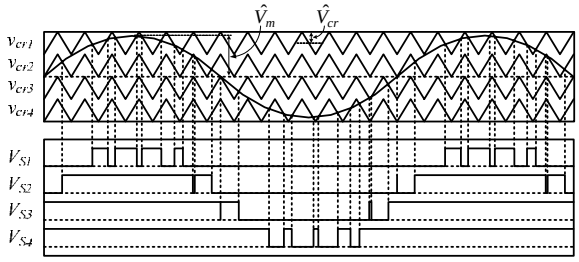
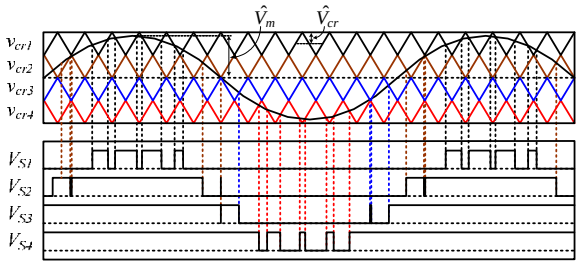
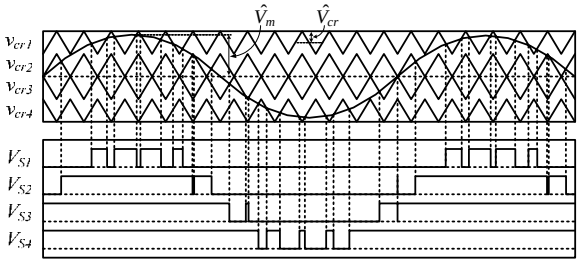


(a) In-Phase Disposition (IPD) .



(b) Alternative Phase Opposite Disposition (APOD).



(c) Phase Opposite Disposition (POD).

Figure 4. Level-shifted multi-carrier modulation for five-level inverter.

The phase-shifted PWM scheme have characteristic as follows.

$$m_a = \hat{V}_m / \hat{V}_{cr}, \quad for \quad 0 \le m_a \le 1, \tag{2}$$

$$f_{sw,dev} = f_{cr}, \tag{3}$$

$$f_{sw,inv} = (m\text{-}1) f_{sw,dev}, \tag{4}$$

where

f_m	Fundamental frequency
f_{cr}	Carrier frequency
$f_{sw,dev}$	Frequency switching device
$f_{sw,inv}$	Switching frequency of inverter
m_f	Frequency modulation index (f_{cr} / f_m)
m_a	Modulation index
m	Voltage levels

As stated earlier, the frequency of the dominant harmonic in the inverter output voltage represents the inverter switching $f_{sw,inv}$. Since the dominant harmonics in v_{AN} and v_{AB} distributed around $(m - 1)m_f$.

The level-shifted PWM scheme have characteristic as follows.

$$m_a = \hat{V}_m / \hat{V}_{cr}(m-1), \quad for \quad 0 \le m_a \le 1, \tag{6}$$

$$f_{sw,dev} = f_{cr}/(m\text{-}1), \tag{7}$$

$$f_{sw,inv} = f_{cr}, \tag{8}$$

As stated earlier, the frequency of the dominant harmonic in the inverter output voltage represents the inverter switching $f_{sw,inv}$. Since the dominant harmonics in v_{AN} and v_{AB} distributed around m_f.

SIMULATION RESULT

The simulations comparisons between both schemes are focused on three topics the output voltage THD, capacitor energy balancing and effect of the dead time. To compare the performance of inverter, it is assumed that the average switching frequency of the solid-state devices is the same in both schemes. Table III shows the important parameters used in the simulations.

Fig. 5 shows the simulated waveforms using phase-shift multi-carrier PWM schemes for the inverter operating under the condition of $m_f = 50$, $m_a = 1.0$, $f_m = 60$ Hz, and $f_{cr} = 750$ Hz. As stated earlier, the frequency of the dominant harmonic in the inverter output voltage represents the inverter switching frequency $f_{sw,inv}$. Since the dominant harmonic in v_{AB} in Fig. 5 are distributed around $4m_f$, the inverter switching frequency can be found from $f_{sw,inv} = 4m_f \times f_m = 4f_{sw,dev}$, which is four times the device switching frequency.

Fig. 6 shows the simulated waveforms using IPD multi-carrier PWM schemes for the inverter operating under the condition of $m_f = 50$, $m_a = 1.0$, $f_m = 60$ Hz and $f_{cr} = 3000$ Hz. Although the carrier frequency of 3000 Hz seems high for high-power converters, the average device switching frequency is only 750 Hz.

Fig. 7 shows the THD profile of the line-to-line voltage v_{AB} produced by the phase- and level-shifted modulation schemes. As can be seen from the Figure, the IPD modulation scheme gives the best THD result all over the length of modulation index. The phase-shift and APOD have the same THD characteristic all the range of modulation index. The THD calculation is performed up to 100th order.

TABLE III
INVERTER OPERATING FOLLOWING

Parameter operating	Phase-shifted PWM	Level-shifted modulation
f_m	50 Hz	50 Hz
f_{cr}	750 Hz	3000 Hz
m_f	15	60
$f_{sw,dev}$	750 Hz	750 Hz
$f_{sw,inv}$	3000 Hz	3000 Hz
load	PF = 0.8 *lagging*, 0.414 kVA	

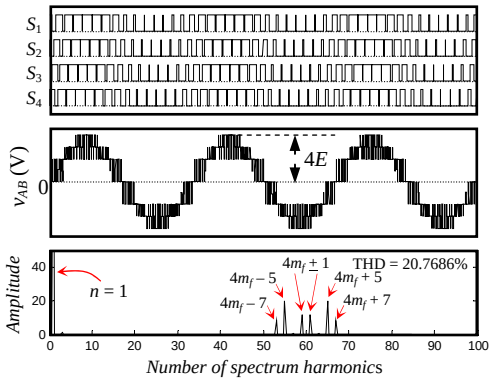


Figure 5. Simulated waveforms for a five-level flying-capacitor inverter with phase-shifted PWM (m_f =15, m_a =1.0, f_m =50 Hz, f_{cr} =750 Hz, and $f_{sw,dev}$ =750 Hz).

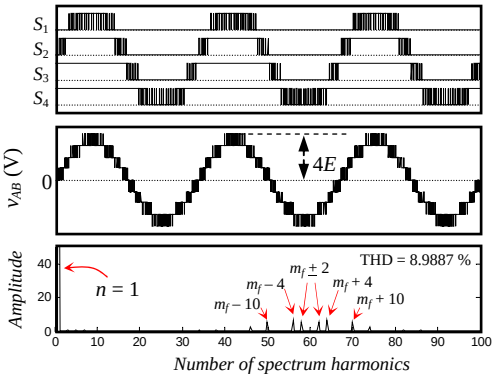

Figure 6. Simulated waveforms for a five-level flying-capacitor inverter with IPD modulation (m_f = 60, m_a = 1.0, f_m = 50 Hz, f_{cr} = 3000 Hz, and $f_{sw,dev}$ = 750 Hz).

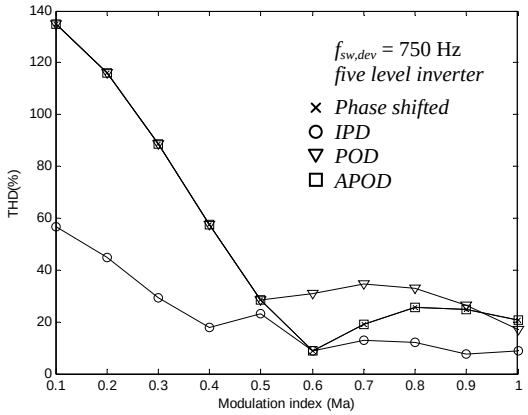

Figure 7. THD profile of v_{AB} produced by the five-level inverter with phase- and level-shifted modulation schemes.

The table IV shows the effect of dead time on THD of the inverter output voltage. The THD increased with the increased dead time but only at a very small fraction.

TABLE IV
PERCENT THD OF V_{AB} AFFECTED BY THE DEAD TIME

		Modulation Index : m_a									
	dead time	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0

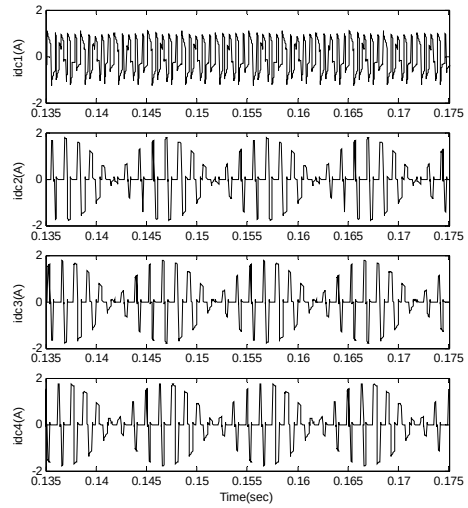
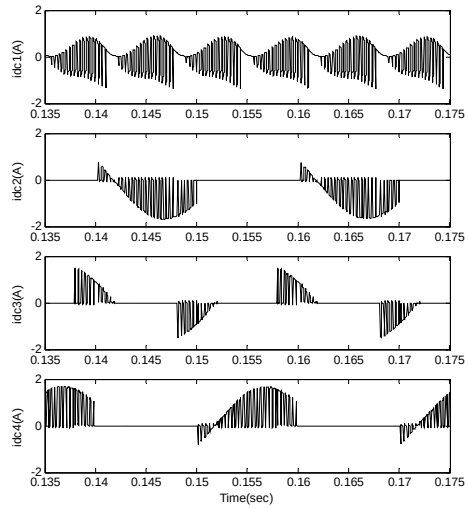
	4μs	135.33	117.03	89.83	58.85	29.35	8.28	17.39	24.09	23.53	19.17



(a) Incase of phase-shifted PWM scheme.



(b) Incase of IPD PWM scheme.

Figure 8. Waveforms of the current flowing through the flying capacitors.

Fig. 8 shows the current flowing through each flying capacitor. In case of phase-shifted PWM scheme the currents flowing in the flying-capacitors are balanced, i.e. the average current is zero. In case of IPD PWM scheme, the currents flowing through the flying-capacitors are not balanced, resulting in a non-zero average current. If no energy source is connected to the flying-capacitor; this would result in uneven level of the output voltage.

CONCLUSION

Simulations of flying-capacitor multilevel inverter have been carried out using phase-shifted and level-shifted PWM schemes. The results of the simulation are compared. The IPD PWM scheme provided the lowest output voltage THD over the range of modulation index. However it could not balance the energy flow of the flying-capacitors and could lead to uneven level of the output voltage. The phase-shifted PWM scheme, while providing a higher output voltage THD, it is capable of balancing the energy flow of the flying-capacitors. Both features, low THD and capacitor energy balancing, could not be attained at the same time by both modulation schemes.

Regarding to the THD performance, IPD PWM scheme will be suitable for adjustable speed-drive application, where full range of modulation is required. Balancing of the capacitor energy under IPD PWM scheme using a technique introduced in [4] as well as other techniques will be reported in the future.

Abstract— **A new online controller based on duty cycle control is presented. The novel control method is based on optimal control theory. The average model of converter has been used to implement the optimal controller. Also In order to acquire the average model of converter a new solution, based on the step-by-step calculation of state variables in each interval of a switching period, is presented. The approximated discrete model of converter is used to get the average model of inverter. The new proposed algorithm will control the converter's flying capacitor voltage and load current very fast and very precise. By application of this controller, the converter will be capable to track very sharp changes of reference signal. Simulation is performed by using *PSCAD/EMTDC* software.**

Keywords- Multicell converter; optimal controller;

I. INTRODUCTION

MULTICELL Converters are the new generation of high power and high voltage converters, which have been introduced, in the early 1990s. Multicell Converters, make it possible to distribute the voltage constraints among series-connected switches and to improve the output waveforms by increasing the number of levels and switching frequency. An important advantage of this circuit lies in having multiple switching combinations for the same output voltage level then they are flexible for controlling purposes**.** Under certain conditions, a simple open-loop control guarantees natural balancing of the flying voltages. Nevertheless, in this case, the dynamics involved in the balancing transient depend on the impedance of load at the switching frequency. If the impedance at the switching frequency is high (small current harmonic at this frequency) then the natural balancing is very slow and inversely. However to get the best performances, the strict conditions of interleaved patterns will not be obeyed and self-balancing will not be obtained. [1], [2]. Some efficient active control strategies, based on the feedback linearization of the nonlinear state equation of the converter, have been introduced in [2], to control the voltage of flying capacitors and output waveforms. The proposed controller algorithm will result some equations, which are very similar to the relations of the feedback linearization method described in [2]. In this paper a simple online controller is presented that controls the state variables of a Multicell inverter very fast and very precise. The $2\pi/n$ phase shift between firing angle of adjacent cells is neglected in this paper, and The main idea of the novel controller is based on optimal control theory.

II. MODELLING OF MULTICELL CONVERTERS

There are three different mathematical model used to represent a Multicell converter [3].

1) Direct or Instantaneous model
2) Average Model
3) Harmonic Model

The instantaneous model contains state variables of system including voltage of flying capacitors and the current of load inductor for any switching condition. The instantaneous model of a Multicell converter is as below:

$$\dot{V}_{c1} = \dot{X}_1 = \frac{S_2 - S_1}{C} X_2 \tag{1}$$

$$\dot{i}_L = \dot{X}_2 = \frac{S_1 - S_2}{L} X_1 + \frac{S_2 - 0.5}{L} E - \frac{R.X_2}{L} \tag{2}$$

$\boldsymbol{S_1}$ and $\boldsymbol{S_2}$ are the state of the switches and are defined as follow:

$$S_i = \begin{cases} 0 & if \quad S_{id} \quad is \quad conducting \\ 1 & if \quad S_{iu} \quad is \quad conducting \end{cases} \qquad i = 1,2 \tag{3}$$

$$\underline{X}(t) = \begin{bmatrix} X_1(t) \\ X_2(t) \end{bmatrix} \quad , \quad \underline{S}(t) = \begin{bmatrix} S_1(t) \\ S_2(t) \end{bmatrix} \tag{4}$$

By defining the $\boldsymbol{S_i}$ as input controlling signals then the controller must generate such a firing signals with proper duty cycle that the flying capacitor voltages remain at a specified DC voltage level and the waveform of the load current tracks a reference waveform.

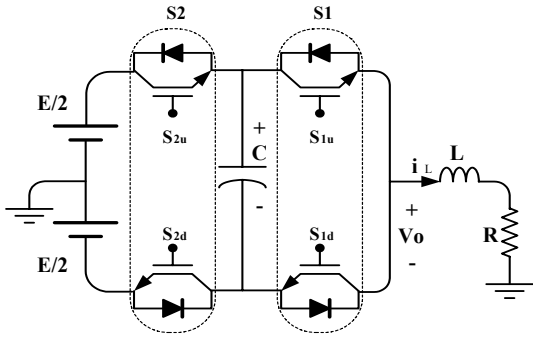

Figure 1. Multicell inverter configuration.

III. PRINCIPLE OF OPERATION OF THE DUTY CYCLE CONTROL METHOD

The main idea of the novel online controller is based on the step-by-step calculation of state variables in each time intervals (fig. 2) within switching periods by using an approximated discrete model of inverter. An approximated discrete model of inverter can be shown as follow:

$$\dot{\underline{X}}(t) = \underline{f}(\underline{X}(t), \underline{S}(t)) \tag{5}$$

$$\underline{X}(t+\Delta t) \approx \underline{X}(t) + \underline{f}(\underline{X}(t), \underline{S}(t)).\Delta t \tag{6}$$

$$\underline{X}([k+1]\Delta t) \approx \underline{X}(k\Delta t) + \underline{f}(\underline{X}(k\Delta t), \underline{S}(k\Delta t)).\Delta t \tag{7}$$

$$\underline{X}(k+1) \approx \underline{X}(k) + \underline{f}(\underline{X}(k), \underline{S}(k)).T \tag{8}$$

For example in the first time interval $kT < t < (k+D_1)T$ with a known value of $\underline{X}(k)$, $\underline{S}(k)$ and using (8) we can calculate the value of $\underline{X}(k+D_1)$ at the end of that time interval. And by successive calculations through entire switching period we can calculate the value of $\underline{X}(k+1)$ as a function of $\underline{X}(k)$, D_1, D_2.

1. $kT < t < (k+D_1)T \quad S_1 = 1 \quad S_2 = 1$

$$\begin{bmatrix} V_c(k+D_1) \\ i_L(k+D_1) \end{bmatrix} = \begin{bmatrix} V_c(k) \\ i_L(k) \end{bmatrix} + \left[\underline{f}(\underline{X}(k), \underline{S}(k)\right] \tag{9}$$

Or

$$\begin{bmatrix} V_c(k+D_1) \\ i_L(k+D_1) \end{bmatrix} = \begin{bmatrix} V_c(k) \\ (1 - RD_1T/L) * i_L(k) + (D_1T/2L) * E \end{bmatrix} \tag{10}$$

2. $(k+D_1)T < t < (k+D_2)T \quad S_1 = 0 \quad S_2 = 1$

$$\begin{bmatrix} V_c(k+D_2) \\ i_L(k+D_2) \end{bmatrix} = \begin{bmatrix} V_c(k+D_1) \\ i_L(k+D_1) \end{bmatrix} + \left[\underline{f}(\underline{X}(k+D_1), \underline{S}(k+D_1)\right] \tag{11}$$

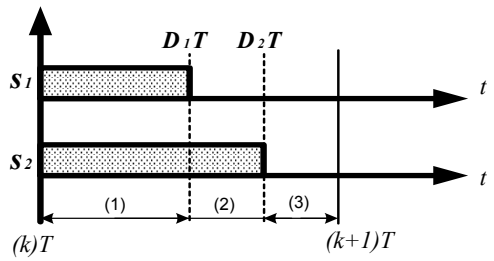

Figure 2. Time intervals created by duty cycles of switches.

$$\begin{bmatrix} V_c(k+D_2) \\ i_L(k+D_2) \end{bmatrix} = \begin{bmatrix} V_c(k) + \dfrac{(D_2 - D_1)T}{C} i_L(k) \\ (1 - \dfrac{RD_2T}{L}) i_L(k) + (\dfrac{(D_1 - D_2)T}{L}) V_c(k) + \dfrac{D_2T}{2L} E \end{bmatrix} \tag{12}$$

We have neglected the T^2, T^3, ... because T is a small number.

3. $(k+D_2)T < t < (1+k)T \quad S_1 = 0 \quad S_2 = 0$

$$\begin{bmatrix} V_c(1+k) \\ i_L(1+k) \end{bmatrix} = \begin{bmatrix} V_c(k+D_2) \\ i_L(k+D_2) \end{bmatrix} + \left[\underline{f}(\underline{X}(k+D_2), \underline{S}(k+D_2)\right] \tag{13}$$

Or

$$\begin{bmatrix} V_c(1+k) \\ i_L(1+k) \end{bmatrix} = \begin{bmatrix} V_c(k) + \dfrac{(D_2 - D_1)T}{C} i_L(k) \\ (1 - \dfrac{RT}{L}) i_L(k) + (\dfrac{(D_1 - D_2)T}{L}) V_c(k) + \dfrac{(D_2 - 0.5)T}{L} E \end{bmatrix} \tag{14}$$

Now we can rearrange (14) as follow:

$$\begin{bmatrix} V_c(1+k) \\ i_L(1+k) \end{bmatrix} = \begin{bmatrix} V_c(k) \\ (1 - \dfrac{RT}{L}) i_L(k) - \dfrac{T}{2L} E \end{bmatrix} + \begin{bmatrix} -\dfrac{T}{C} i_L(k) & \dfrac{T}{C} i_L(k) \\ \dfrac{T}{L} Vc(k) & -\dfrac{T}{L} Vc(k) + \dfrac{TE}{L} \end{bmatrix} \begin{bmatrix} D_1 \\ D_2 \end{bmatrix} \tag{15}$$

As figure 3 shows, in order to minimize J we must hold the following conditions:

$$\text{Minimize } J = \frac{1}{2} \|\underline{X}(k+1) - \underline{ref}(k+1)\|^2 = \theta[X_{k+1}] \tag{16}$$

$$\text{Subjected to: } X_{k+1} = f(X_k, S_k) \tag{17}$$

By defining the *Lagrange* function as follow we must have (18), (19) to guarantee (16):

$$L = \theta[X_{k+1}] + \lambda_{k+1}{}^T (-X_{k+1} + f(X_k, S_k)) \tag{18}$$

$$\frac{\partial L}{\partial X_{k+1}} = 0 \quad \Rightarrow \quad \lambda_{k+1}{}^T = \frac{\partial \theta[X_{k+1}]}{\partial X_{k+1}} \tag{19}$$

$$\frac{\partial L}{\partial S_k} = 0 \quad \Rightarrow \quad \lambda_{k+1}{}^T \frac{\partial f(X_k, S_k)}{\partial S_k} = 0 \tag{20}$$

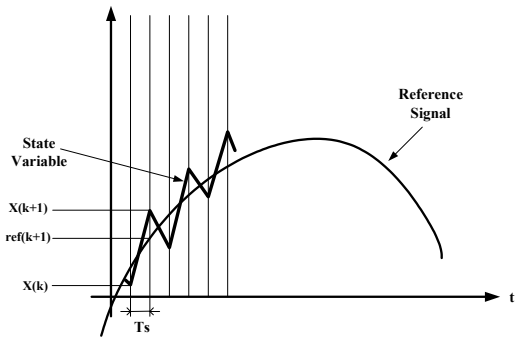

Figure 3. Tracking a reference signal by State Variable.

One apparent answer of the above equation is as follow:

$$\lambda_{k+1}{}^{T} = 0 \qquad \Rightarrow \quad \underline{X(k+1)}=\underline{ref(k+1)} \qquad (21)$$

By using (15), (21) it is possible to calculate the duty cycles.

IV. Simulation Results

By applying the controller to a 2-cell inverter with the following parameters values, the state variable waveforms are derived by using *PSCAD/EMTDC* software.

E=200kV, C=40 μ f, L=5mH, R=12 Ω , T_s=40 μ s

A. Changes in the Load Current reference signal without any changes in the capacitor reference voltage.

At the first section of simulation we will verify the capability of the controller in the tracking the sharp changes only in load current reference signal. The capacitor voltage must remain at the E/2 in order to balance the voltage consideration of the power devices.

Figure 4 shows a typical reference signal. In figure 5 the load current is presented. The ripple of the load current is negligible and controller tracks the sharp changes of the reference signal in a very short time. Also the duty cycles of switches S1, S2 are presented in figure 7. At the steady state condition the duty cycles are equal and have same waveform as the load reference current.

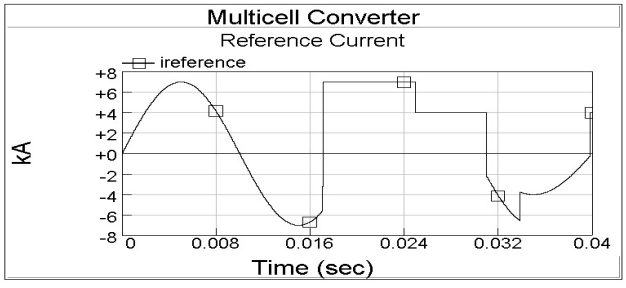

Figure 4. Load Reference Current.

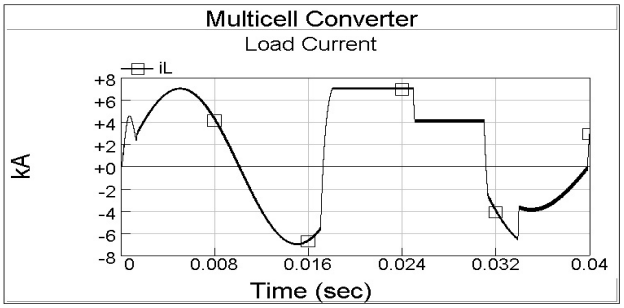

Figure 5. Load Current.

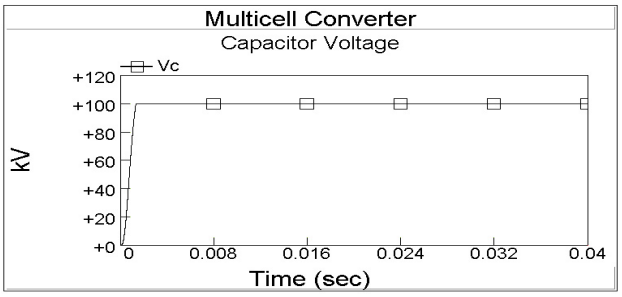

Figure 6. Capacitor Voltage.

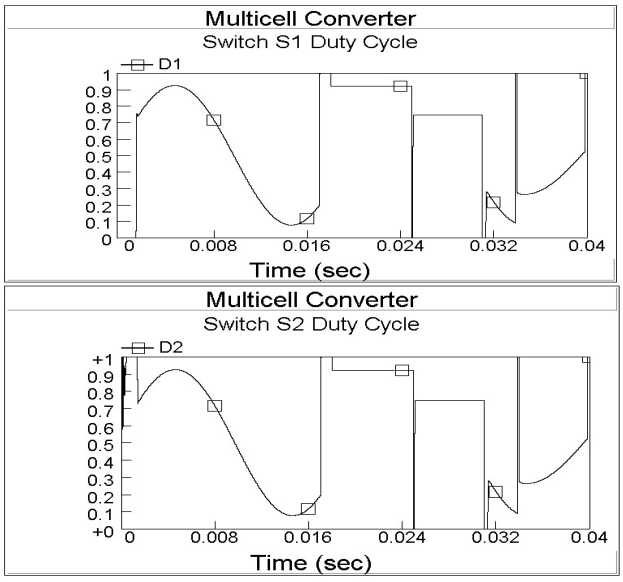

Figure 7. Switches Duty Cycle.

B. Changes in both flying Capacitor reference voltage and load current reference signal.

In this section we will verify the efficiency of the controller under more complex situation. The reference signal changes will apply to the both load current and flying capacitor voltage reference signals.

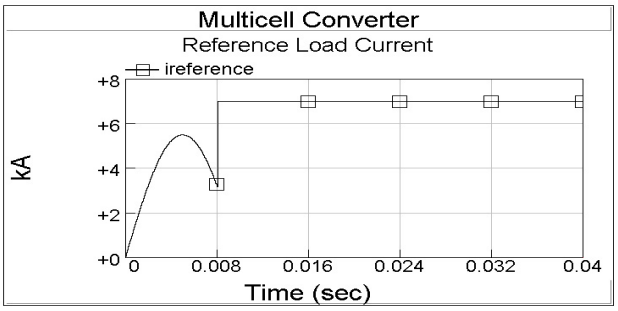

Figure 8. Load Reference Current.

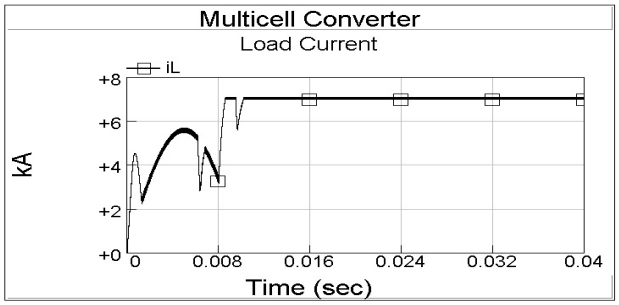

Figure 9. Load Current.

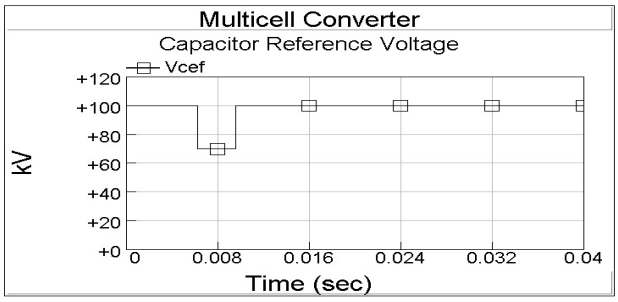

Figure 10. Capacitor ReferenceVoltage.

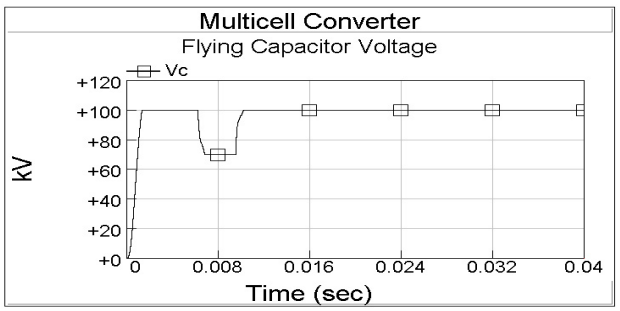

Figure 11. Capacitor Voltage.

It is desired that the state variables track the reference signals. Figures 8-11 prove the efficiency of the controller in tracking the reference signals.

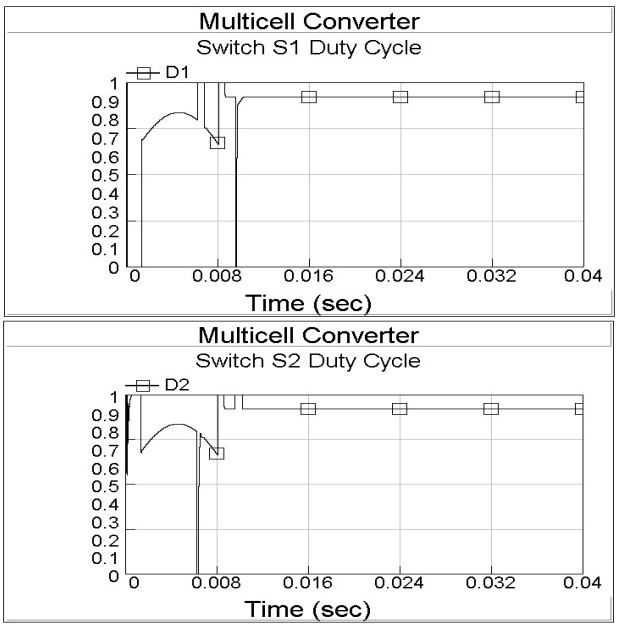

Figure 12. Switches Duty Cycle

V. CONCLUSION

A simple controller is introduced to control the state variables of a Multicell converter. The proposed controller tracks the reference signal changes very fast. Also it has a good response in the presence of the sharp changes in both load current and capacitor voltage reference signals.

Abstract-**The paper describes an induction cooker using a quasi-parallel resonant converter. Converter is implemented by using IGBT as its switching. The switching loss is minimized by operating the IGBT in the zero voltage resonance modes. The output power can be adjust by varying the switching frequency of converter. The prototype is rated at approximately 650 W, with operating frequency ranging from 25-31 kHz. It can heat the water about 0.5 liters from room temperature to approximately $100°C$ within 6 minutes with the input power factor about 0.99.**

I. INTRODUCTION

The principles of induction heating are used in various applications such as brazing, surface hardening, forming and annealing. Each application uses different appropriate frequency [3]. The induction cooking is one of many applications for induction heating. It is designed to replace common stove plates. The advantages of induction cooking are the plate stays cool when the vessel is heated and less energy is used for cooking.

Inverter topology commonly used for induction cooking is the half-bridge inverter topologies [4], [6]. But it has some demerit as the half-bridge inverter requires two switching circuit, the overall working process becomes more complicated and the size of the heat sink and PCB should also be larger. In addition, the gate operating circuits must be isolated. Due to the induction cooking is the high cost compared to a conventional stove plate. So the quasi-resonant converter is another choice in induction cooking application because it needs only one switching circuit inside. This enables a relatively smaller design for the heat sink and PCB making the working process simple and its ground of circuit and control circuit can be shared.

This paper describes the quasi-parallel resonant converter for induction cooking application. It operates in zero voltage switching modes. The operation principles of quasi-parallel resonant circuit are investigated and validity is verified by experimental results.

II. PRINCIPLE OF INDUCTION COOKING

The induction coil is connected to a medium- frequency (20-100 kHz) power source producing an alternating magnetic field, which causes eddy currents to occur at the bottom of vessel and these give rise to the heating effect.

Since the spiral current flows at the heating coil side only the bottom of the vessel according to the skin effect, the current value depends on the skin depth as well as on the specific resistance of the vessel material.

Skin depth δ is determined by the vessel-specific resistance ρ , relative magnetic permeability μ_r, and frequency f, as shown in the expression below.

$$\delta = \sqrt{\frac{\rho}{\pi \mu f}} \tag{1}$$

The pan skin resistance R_s is determined by the pan skin depth and specific resistance, as shown in the expression below.

$$R_s = \frac{\rho}{\delta} = \sqrt{\frac{\rho \omega \mu}{2}} \tag{2}$$

The parameter of induction heating load (induction coil and vessel) depend on several variables including the shape of the heating coil, the space between the work-piece and coil, their electrical conductivities and magnetic permeabilities, and the frequency [3].

III. CIRCUIT DESCRIPTION AND OPERATION

The main power circuit features a quasi-resonant converter as in Fig. 1 It consists of full bridge rectifier diode, a bus filter (L1, C1), the IGBT and a diode connected to it in parallel. The resonant circuit is comprised of resonant inductor Lr, and a resonant capacitor Cr.

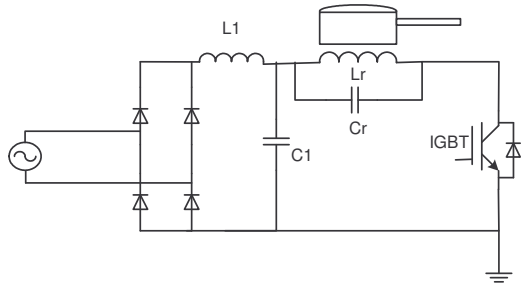

Figure 1. Equivalent circuit of each mode of operation.

A. *Converter operation*

The quasi-resonant converter has four operating modes. The ideal waveform and equivalent circuit of each mode are shown

in Fig. 2 and Fig. 3, respectively. It assumed that all components are ideal. The operations of each mode are explained as following

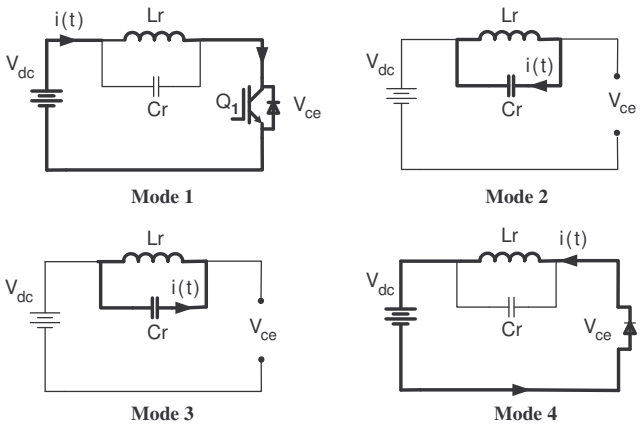

Figure 2. Equivalent circuit of each mode of operation.

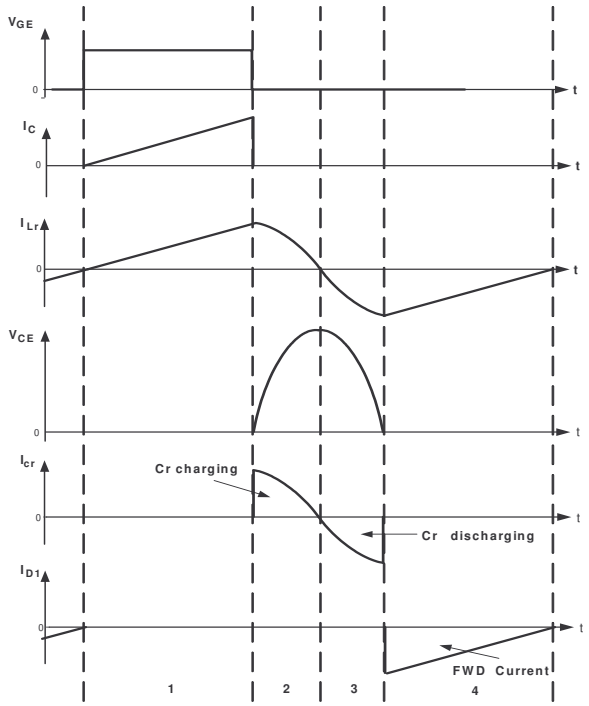

Figure 3. Ideal waveform of quasi-resonant converter.

The operations of each mode are explained as following:

Mode 1: Switch Q_1 is turn on by V_{GE}. Current is biased in the forward direction between the collector and emitter of Q_1. The current flows in the right direction through L_r. The inductor starts to store the energy which makes it possible to do a zero voltage turn-on switching.

Mode 2: when the switch Q_1 is turned off, the current keeps incrementing to reach its maximum at t0. At this point, the energy stored in L_r move to C_r.

Mode 3: Conversely with mode 2. After the current decrease to zero where the voltage S1 reaches its maximum. C_r starts discharging the energy to L_r, which causes the current flowing in inverse to decrement.

Mode 4: In this mode the voltage of L_r converted to polarity and exceeded the voltage at V_{dc}. The current of L_r flows through diode until this current reach the zero.

The used IGBT's is from International rectifier and IRGPH4UD device. The photo coupler TLP250 is used to drive gate of IGBT. To drive the gate of IGBT on at voltage +15 V this is a suitable value to minimize losses. When IGBT is drive off -5V, self-conduction due to external noise is prevented.

B. Filter

The quasi-resonant converter takes the energy from the mains voltage, which is rectified by a full bridge of diodes. A bus filter is designed to allow a big voltage ripple getting a consequence input power factor near to one.

C. Heating coil and load

The coil is a flat pancake with litz wire in order to reduce the losses due to skin effect. The pancake coil is placed underneath a conductive cooking vessel with a thermal insulator between them. The ferrite plates beneath the coil with the work piece (a stainless vessel used for cooking) are intended to obtain a proper shaping of the magnetic field. A thermal insulator is placed underneath stainless vessel to prevent coil damage by heat. The heating coil is air cooled to circulate heat away from it. Fig. 4 represents the equivalent circuit model of the heating coil and stainless vessel. The induction heating load parameters (R_L and L_r) depend on the inverter operating frequency, the position of the load, the distance between the heating coil and vessel. The parameters R_L and L_r are respectively 4.3 Ω and 120 μH. [3]

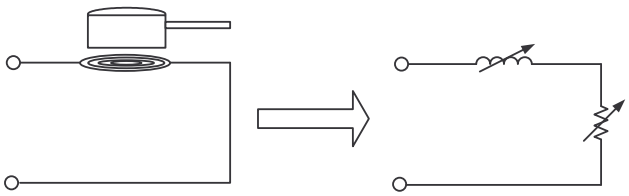

Figure 4. Equivalent circuit model of the heating coil and load.

D. Quasi-resonant Capacitor

The operating frequency is selected at 26 kHz. We can calculate $L_s = 120\,\mu H$ from parameter of induction coil [3].We can select the capacitor which will connect with parallel induction coil for required interval by $C = 1/(\omega^2 Lp) = 0.3\,\mu F$.

IV. Experimental Results

A prototype is built and tested by feeding heat to a stainless vessel which contains water about 0.5 liters. The AC input voltages was 200 V_{rms}. The resonant frequency was about 26.5 kHz. All measured signals are taken at around $100°C$ water temperature.

The experimental waveforms of line voltage and line current are shown as Fig. 5. The line current is in phase with line voltage without any sign of distortion at zero crossing. Fig. 6 shows the coil voltage and coil current waveforms. Fig. 7 shows the switching voltage across the IGBT and coil current waveform. Fig. 8 shows the voltage waveform and current waveform across IGBT at 25.6 kHz, it obvious that zero-voltage soft-switching and no current spikes. Fig. 9 shows the voltage and current waveform of induction coil where measured at 2 ms/div. Fig. 10 shows the relative graph of input power and operating frequency. The parameters of induction coil are varied by adjust switching frequency. In this reason, input power decreased due to increasing parameters of induction coil.

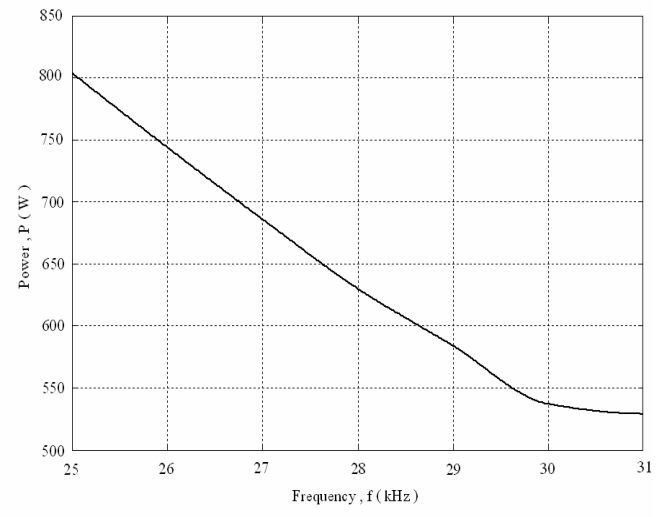

Figure 10. The relative graph of input power and operating frequency

V. CONCLUSION

The induction cooker has been built with quasi-parallel resonant converter. It can heat the water about 0.5 liters which contain in a stainless vessel from room temperature to approximately 100 $^{\circ}C$ within 6 minutes. The switching loss is minimized by operating the IGBT in the zero voltage resonance modes in order to avoid a high current. This converter topology is simple because it has low number of components. But its IGBT switch must withstand high voltage.

***Abstract*- Using two new filters in which Jacobian is replaced by divided difference for nonlinear state estimation single machine infinite bus is proposes. Simulation result shows the performance is comparable with extended Kalman filter, which is used normally for on-line assessment of power system dynamic stability of single-machine infinite-bus system.**

I. INTRODUCTION

In a practical power system, not only the state variables can not be measured directly, but also unexpected disturbances and inaccuracy in the system model would prevent the exact prediction of system states. Therefore, the system states should be monitored to ascertain a compliance with the desired operation of the system. In a stochastic system, state estimation provides the necessary feedback to allow reliable control of the system. Modern state estimation algorithms have recently been applied to power systems. Naggar uses an estimation procedure to estimate the asymmetrical components of power system [1]. C. Madtharad et all [2] use a weighted least square estimation technique, which is based on singular value decomposition. Feilat and et all [3] use Kalman filter as a powerful estimation tool to estimate synchronizing and damping torque coefficients in order to determine dynamic stability [4,5]. Miller and Lewis [6] use a linear Kalman filter to estimate dynamic states of the power system [7,8].
In this work, using two new filters as DD1 and DD2 are proposed and tested.

II. PROBLEM FORMULATION

The system under study is shown in Figure 1. The system comprises a steam- generator connected via a tie-line to a large system represented as an infinite bus.

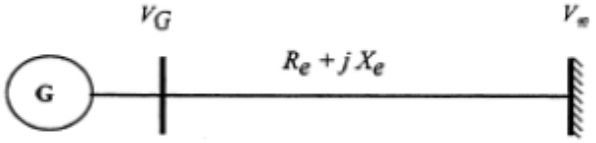

Figure 1. Single machine infinite bus system

For the power system shown in Figure 1, the seventh- order nonlinear dynamic model can be written as follows [9]:

$$\dot{x} = Ax + Bu + N(x)$$

$$y = \begin{bmatrix} x_1 \\ x_2 \\ y_{1q}x_3x_6 + y_{3q}x_3x_7 - y_{1d}x_6x_3 - y_{4d}x_6x_4 - y_{5d}x_6x_5 \end{bmatrix} \quad (1)$$

Where $N(x)$ is the nonlinear term,

$$x = [\delta \;\; \omega \;\; \omega_0\varphi_d \;\; \omega_0\phi_f \;\; \omega_0\phi_D \;\; \omega_0\phi_q \;\; \omega_0\phi_Q]^T$$

is the state vector and

$$u = [T_m \;\; v_f]^T = [u_1 \;\; u_2]^T$$

is the control vector. The relation between fluxes and currents are as follows:

$$\begin{bmatrix} \omega_0\phi_d \\ \omega_0\phi_f \\ \omega_0\phi_D \end{bmatrix} = \begin{bmatrix} -X_d & X_{md} & X_{md} \\ -X_{md} & X_f & X_{md} \\ X_{md} & X_{md} & X_D \end{bmatrix} \begin{bmatrix} i_d \\ i_f \\ i_D \end{bmatrix} \quad (2)$$

and

$$\begin{bmatrix} \omega_0\phi_q \\ \omega_0\phi_Q \end{bmatrix} = \begin{bmatrix} -X_q & X_{mq} \\ X_{mq} & X_Q \end{bmatrix} \begin{bmatrix} i_q \\ i_Q \end{bmatrix} \quad (3)$$

by inversing these two equations we have:

$$\begin{bmatrix} i_d \\ i_f \\ i_D \end{bmatrix} = \begin{bmatrix} y_{1d} & y_{4d} & y_{5d} \\ y_{4d} & y_{2d} & y_{6d} \\ y_{5d} & y_{6d} & y_{3d} \end{bmatrix} \begin{bmatrix} \omega_0\phi_d \\ \omega_0\phi_f \\ \omega_0\phi_D \end{bmatrix} \quad (4)$$

and

$$\begin{bmatrix} i_q \\ i_Q \end{bmatrix} == \begin{bmatrix} y_{1q} & y_{3q} \\ y_{3q} & y_{2q} \end{bmatrix} \begin{bmatrix} \omega_0\phi_q \\ \omega_0\phi_Q \end{bmatrix} \quad (5)$$

In the above equations, the indexes q and Q refer to the quadrature and Damper Q on the q-axis of stator; and, d, D and f refer to the direct, damper D and field exciter on the d-axis of stator, respectively [9].

III. STATE ESTIMATION FOR NONLINEAR SYSTEMS

We have now arrived at the central issue of this note, namely state estimation for nonlinear systems. Two new filters will be suggested that are based on the derived polynomial approximations [10]. The filters are fundamentally different from filters based on Taylor approximations in that the polynomial approximations underlying the new filters take into account the uncertainty on the state estimate. The Taylor approximation underlying conventional filter designs for nonlinear systems, such as The EKF, depends only on the current state estimate and not on its variance. The new filters can generally be implemented more easily as no derivatives are required.

The first filter we shall derive is based on a first-order polynomial approximation. This estimator is a generalized version of the filter presented in [11]. Subsequently, a more accurate filter will be derived that also includes second –order terms. It turns out that this filter has certain similarities with the unscented filter described in [12], [13].

IV. THE DD1 FILTER

In this section a generalized version of the nonlinear state estimation scheme suggested in [11] will be described. The filter is derived by employing the first-order approximation presented in [10]. Basically, this corresponds to the extended Kalman filter (EKF) except that the Jacobian is replaced by divided differences. The state update is therefore the same as in the EKF. The difference is alone found in the update of the various covariance matrices. Generally, they can be implemented more easily. First we will introduce the following four square Cholesky factorization

$$\begin{aligned} Q &= S_v S_v^{\,T} & R &= S_w S_w^{\,T} \\ \overline{P} &= \overline{S}_x \overline{S}_x^{\,T} & \hat{P} &= \hat{S}_x \hat{S}_x^{\,T} \end{aligned} \tag{6}$$

Let the jth column of $\overline{S}_x$ be denoted $\overline{s}_{x,j}$ and vice versa for the other factors. Four matrices containing divided differences are defined by

$$\begin{aligned} S_{x\hat{x}}^{(1)}(k) &= \left\{S_{x\hat{x}}^{(1)}(i,j)\right\} = \{(f_i(\hat{x}_k + h\hat{s}_{x,j}, u_k, \overline{v}_k) \\ &- f_i(\hat{x}_k - h\hat{s}_{x,j}, u_k, \overline{v}_k))/2h\} \end{aligned}$$

$$\begin{aligned} S_{xv}^{(2)}(k) &= \left\{S_{xv}^{(1)}(i,j)\right\} = \{(f_i(\hat{x}_k, u_k, \overline{v}_k + hs_{v,j}) \\ &- f_i(\hat{x}_k, u_k, \overline{v}_k - hs_{v,j})/2h\} \end{aligned}$$

$$\begin{aligned} S_{y\bar{x}}^{(1)}(k) &= \left\{S_{y\bar{x}}^{(1)}(i,j)\right\} = \{(g_i(\overline{x}_k + h\overline{s}_{x,j}, \overline{w}_k) \\ &- g_i(\overline{x}_k - h\overline{s}_{x,j}, \overline{w}_k))/2h\}\} \end{aligned}$$

$$\begin{aligned} S_{yw}^{(1)}(k) &= \left\{S_{x\hat{x}}^{(1)}(i,j)\right\} = \{(g_i(\overline{x}_k, \overline{w}_k + hs_{w,j}) \\ &- g_i(\overline{x}_k, \overline{w}_k - hs_{w,j}))/2h\} \end{aligned} \tag{7}$$

V. THE DD2 FILTER

The DD2 filter obtained by using the estimates of mean and covariance derived in [10]. First we shall define four additional matrices containing divided differences:

$$S_{x\hat{x}}^{(2)}(k) = \left\{ \frac{\sqrt{h^2-1}}{2h^2} \begin{array}{l} (f_i(\hat{x}_k + h\hat{s}_{x,j}, u_k, \overline{v}_k) + \\ f_i(\hat{x}_k - h\hat{s}_{x,j}, u_k, \overline{v}_k) - 2f_i(\hat{x}_k, u_k, \overline{v}_k)) \end{array} \right\}$$

$$S_{xv}^{(2)}(k) = \left\{ \frac{\sqrt{h^2-1}}{2h^2} \begin{array}{l} (f_i(\hat{x}_k, u_k, \overline{v}_k + h\hat{s}_{x,j}) + \\ f_i(\hat{x}_k, u_k, \overline{v}_k - hs_{v,j}) - 2f_i(\hat{x}_k, u_k, \overline{v}_k)) \end{array} \right\}$$

$$S_{y\bar{x}}^{(2)}(k) = \left\{ \frac{\sqrt{h^2-1}}{2h^2} \begin{array}{l} (g_i(\overline{x}_k + h\overline{s}_{x,j}, \overline{w}_k) + \\ g_i(\overline{x}_k - h\overline{s}_{x,j}, \overline{w}_k) - 2g_i(\overline{x}_k, \overline{w}_k)) \end{array} \right\}$$

$$S_{y\bar{x}}^{(2)}(k) = \left\{ \frac{\sqrt{h^2-1}}{2h^2} \begin{array}{l} (g_i(\overline{x}_k, \overline{w}_k + hs_{w,j}) + \\ g_i(\overline{x}_k, \overline{w}_k - hs_{w,j}, \overline{w}_k) - 2g_i(\overline{x}_k, \overline{w}_k)) \end{array} \right\}$$

The priori update proceeding is the same as the DD1 filter.

VI. THE COMPLETE FILTER ALGORITHM

The following procedure outlines the implementation of the new filters.

1. Initialize

$$\overline{x}_0, \overline{P}(0), k = 0.$$

2. Compute

$$\overline{y}_k, S_{y\bar{x}}^{(1)}(k), S_{yw}^{(1)}(k), S_{y\bar{x}}^{(2)}(k), S_{yw}^{(2)}(k)$$

3. Compute P_{xy} according to and determine $S_y(k)$ using Houscholder Triangularization (HT).
4. Solve

$$K_k[\bar{S}_y(k)S_y(k)^T] = P_{xy}$$

for the Kalman gain. Since S_y is square and triangular only forward and back-substitutions are needed: First solve for

$$k' : k'S_y^T = P_{xy}$$

then solve for

$$K_k : K_k S_y = k'.$$

5. A posteriori update of the state estimate

$$\hat{x}_k = \bar{x}_k + K_k(y_k - \bar{y}_k).$$

6. A posteriori update of covariance matrix factor, $\hat{S}_x(k)$, is performed using HT.
7. Determine

$$\bar{x}_{k+1}\ ,\ S_{x\hat{x}}^{(1)}(k+1)\ ,\ S_{xw}^{(1)}(k+1)\ ,\ S_{x\hat{x}}^{(2)}(k+1)\ ,\ S_{xw}^{(2)}(k+1).$$

8. Use HT to compute $\bar{S}_x(k)$
9. $k = k+1$, go to step 2

VII. SIMULATION AND RESULTS

We will compare the performance of the DD1 and DD2 filters with Extended Kalman filter for power system dynamic stability of single-machine infinite-bus system. The state equations are integrated using a fourth – order Runge Kutta method with 200 steps taken between each observation. It is straightforward to implement continues or discrete versions of the DD1 and DD2 filters. We measure δ , ω, T_e and estimate

$$\omega_0\varphi_d\,,\ \omega_0\phi_f\,,\ \omega_0\phi_D,\ \omega_0\phi_q,\ \omega_0\phi_Q$$

in single machine infinite bus system.
To enable a fair comparison of the estimates produced by each of the three filters, the estimations are averaged across a Monte Carlo simulation consisting of 20 runs. Each run is carried out with a different noise sample. The results of the Monte Carlo simulation are shown in Figure 2. Surprisingly, Figure2 shows that the DD2 filter exhibits a performance, which is completely superior to the EKF and the DD1 filter.

VIII. CONCLUSION

In this paper we compare performance of three nonlinear state estimation techniques for estimation of Single Machine Infinite Bus System. The result of simulation demonstrates that the DD2 filter is better than EKF. The implementation is very simple as the filters do not require derivative information and the range of application is wider than for the EKF**.**

***Abstract*- This paper presents a time sequential Monte Carlo simulation approach to distribution reliability worth, taking into account equipment failure originated from substations. Stations, which transfer electrical energy between subtransmission systems and distribution systems, can have significant impact on the overall system reliability of customers. With average disconnected load, outage duration, average interruption cost, reliability worth at the load points can be estimated. The method is illustrated by the Roy Billinton test system with different substation configurations. The study results show that the simulation method can provide reliability worth of load points in terms of expected cost and their probability distributions, and interrupted energy assessment rate.**

Keywords: **Monte Carlo simulation, Reliability worth, Distribution reliability, Substation reliability.**

I. INTRODUCTION

The basic function of a power system is to supply the electrical energy to customers as economically as possible with an acceptable level of reliability [1]. The acceptable level reliability can be quantified in forms of reliability worth. One approach to assess reliability worth is to relate it to the costs or losses incurred by utility customers due to electric supply interruption [2]. The distribution system is an important part of the total electrical supply, as it provides the final connection between bulk transmission system and customers' facilities. It has been reported that more than 80% of all customer interruptions are caused from failed events in the distribution system [3].

In many cases, distribution systems are designed and constructed as radial feeders systems which make them more susceptible to outage in a single event. However, many other systems, although operated as radial systems, can be switched to meshed systems using normally open switches in the event of a system failure [3]. Distribution systems have a set of series components between substations and load points. Therefore, the interruption of load point is not only due to the failure of components in the distribution system but also from those in the substations. Substation configuration can, obviously, have a direct impact on the load points. An appropriate substation configuration can improve the customers' reliability.

A common way to analyze reliability worth is to determine customer costs due to electric power supply interruptions. One convenient way is an interpretation of customer interruption costs in terms of customer damage functions (CDF). The CDF can be determined for given customer types and aggregated to make sector customer damage functions (SCDF), which reflect economic consequences of supply interruption as a function of cost in different groups of customers. The SCDF is normally obtained from customer surveys, the data of which are complied according to major sectors or industrial categories. With the SCDF, outage duration and average disconnected load, customer interruption cost can be evaluated. A useful index known as the interrupted energy assessment rate (IEAR) that relates the reliability indices and the momentary implications of customer supply interruptions can also be obtained.

This paper presents an assessment of reliability worth with substation originated outage using a time sequential Monte Carlo simulation technique. The method represents the random behaviors of system components, such as time to failure, time to repair and switching time by randomly sampling sequences of component states in chronological manner for several periods of time. Each of the component state is superimposed to determine system states for reliability and cost evaluation. The method is demonstrated with the Roy Billinton test system (RBTS) with different substation configurations.

II. MONTE CARLO SIMULATION

Monte Carlo simulation generates historical data for each of the system equipment. The historical data consist of time-to-failure (TTF), time-to-repair (TTR), and time-to-switching (TTS). In this paper, the exponential distribution function is used to represent TTF, TTR and TTS. Given uniformly distributed random numbers U_F, U_R, and U_S, the conversion of TTF, TTR and TTS into the exponential function using the inverse transform method is given in (1)-(3).

$$TTF = -\frac{1}{\lambda}\ln(1-U_F) \tag{1}$$

$$TTR = -\frac{1}{\mu_r}\ln(1-U_R) \tag{2}$$

$$TTS = -\frac{1}{\mu_{sw}}\ln(1 - U_S) \quad (3)$$

where

λ = average failure rate (occ/year)

μ_r = average repair rate (occ/year)

μ_{sw} = average switching rate (occ/year)

The annual expected interruption cost (ECOST) and IEAR of each load point are calculated by the following equations [3]:

$$ECOST_{p,i} = \sum_{j=1}^{N} C_{j,p}(r_j) L_{av,p} \quad (4)$$

$$IEAR_{p,i} = \frac{ECOST_{p,i}}{\sum_{j=1}^{N} L_{av,p} r_j} \quad (5)$$

where

r_j = outage time due to event j

$C_{j,p}$ = cost of interruption for load point p due to event j

N = number of events in each year

$L_{av,p}$ = average connected load at load point p

The simulation process consists of the following steps:

1) Generate three random numbers between 0 and 1 for each component to represent TTF, TTR and TTS.

2) Convert the random numbers to up time, down time and switching time on given TTF, TTR and TTS distributions using (1) – (3).

3) On each year during simulation, the failure of a component defines event j and down time r_j for each load point concerning distribution system failures and substation originated failures.

4) ECOST is calculated for failure events and accumulated for each year. Annual ECOST and IEAR are calculated at the end of each year by (4) and (5).

5) Repeat steps 3) and 4) for a simulation period of 50,000 years.

III. Substation Component Model

Substation reliability evaluation is considered up to second order failure events. The components in the substation to be evaluated consist of busbars, transformers and circuit breakers. All the components can be isolated after failures and can be modeled by the four-state model in Fig. 1 [4].

A. Active failure events (1 – 2 – 3 – 1)

For a failure event that causes the operation of protection and the associated circuit breakers to trip, the failed component can be restored to service only by repair or replacement.

B. Passive failure events (1 – 3 – 1)

For a failure event that does not cause the operation of protection, the failed circuit breaker can be restored to service only by repair or replacement.

The failure mode of the components is defined as follows.

1) Circuit breaker: The circuit breaker failure model is defined for both active and passive failure events.

2) Transformer and busbar: The transformer and busbar failure model is defined only for active failure events.

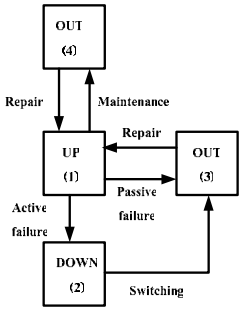

Figure 1. Four-state failure model of substation components.

IV. Substation Configurations and Distribution System

A. Substation Configurations

Four types of substation configurations are considered in this paper: scheme a) single bus configuration without circuit breaker at primary side of transformer (defined at bus 2 of the RBTS), scheme b) breaker-and-a-half configuration, scheme c) ring bus configuration and scheme d) single bus configuration with circuit breaker at primary side of transformer. These four substation configurations are shown in Fig. 2. The recovery of a transformer in the substations is made by repair.

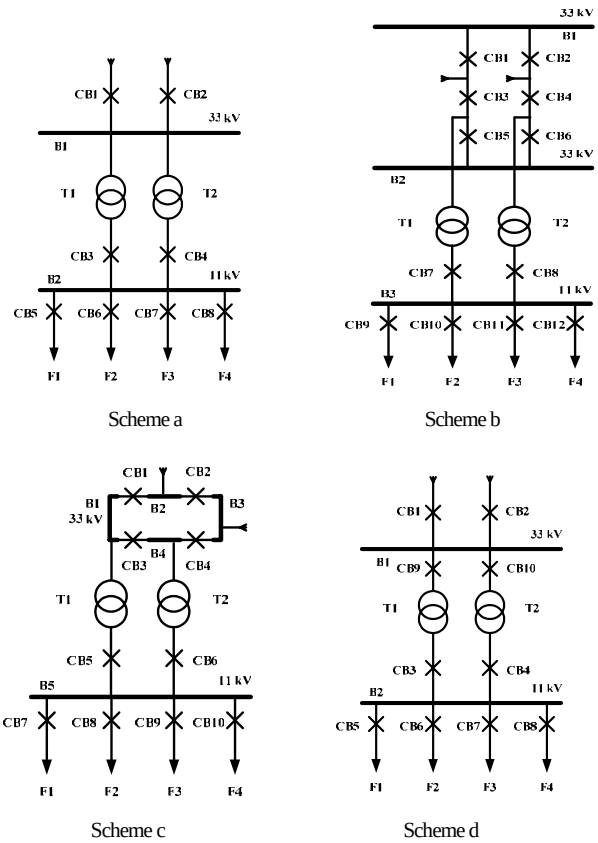

Figure 2. Four different substation configurations.

B. Distribution System

Distribution system at bus 2 of RBTS is employed in this study, as shown in Fig. 3. The reliability data of the components are provided in Table I [5]. The feeders are operated as radial feeders but connected as a mesh through normally open sectionalizing points. The system has disconnecting switches in the main feeders, fuses in each lateral branch and alternative supply at the end of each feeder. The failure of transformer is recovered by replacement.

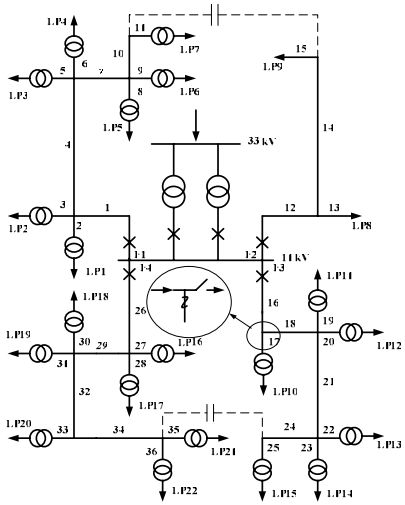

Figure 3. Distribution system at bus 2 of RBTS .

TABLE I
RELIABILITY AND SYSTEM DATA

Component	λ_a	λ_p	r	r_p	s
Transformer					
33/11 kV	0.0150	0.0150	-	15	1.0
11/0.4 kV	0.0150	0.0150	200	10	1.0
Circuit breaker					
33 kV	0.0015	0.0020	4	-	1.0
11 kV	0.0040	0.0060	4	-	1.0
Bus bar					
33 kV	0.0010	0.0010	2	-	1.0
11 kV	0.0010	0.0010	2	-	1.0
Line					
11 kV	0.0650*	0.0650*	5	-	1.0

λ_a = Active failure rate) occ/yr ([*line (occ/km-yr)]

λ_p = Permanent (total) failure rate)occ/yr) [*line (occ/km-yr)]

r, r_p = Repair time and replacement time (hr)

s = Switching time (hr)

C. Customer and Loading Data

The customer and loading data are given in Table II [5]. The customers connected at bus 2 are composed of residential, small industrial, commercial and government customers.

TABLE II
CUSTOMER DATA

Load point (LP)	Cust.type	Average load (MW)	No. of cust. /LP
1,2,3,10,11	Residential	0.535	210
12, 17, 18, 19	Residential	0.450	200
8	Small industrial	1.00	1
9	Small industrial	1.15	1
4, 5, 13, 14, 20, 21	Government	0.566	1
6, 7, 15, 16, 22	Commercial	0.454	10

D. Customer Damage Function

The sector customer damage function (SCDF) of each group of customers is used to calculate customer interruption cost at each load point and is shown in Fig. 4 [2].

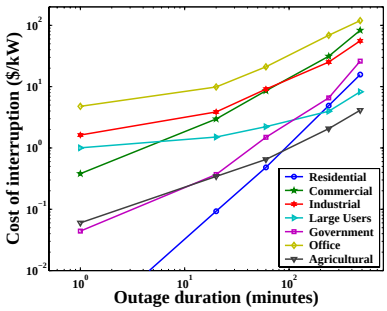

Figure 4. Sector customer damage functions.

RESULTS OF EXPECTED CUSTOMER INTERRUPTION COST AND INTERRUPTED ENERGY ASSESSMENT RATE

The contingency enumeration method is used to estimate ECOST and IEAR [6]. This method considers each outage event in association with the interruption cost data of the customers. A time sequential Monte Carlo simulation is developed to evaluate ECOST and IEAR. Fig. 5 shows the ECOST of the four feeders connected at bus 2 for the four different substation configurations, which are shown in Fig. 2. As can be seen, scheme A is the worst because the failure of a transformer causes the whole substation to be forced outage and the failed transformer needs repairing. Scheme B has the lowest ECOST mainly because it has the highest number of circuit breakers. Although scheme D has only 1 busbar (i.e., no redundancy), its ECOST is slightly higher than that of scheme C, which contains 4 busbars, because of low probability to failure of the busbars and a small amount of repair time (2 hours). A significant difference could be seen if the probability were higher. It is very interesting to note from Fig. 6 that the IEAR of each feeder is quite insensitive to the substation configurations. Fig. 7 illustrates the ECOST of bus 2 for the four different substation configurations. This system ECOST follows the pattern of Fig. 5. The ECOST of load points 1, 9, 14 and 22 for a simulation time of 50,000 years for scheme A is shown Fig. 8. Fig. 9 and 10 show the probability distribution of the ECOST for feeder 1 and bus 2 owing to substation originated outage for the four schemes.

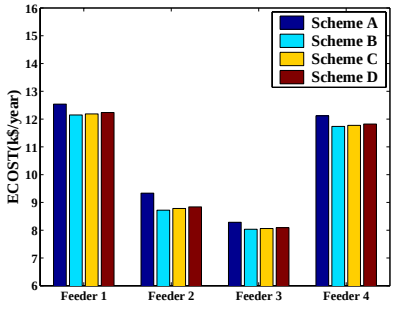

Figure 5. ECOST of feeders at bus 2 in RBTS for four different substation configurations.

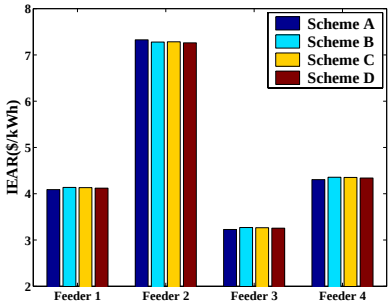

Figure 6. IEAR of feeders at bus 2 in RBTS for four different substation configurations.

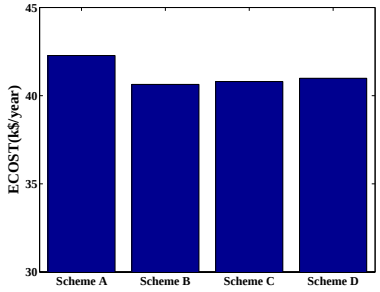

Figure 7. ECOST of bus 2 in RBTS for four different substation configurations.

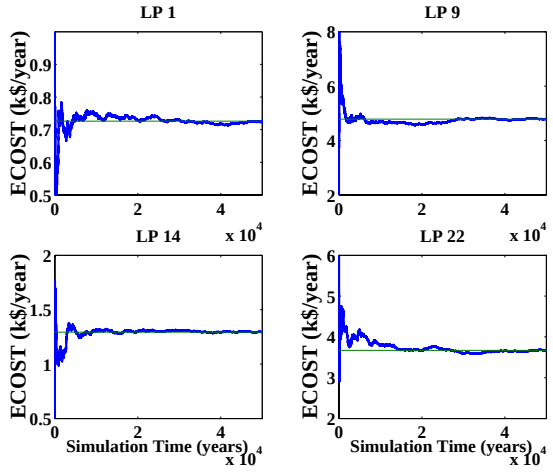

Figure 8. ECOST of load points 1, 9, 14 and 22 as function of simulation time for scheme A.

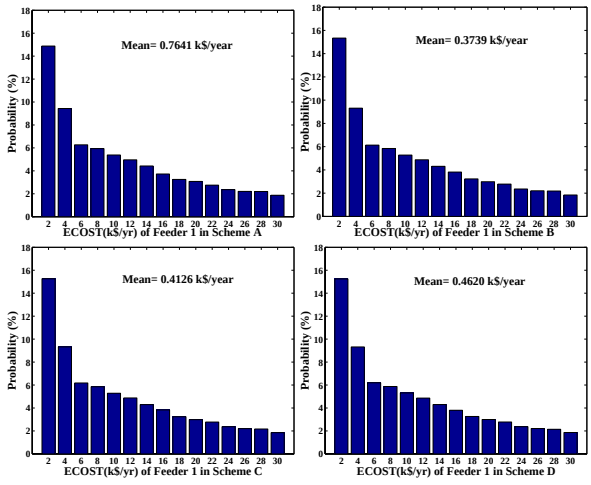

Figure 9. Probability distribution of ECOST for feeder 1 due to substation originated outage.

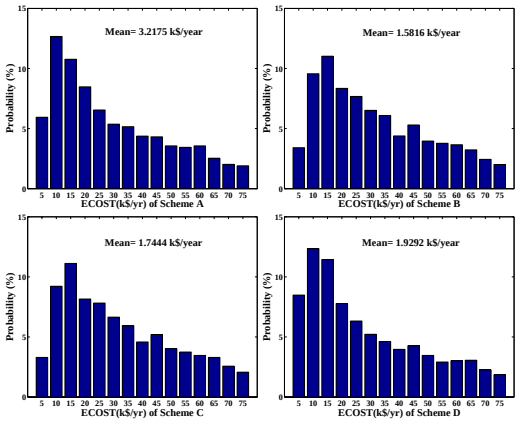

Figure 10. Probability distribution of ECOST due to substation originated outage.

CONCLUSION

This paper presents the application of a sequential Monte Carlo simulation to reliability worth in distribution systems with substation originated outages. The fundamental concept behind this technique is to mimic component behaviors by randomly sampling sequences of component states in chronological manner for several periods of time. The distributions of active or passive failure, switching time and repair time are assumed to be exponentially distributed. Reliability worth at load points are evaluated as expected interruption cost of customers based on the contingency enumeration technique, in which each outage event is taken into consideration in association with the interruption cost data of the customers. The results from a case study show that different substation configurations have different impacts on customers' reliability and therefore their interruption costs. However, a more reliable substation requires more investment cost. Thus, the reliability worth gaining from the substation needs to be justified in conjunction with the additional investment cost for the optimum balance between the utility and customers.

Abstract*—This paper presents the detailed analysis of load voltage compensation for dynamic voltage restorer (DVR) that used for enhancing power quality. DVR is a custom power device used to correct voltage sag (dip) by injecting voltage as well as power into power distribution system. A method of determining the exact amount of voltage injection required to correct a specific voltage reduction with minimum power injection is described. Analytical expressions for both magnitude and angle of the injected voltage are also derived. It has been shown that a voltage reduction and power factor should be analyzed before compensating the voltage. Simulation results show the performance of the proposed analysis though Matlab/simulink tool.

Keywords*—dynamic voltage restorer, power quality, voltage sag, custom power.

I. INTRODUCTION

Voltage sags are now one of the most important power quality problems in the power distribution systems [1]. A voltage sag is a momentary decrease in *rms* ac voltage (0.1 – 0.9 p.u. of the nominal voltage), at the power frequency, of duration from cycles to a few seconds as shows in Fig. 1. Most voltage sags are caused by remote faults, such as single-line-to-ground fault, double line to ground fault on the power distribution system or due to starting of large induction motors and switching of capacitor bank [2].

A dynamic voltage restorer (DVR) is a custom power device capable of protecting sensitive loads against the voltage variations or disturbances [2]. A DVR is a forced commutated voltage source converter (VSC) that injects a dynamically controlled voltage in series with the supply voltage through three single-phase transformers for correcting the load voltage. When the injected voltage is in phase with the supply voltage, the desired voltage correction can be achieved with a minimum voltage injection but it may required a considerable amount of active power injection into the system [3]. When the injected voltage leads the supply voltage, the same correction can be made with a lower value of power injection. When the power injection by the DVR is minimized, the same energy storage can be used for a longer period. Such an operation requires careful determination of injected voltage magnitude and angle, however.

Most papers have had concentrated in the energy storage devices [5]-[8]. They tried to minimize the energy storage by used the optimization techniques or did not use energy storage device by directly connecting the dc-link of VSC to the supply source and used the rectifier converter to change the supply from ac to dc [9]. It made costly when we connected the supply of VSC directly. This paper will propose the DVR that uses the energy storage device. The objective of this paper is to determine the magnitude and angle of the DVR injected voltage so that a given voltage sag can be corrected with minimum active power injection into the system. Analytical expressions for the injected voltage magnitude and angle, in terms of voltage sag and power factor, are also derived.

This paper is organized as follows. Section II discusses the principle operation and equation of DVR. The detail analysis of voltage compensation for DVR is presented by showing the power injection analysis and voltage injection analysis in section III. The simulation results and conclusion are given in section IV and V, Respectively.

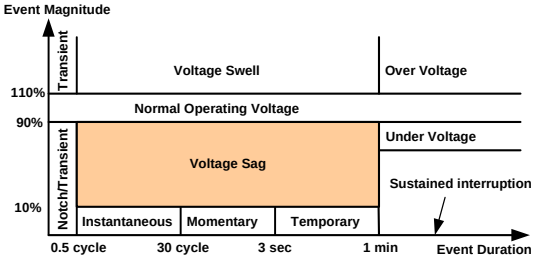

Fig. 1. Voltage Reduction Standard of IEEE Std. 1159-1995.

II. DYNAMIC VOLTAGE RESTORER

DVR is a series-connected device with the grid and case a power disturbance appears, it will inject a power into the grid for mitigating their disturbances, such as voltage sag/swell. In principle, DVR can be installed at any voltage level, but for the low voltage applications, the DVR may be cost-ineffective compared to the uninterruptible power supply (UPS). To be able to mitigate voltage sag, the DVR should be capable of generating and absorbing active and reactive power to/from the grid. Basically, DVR is designed to dynamically inject a voltage V_i into the power system. Figure 2 shows the schematically diagram of a typical DVR used for voltage correction. When the supply voltage V_s changes, the DVR injects a voltage V_i in such a way that the desired load voltage magnitude can be maintained. DVR is simply a VSC that produces an ac output voltage and injects in series with the supply voltage through a transformer. To correct a given voltage sag, not only voltage but also active and/or reactive power injections are needed. The DVR itself is capable of generating the reactive power, but the injected active power must come from the energy storage part of the DVR. Thus minimization of active power injection is essential to increase the lift of the energy storage.

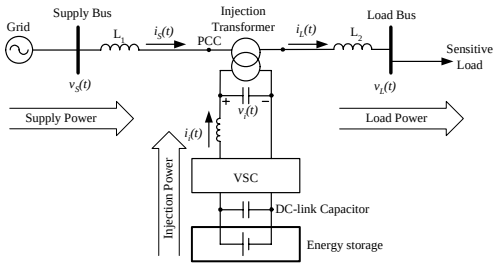

Fig. 2. Schematic diagram of a typical DVR.

III. VOLTAGE COMPENSATING

From Fig. 2, the analysis of voltage compensating can be divided into two parts. First analyzes the injected power and second analyzes the voltage and angle to be the command of VSC in DVR. We can show step by step as the following.

A. *Injected Power Analysis*

The active and the reactive power flow at the load and supply sides of Figure 1 can be written as

$$P_L = V_L I_L \cos\theta_L \quad (1)$$

$$Q_L = V_L I_L \sin\theta_L \quad (2)$$

$$P_S = V_S I_L \cos\theta_S \quad (3)$$

$$Q_S = V_S I_L \sin\theta_S \quad (4)$$

Here θ_L and θ_S are the angle between V_L and I_L and V_S and I_L, respectively. Note that θ_L is the load power factor angle and I_L is the current in both load and source sides. DVR injected active power (P_i) and reactive power (Q_i) are the difference between (1) and (2) and (3) and (4), respectively, and are given by

$$P_i = (P_L - P_S) = V_L I_L \left(\cos\theta_L - \left(\frac{V_S}{V_L}\right)\cos\theta_S \right) \quad (5)$$

$$Q_i = (Q_L - Q_S) = V_L I_L \left(\sin\theta_L - \left(\frac{V_S}{V_L}\right)\sin\theta_S \right) \quad (6)$$

Consider the load voltage magnitude (V_L) and load apparent power ($V_L I_L$) as base quantities. Thus, the injected power in p.u. can be written as

$$P_i = pf_L - V_S \cos\theta_S \quad (7)$$

$$Q_i = \sqrt{1 - pf_L^2} - V_S \sin\theta_S \quad (8)$$

Here $pf = \cos\theta_L$ = load power factor, and V_S is the supply voltage magnitude in p.u. For given values of load power factor and supply voltage magnitude, the injected active power is minimum when:

$$\cos\theta_S = 1 \quad (9)$$

In other words, when $\theta_S = 0$ or V_S and I_L are in phase. Thus, V_L must be lead V_S by the power factor angle θ_L and it can be realized by careful injection of V_i. The main purpose of the DVR is to maintain the desired load voltage magnitude despite a injected voltage of V_i p.u. In this case, the supply voltage magnitude in p.u. can be written as:

$$V_S = (V_L - V_{drop}) \quad (10)$$

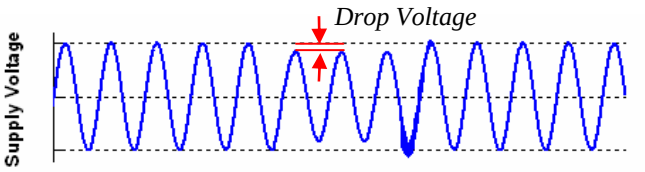

Fig. 3. Definition of voltage drop.

Using equation (5) to (6), the minimum active power $P_i^{\min}$ and reactive power injection $Q_i^{\min}$ of the DVR can be written as

$$P_i^{\min} = V_{drop} - (1 - pf) \quad (11)$$

$$Q_i^{\min} = \sqrt{1 - pf^2} \quad (12)$$

Equation (11) indicates, when $V_{drop} < (1 - pf)$, $P_i^{\min}$ becomes negative and thus the power flows in reverse direction. DVR may not cater to reverse power flow, however. Such a situation can be avoided by adjusting the value of θ_S (instead of zero) so that the power flow becomes zero. The value of θ_S for zero power flow can be obtained from (4) and is given by (13). $Q_i^{\min}$ does not depend on the voltage injection but it depends on the load power factor as given by equation (12) for minimum power injection.

$$\theta_S = \cos^{-1}\left(\frac{pf}{1 - V_{drop}}\right) \quad (13)$$

Figure 4 shows the variation of DVR active power injection against the voltage sag and load power factor. It can be observe, when the voltage drop V_{drop} is less than or equal to ($1\text{-}pf_L$), no active power injection is required to correct the voltage. When V_{drop} exceeds ($1\text{-}pf_L$), the injected power increases linearly with V_{drop}. In this region of voltage drop, the injected power depends on the load factor, and for a given value of V_{drop}, it increase with the increase of load power factor.

Figure 5 presents the variation of injected reactive power against load power factor and Fig. 6 shows the input angle between input voltage and current compare with load power factor and dropped voltage. Note that, the load power factor has effect to the power injection and input phase between voltage and current. If we would like to minimize the energy storage, we need to consider the type of sensitive that we want to protect the systems.

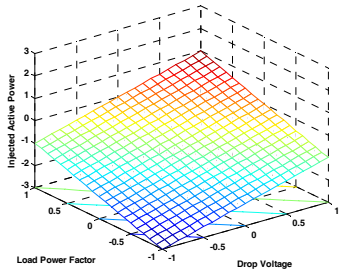

Fig. 4. Variation of DVR active power injection against the dropped voltage.

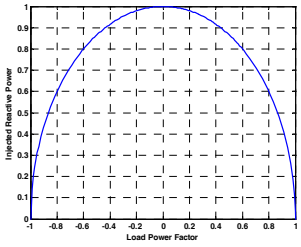

Fig. 5. Variation of DVR reactive power injection against load power factor.

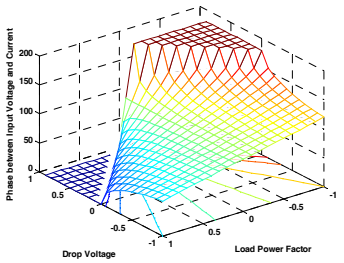

Fig. 6. Variation of the angle of input voltage and current against load power factor and dropped voltage.

B. *Injected Voltage Analysis*

It is demonstrated in the previous section that, when $V_{drop} \le (1-pf)$ the voltage correction can be made without injecting any active but the phase shift between V_S and I_L must be governed by (13). On the other hand, when $V_{drop} > (1-pf)$, injection of active power is required to correct the voltage but its value can be minimized if V_S and I_L are kept in phase. Thus the voltage correction required careful determination of injected voltage so that the desired phase shift (between V_S and I_L) as well as load voltage magnitude can be maintained. The procedure of finding the injected voltage is discussed next.

When $V_{drop} \le (1-pf)$: In this case, the DVR should inject a voltage in such a way that (13) is satisfied as well as the desired load voltage magnitude (1.0 p.u.) is maintained. From Figure 1, the injected voltage V_i can be written as

$$\mathbf{V_i} = \mathbf{V_L} - \mathbf{V_S} \qquad (14)$$

Consider V_S as reference. Thus V_L must have an angle of $(\theta_L - \theta_S)$ to avoid reverse power flow. Note that the angle between V_L and I_L is the power factor angle θ_L. Thus in polar form, (14) can be written as

$$V_i \angle\beta = 1\angle(\theta_L - \theta_S) - (1-V_{drop})\angle 0^\circ \qquad (15)$$

Here V_i and β are the magnitude and angle, respectively, of the injected voltage. After some mathematical manipulations, V_i and β can be expressed as

$$V_i = \sqrt{V_d^2 + 2(1-V_{drop})[1-\cos(\theta_L - \theta_S)]} \qquad (16)$$

$$\beta = \tan^{-1}\left[\frac{\sin(\theta_L - \theta_S)}{\cos(\theta_L - \theta_S) - (1-V_{drop})}\right] \qquad (17)$$

When $V_{drop} > (1-pf)$: In this case, the DVR should inject a voltage in such away that V_S and I_L are kept in phase while maintaining the desired load voltage magnitude. Since V_S is considered as reference, the angle of both V_S and I_L should be zero. To satisfy the power factor angle (between V_L and I_L), however, V_L must lead V_S by θ_L. Thus in phase form, (15) can again be written as

$$V_i \angle\beta = 1\angle\theta_L - (1-V_{drop})\angle 0^\circ \qquad (18)$$

After some mathematical manipulations, the magnitude and angle of the injected voltage can be expressed as

$$\begin{aligned} V_i &= \sqrt{V_{drop}^2 + 2(1-V_{drop})[1-\cos\theta_L]} \\ &= \sqrt{V_{drop}^2 + 2(1-V_{drop})[1-pf]} \end{aligned} \qquad (19)$$

$$\beta = \tan^{-1}\left[\frac{\sin\theta_L}{\cos\theta_L - (1-V_{drop})}\right] = \tan^{-1}\left[\frac{\sqrt{1-pf^2}}{pf - (1-V_{drop})}\right] \qquad (20)$$

The variations of DVR injected voltage magnitude, and angle against the voltage drop are shown in Figure 7-10, respectively. In this region of voltage drop, the injected voltage magnitude increase rapidly with the increase of V_{drop}. When V_{drop} reaches (1-*pf*), the magnitude and angle of the injected voltage become $\sqrt{1-pf^2}$ p.u. and 90°. Note that for

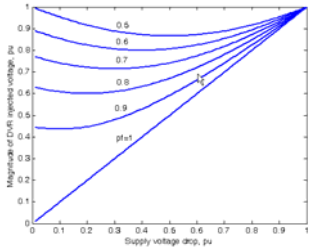

Figure 7. Variation of the magnitude of DVR injected voltage against the voltage drop

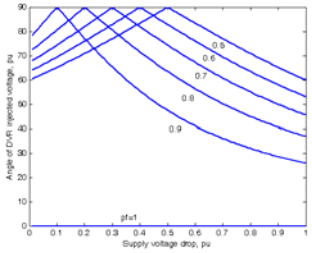

Figure 8. Variation of the angle of DVR injected voltage against the voltage drop.

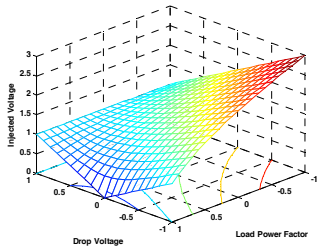

Figure 9. Variation of the magnitude of DVR injected voltage against the voltage drop and power factor.

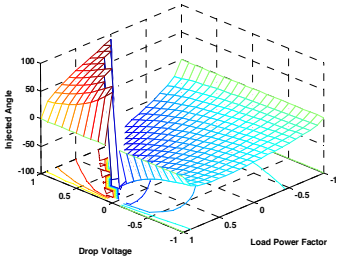

Figure 10. Variation of the magnitude of DVR injected phase against the voltage drop and power factor.

unity power factor, the injected voltage magnitude for V_{drop} = (1-*pf*) is zero and thus its angle is meaningless. In this region, the injected voltage magnitude increases while its angle decreases with the increase of V_{drop}. Finally, when V_{drop} approaches 1 p.u. the entire load power is supplied by the DVR and the injected voltage magnitude and angle become the same as the desired load voltage magnitude and power factor angle, respectively.

IV. Simulation Results

The configuration of the studied system is shown in Figure 1 and the system parameters are given in appendix. The dc/ac inverter used in the DVR is assumed to be a PWM voltage source converter. The total voltage harmonic distortion for 22-kV distribution system cannot be greater than 5.0%. Assuming that the utility source is deal, then the rms value of total harmonics voltage on the primary side of the injection transformer will be 11 kV. suppose the turn ratio of the injection transformer is 7. In practice, the magnitude modulating ratio m_a of the PWM converter used in the DVR my range from 0.0 more than 0.9. The exact value of m_a will depends on the voltage sag depth the DVR attempts to correct, if the filter loading effect is negligible. Figure 11 shows the supply, injected and load voltage when the load power is utility and the balanced voltage sag occurred. And Fig. 12 shows the supply, injected and load voltage when unbalanced voltage sag occurred. It can be observed that when the power factor of load is unity, the DVR can compensate the voltage magnitude and angle by using the minimum energy storage system.

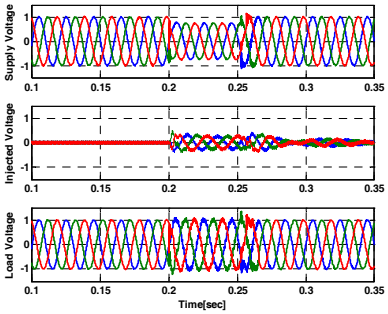

Figure 11. Voltage on supply, injection, and load side.

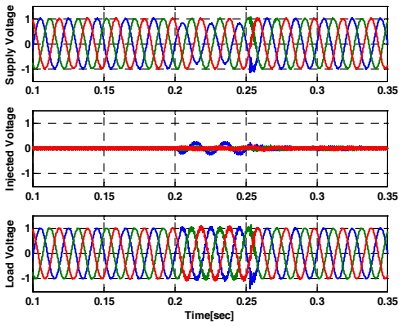

Figure 12. Voltage on supply, injection, and load side.

V. Conclusion

A technique of correcting the voltage drop or sag by a DVR is described in this paper. The expressions for the injected voltage magnitude and angle that minimize the active power injection are also derived. It has been found that a voltage drop of less than or equal to (1-pf) pu can be corrected without drawing any power from the energy storage of the DVR. In this case, only reactive power injection is required to correct the voltage and which can be generated by the DVR. For higher voltage drop, however, both active and reactive power injections are required to correct the voltage. In this case, taking as much power as possible from the energy storage. This can be achieved by maintaining unity power factor at the supply side.

***Abstract*- This paper presents the application of the proposed efficient least squares algorithm in power supply voltage dip and unbalance detection for mitigation using a distribution static synchronous compensator (D-STATCOM). The proposed voltage dip detection method is based on an efficient least squares algorithm which offers structural simplicity and less computational complexity. The proposed method is capable of identifying the instantaneous symmetrical components of the fundamental frequency accurately even though the point of common coupling voltage is strongly corrupted by the voltage harmonics. The proposed method extracts detecting the positive- and negative-sequence components and then using those sequence components for generating reference values of current that need to be injected into the point of connection D-STATCOM in order to compensate the voltage errors. The effectiveness of the voltage dip detection method in the D-STATCOM application has been verified by simulation results.**

I. INTRODUCTION

Recently, the distribution static synchronous compensator (D-STATCOM) has been introduced to distribution networks to manage the system reactive power and regulate the voltage at the distribution buses. A D-STATCOM usually consists of a shunt connected voltage source converter (VSC) [1].

The extraction and tracking technique of voltage dip is the core of the D-STATCOM mitigating control strategy. In order to obtain the required information to control the D-STATCOM further processing during voltage unbalance or dip is required and the processed information is required to be updated as fast as possible. Moreover, the choice of techniques for the voltage dip detection is highly dependent on the real-time implementation, the available computational hardware, and the amount of computational effort.

In this paper the voltage dips detection and unbalances detection based on the proposed efficient least squares (ELS) algorithm for using in D-STATCOM applications is introduced. The proposed voltage dip detection system extract the fundamental component and positive and negative-sequence component of the voltage to generate a current reference signal for the D-STATCOM to compensate voltage dips. Simulation results with practical parameter are provided to demonstrate that the proposed balanced and unbalanced voltage dip detection system is an excellent tool for extracting the required information for a D-STATCOM application.

II. VOLTAGE DIP DETECTION BASED ON PROPOSED ELS METHOD

A. Overview of the Proposed Efficient Least Squares Method

The instantaneous voltages waveforms in a three-phase power system can be generally expressed as:

$$v_{Sa}(t) = \sum_{i=1,5,7,\ldots}^{k} V_{Sai}\cos\left(\omega_i t + \beta_{ai}\right) \tag{1}$$

$$v_{Sb}(t) = \sum_{i=1,5,7,\ldots}^{k} V_{Sbi}\cos\left(\omega_i t + \beta_{bi}\right) \tag{2}$$

$$v_{Sc}(t) = \sum_{i=1,5,7,\ldots}^{k} V_{Sci}\cos\left(\omega_i t + \beta_{ci}\right) \tag{3}$$

In which V_{Sai} , V_{Sbi} and V_{Sci} are the unknown magnitude values of the three-phase voltages, and β_{ai} , β_{bi} , and β_{ci} are the unknown phase angles. Subscript $i = 1,5,7,\ldots k$ refers to the fundamental and harmonic components respectively. The symbol ω_i is known angular frequency of the i^{th} harmonic.

The proposed method is used to extract the fundamental component of the three-phase voltages. The discrete-time version of three-phase voltage can be written in matrix notation as

$$y = \mathbf{A}\boldsymbol{x} \tag{4}$$

$\mathbf{A}$ is a complex rotation matrix, $\boldsymbol{x}$ is a complex vector consisting of magnitude and phase angle of the input signal. The vector y is the input signal. The proposed method is based on the conventional least squares algorithm. The aim is to solve the system equations without inverting any matrix with real number elements. The proposed ELS algorithm can calculate harmonic components by simply multiplying each set of input signals by a constant matrix. Consequently, the proposed method is immune to transient distortions and unbalanced conditions. The proposed method is computationally efficient, the size of the matrix is required is only $2 \times L$, since only the fundamental component needs to be identified. The vector $\boldsymbol{x}$ which consists of a complex signal of fundamental and harmonic component can be found using the proposed method as follows:

$$\boldsymbol{x} = \left((\mathbf{R})^{\mathrm{T}}\mathbf{R}\right)^{-1}(\mathbf{R})^{\mathrm{T}} y = \mathbf{C}y \tag{5}$$

where $\mathbf{R} = \begin{bmatrix} H_1^0 & H_{-1}^0 \\ H_1^1 & H_{-1}^1 \\ H_1^2 & H_{-1}^2 \\ \vdots & \vdots \\ H_1^l & H_{-1}^l \end{bmatrix}$

H_1^l is the rotation matrix , ie. $\begin{bmatrix} \cos\omega_1 nT & -\sin\omega_1 nT \\ \sin\omega_1 nT & \cos\omega_1 nT \end{bmatrix}$

L is the number of measured samples,

$\mathbf{C}$ is a constant matrix, ie. $\left(\mathbf{R}^{\mathsf{T}}\mathbf{R}\right)^{-1}\mathbf{R}^{\mathsf{T}}$

B. Voltage Dip Detection Based on Proposed ELS Method

The fundamental component in term of the complex signals can thus be obtained as follows:

$$\begin{bmatrix} v_{Sa1}^{\cos} \\ v_{Sa1}^{\sin} \\ \vdots \\ v_{Sb1}^{\cos} \\ v_{Sb1}^{\sin} \\ \vdots \\ v_{Sc1}^{\cos} \\ v_{Sc1}^{\sin} \end{bmatrix} = \begin{bmatrix} V_{Sa1}\cos\left(\omega_1 t + \beta_{a1}\right) \\ V_{Sa1}\sin\left(\omega_1 t + \beta_{a1}\right) \\ \vdots \\ V_{Sb1}\cos\left(\omega_1 t + \beta_{b1}\right) \\ V_{Sb1}\sin\left(\omega_1 t + \beta_{b1}\right) \\ \vdots \\ V_{Sc1}\cos\left(\omega_1 t + \beta_{c1}\right) \\ V_{Sc1}\sin\left(\omega_1 t + \beta_{c1}\right) \end{bmatrix} = \mathbf{C} \times \begin{bmatrix} v_{Sa}(n) \\ v_{Sa}(n-L+1) \\ \vdots \\ v_{Sb}(n) \\ v_{Sb}(n-L+1) \\ \vdots \\ v_{Sc}(n) \\ v_{Sc}(n-L+1) \end{bmatrix} \tag{6}$$

The fundamental positive- and negative- sequence components are extracted by using equations (7) and (8) respectively.

$$\begin{bmatrix} v_a^+ \\ v_b^+ \\ v_c^+ \end{bmatrix} = \frac{1}{3}\begin{bmatrix} 1 & 0 & -\frac{1}{2} & -\frac{\sqrt{3}}{2} & -\frac{1}{2} & \frac{\sqrt{3}}{2} \\ -\frac{1}{2} & \frac{\sqrt{3}}{2} & 1 & 0 & -\frac{1}{2} & -\frac{\sqrt{3}}{2} \\ -\frac{1}{2} & -\frac{\sqrt{3}}{2} & -\frac{1}{2} & \frac{\sqrt{3}}{2} & 1 & 0 \end{bmatrix}\begin{bmatrix} v_{Sa1}^{\cos} \\ v_{Sa1}^{\sin} \\ v_{Sb1}^{\cos} \\ v_{Sb1}^{\sin} \\ v_{Sc1}^{\cos} \\ v_{Sc1}^{\sin} \end{bmatrix} \tag{7}$$

$$\begin{bmatrix} v_a^- \\ v_b^- \\ v_c^- \end{bmatrix} = \frac{1}{3}\begin{bmatrix} 1 & 0 & -\frac{1}{2} & \frac{\sqrt{3}}{2} & -\frac{1}{2} & -\frac{\sqrt{3}}{2} \\ -\frac{1}{2} & -\frac{\sqrt{3}}{2} & 1 & 0 & -\frac{1}{2} & \frac{\sqrt{3}}{2} \\ -\frac{1}{2} & \frac{\sqrt{3}}{2} & -\frac{1}{2} & -\frac{\sqrt{3}}{2} & 1 & 0 \end{bmatrix}\begin{bmatrix} v_{Sa1}^{\cos} \\ v_{Sa1}^{\sin} \\ v_{Sb1}^{\cos} \\ v_{Sb1}^{\sin} \\ v_{Sc1}^{\cos} \\ v_{Sc1}^{\sin} \end{bmatrix} \tag{8}$$

As may be seen from the (7) and (8), the instantaneous positive- and negative-sequence components can be easily obtained using the instantaneous cosine and sine terms of the proposed ELS algorithm.

The D-STATCOM application that is discussed in the next section uses synchronously rotating reference frame controllers (i.e. $dq-$controllers). Therefore, transformation of the instantaneous positive- and negative- sequence voltage components into the $dq-$axes is required. The transformation of the positive- and negative- sequence components into the $dq-$reference frame is given in (9) and (10) respectively.

The overview of the complete proposed voltage dip detection method is illustrated in Fig. 1. The negative- and positive- sequence components at fundamental frequency are obtained from the instantaneous cosine and sine terms. Then, the $dq-$transformation is carried out to obtain the $d-$ and $q-$components for each sequence.

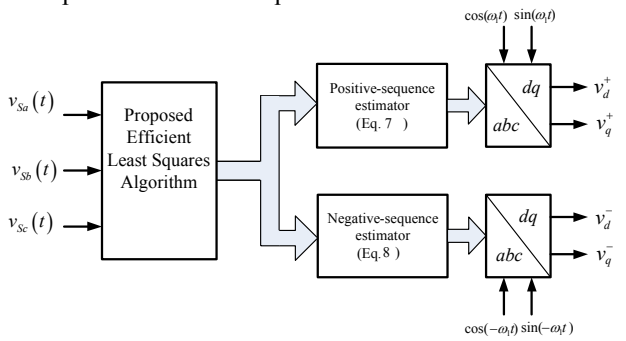

Figure 1 Block diagram of voltage dip detection method based on proposed ELS algorithm.

III. APPLICATION OF PROPOSED VOLTAGE DIP DETECTION METHOD IN D-STATCOM

A. System Configuration

The configuration of the D-STATCOM with the proposed voltage dip detection method is illustrated in Fig.2. The D-STATCOM consists of a three-phase voltage source converter (VSC), a dc-side capacitor C_{dc} with its leakage resistance R_{dc}, and an inductance L_F on the *ac*-side of the converter. The resistance R_F represents the cable resistance of the *ac*-side of the converter. A shunt filter capacitor with capacitance C_F and an inductance L_{tr} that represents transformer leakage inductance are added to the ac- side of the voltage source converter that forms a LCL filter. This filter helps in effectively filtering out the switching ripple in the output voltage waveform. The grid is represented by using an ideal voltage source and impedance. This impedance consists of an inductance L_{line} and a resistance R_{line} which characterizes the transformer and power line respectively. The analysis and design of the D-STATCOM controller are conducted in the rotating reference frame which is synchronized to the voltage vector. The D-STATCOM mitigates the voltage dips by dynamically injecting a current of desired amplitude and phase angle into the grid line. The two inner $dq-$ current regulators in Fig.2 force the converter currents i_{Fd} and i_{Fq} to follow the command currents i_{Fd}^* and i_{Fq}^* respectively. The command i_{Fd}^* to the $d-$axis current loop is obtained by summing the *dc*-link V_{dc}^2 -controller output and $d-$axis component of the reactive power controllers output i_{Cd} . The command i_{Fq}^* is obtained from the $q-$axis component of the reactive power controller output i_{Cq} . The purpose of the outer loop V_{dc}^2 -controller is to regulate the *dc*-link voltage to a required level. The modulation signals m_a , m_b and m_c for the PWM generator are derived from the output of the current controllers.

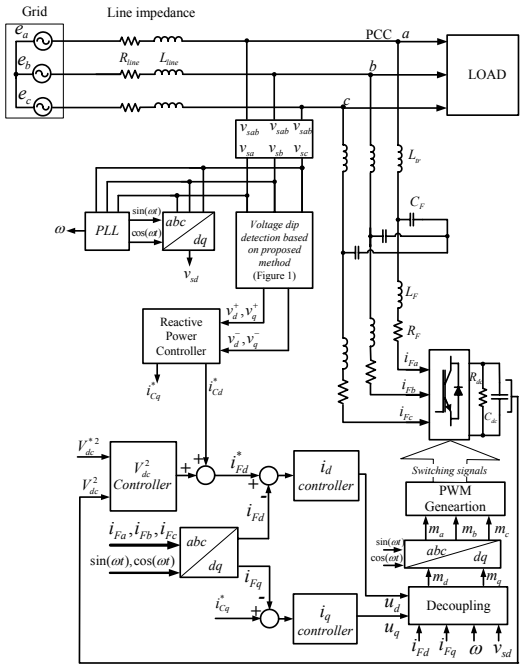

Figure 2 Overall schematic diagram of D-STATCOM with proposed voltage dip detection method.

The decoupling terms are added to the output of the current controllers in order to remove the coupling and are then transformed into the $abc-$ stationary reference frame to obtain the modulation signal for the VSC. The $\sin(\omega_1 t)$ and $\cos(\omega_1 t)$ terms required for the transformation between the $abc-$ and $dq-$ reference fames are obtained via a phase locked loop (PLL) which is synchronized to the fundamental component of the voltage. All of the above are illustrated in Fig. 2.

B. Positive-Negative-Synchronous Reference Frame Controller (Reactive Power Controllers)

In the case of balanced three-phase voltage, the direct transformation of abc voltages into the $d-q$ reference frame will result in dc-quantities. Hence, the D-STATCOM can use a conventional PI-controller to control the injected reactive currents. However, if the grid voltage or the load voltages are unbalanced, a ripple of double the grid frequency will occur in the $d-q$ reference frame. In the case of unbalance three-phase voltages, breaking the voltage signals into positive- and negative- sequence components and then transforming into $d-q$ synchronous reference frame (SRF) results in dc-quantities and these $d-q$ feedback signals allow in control design reactive power control. Transformation of three-phase balance voltages with unity magnitude into the positive- and negative- $d-q$ synchronous reference frame results in dc-quantities with following values.

$$v_d^+ = 1 \text{ pu}\,,\quad v_q^+ = 0 \text{ pu}\,, \text{ and } v_d^- = 0 \text{ pu}\,,\quad v_q^- = 0 \text{ pu}$$

where v_d^+, v_q^+ - dq components of positive-sequence voltage, and v_d^-, v_q^- - dq components of negative-sequence voltage.

The voltage dips (both balanced and unbalanced) in power systems can be corrected by regulating positive- and negative-synchronous dq components to the values corresponding to the balanced case given above. Three controllers are utilized to regulate these dq components of the positive- and negative-sequence voltages as shown in Fig. 3. As shown in Fig. 3 v_d^+ is regulated to 1 pu via i_q^{+*} in the positive-sequence synchronous reference frame. v_d^- and v_q^- are regulated to zero via the i_q^{-*} and i_d^{-*} in the negative-sequence synchronous reference frame. These dq - current components in the positive- and negative- synchronous reference frames are converted into three axes components and added those together to obtain three- phase currents that need to be injected to the line in order to compensate for the voltage dips. These abc current commands are then converted to the positive-sequence synchronous reference frame dq components to generate the current commands (i.e i_{Cd}^* and i_{Cq}^*) for the current controllers. All these are indicated in Fig. 3.

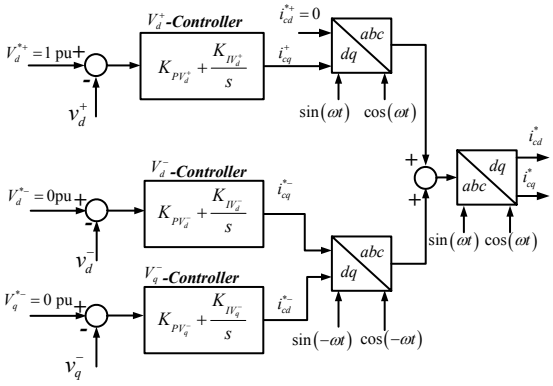

Figure 3 Block scheme of reactive power controller for D-STATCOM.

$$\begin{bmatrix} v_d^+ \\ v_q^+ \end{bmatrix} = \frac{2}{3}\begin{bmatrix} \sin(\omega t) & \frac{1}{2}\left(-\sin(\omega t)-\sqrt{3}\cos(\omega t)\right) & \frac{1}{2}\left(-\sin(\omega t)+\sqrt{3}\cos(\omega t)\right) \\ \cos(\omega t) & \frac{1}{2}\left(-\cos(\omega t)+\sqrt{3}\sin(\omega t)\right) & \frac{1}{2}\left(-\cos(\omega t)-\sqrt{3}\sin(\omega t)\right) \end{bmatrix}\begin{bmatrix} v_{Sa}^+ \\ v_{Sb}^+ \\ v_{Sc}^+ \end{bmatrix} \quad (9)$$

$$\begin{bmatrix} v_d^- \\ v_q^- \end{bmatrix} = \frac{2}{3}\begin{bmatrix} -\sin(\omega t) & \frac{1}{2}\left(\sin(\omega t)-\sqrt{3}\cos(\omega t)\right) & \frac{1}{2}\left(\sin(\omega t)+\sqrt{3}\cos(\omega t)\right) \\ \cos(\omega t) & \frac{1}{2}\left(-\cos(\omega t)-\sqrt{3}\sin(\omega t)\right) & \frac{1}{2}\left(-\cos(\omega t)+\sqrt{3}\sin(\omega t)\right) \end{bmatrix}\begin{bmatrix} v_{Sa}^- \\ v_{Sb}^- \\ v_{Sc}^- \end{bmatrix} \quad (10)$$

where v_d^+ and v_q^+ are the $dq-$ components of the positive-sequence voltage, and

v_d^- and v_q^- are the $dq-$ components of the negative-sequence voltage.

IV. Simulation Results

In this section, the simulation results for the D-STATCOM with the proposed voltage dip detection method will be presented. The configuration of the D-STATCOM system with the proposed ELS algorithm based voltage dip detection that is shown in Fig. 2 is modelled using the MATLAB/SIMULINK software package. The modelling and simulations of the D-STATCOM have been carried out for unbalanced voltage dip. The system has been tested for mitigation of the unbalanced voltage dips. Three-phase grid voltages with 25% voltage dip and 20% amplitude unbalance are shown in Fig. 4 and the corresponding positive- and negative-sequence $dq-$ components are shown in Fig. 5. As shown in Fig. 5, the amplitude of the positive- sequence $d-$ component decreases to 0.75 pu and the $q-$component remains zero. In negative-sequence, the $d-$and $q-$components have amplitudes of 0.08 pu and -0.04 pu respectively during the unbalanced voltage dip. Fig. 6 shows the voltage waveform after compensation by the D-STATCOM with the proposed dip detection method in the case of unbalanced voltage dip. As expected, the PCC voltage is constant at 1 pu before, during and after the voltage dip, apart from the transient at the beginning and at the end of the voltage dip. The error in the voltage waveform is also shown in Fig. 6. As may be seen, the error is very small in the steady-state and the transient errors of less than 0.2 pu appear for short durations.

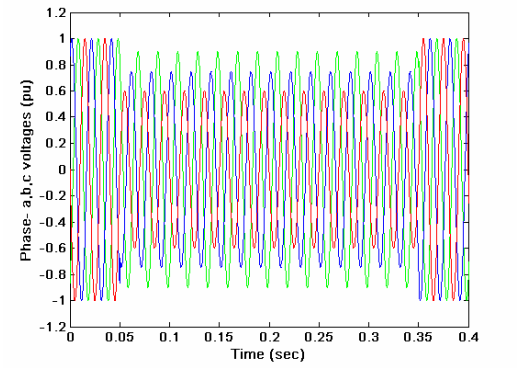

Figure 4 Simulated three-phase grid voltages during unbalanced voltage dip.

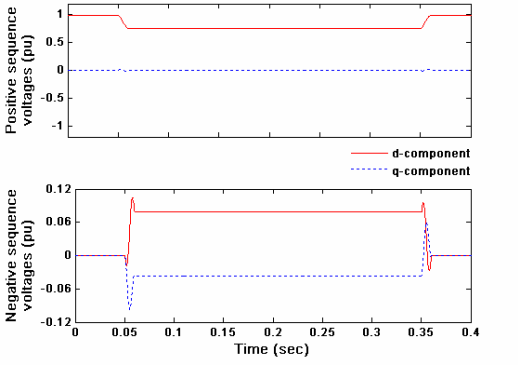

Figure 5 Simulated grid voltages in SRF $dq-$components in case of 25% voltage dip with 20% amplitude unbalance. Top: positive- sequence in positive SRF; bottom: negative-sequence in negative SRF.

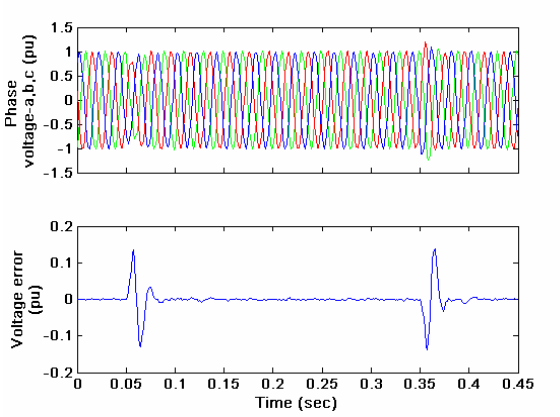

Figure 6 Compensated voltage waveforms at PCC and voltage waveform error in the case of unbalance voltage dip.

V. Conclusions

This paper has shown that the proposed ELS algorithm can be used for voltage dip and unbalanced mitigation in the D-STATCOM. The D-STATCOM consists of positive- and negative-synchronous reference frame controllers that regulate the $dq-$components of the positive and negative voltage to result in balanced three-phase voltages at the point of common coupling. The *dc*-link voltage is regulated to a set value via the $d-$axis current. The synchronous reference frame $dq-$axes current controllers are utilized to force the currents into the grid. The instantaneous positive- and negative- sequence components of the voltages are obtained using the instantaneous cosine and sine terms of the fundamental components of phases -*a*, -*b* and -*c*. The identified positive- and negative-sequence components are then represented in the positive- and negative- synchronous reference frames respectively. These voltage components are regulated to set values that correspond to the three-phase balance voltages in order to mitigate the voltage dips and unbalances. The proposed voltage dip and unbalance detection method allows for extraction of these sequence component within a half fundamental cycle. In addition the proposed method is capable of identifying the voltage dips and unbalances accurately even though the point of common coupling is strongly corrupted by the voltage harmonics. A prototype D-STATCOM system is modelled and simulated using MATLB/SIMULINK. The modelled system is tested for identification and mitigation of the unbalanced voltage dip. Extensive simulation studies showed that the proposed voltage unbalance and dip detection method allows fast and accurate extraction of information that is required for successful operation of the D-STATCOM system.

***Abstract*- In this paper a starting jerk reduction method for switched reluctance motors has been proposed. The method is based on an improved initial rotor-position estimation technique at standstill condition. In the propose method, the rotor position is simply estimated using only the phase current data from three current sensors without any priori knowledge of motor parameters. The results from this research have shown reasonable outputs. This could be proved that the purposed method has more accuracy than the previous methods.**

***Index Term*- Reluctance machines, estimation, starting.**

I. INTRODUCTION

With various merits of switched reluctance motors (SRMs), such as rugged low-cost construction, no permanent magnet inside, simple stator and rotor structure, easily cooling system, high reliability and good performance over a wide speed range, have make it a comparable competitor to the other drives and suitable for propulsion systems of the electric vehicle (EV) and hybrid vehicle (HV). Also, its performance can be easily adjusted for various load profile.

For traction drive applications, a high starting torque is required. Therefore, a 3-phase, 6/4 pole (i.e., 6 stator poles, and 4 rotor poles) SRM which has higher inductance ratio is suitable for these applications. In the view point of starting performance, the 6/4 pole SRM which has a large stroke angle may have a poor accelerating characteristic including starting jerk caused by an error on initial rotor position estimation. The oscillation and backward movement from the starting jerk problem are ones of the sensitive problems for EV application.

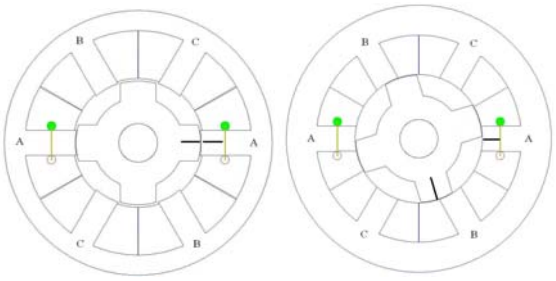
To solve this problem, incremental encoders, which are much less costly than absolute encoders, are widely used. However, incremental encoders do not have any data at the initial position, thus various estimating methods have been proposed. Most methods are based on complex calculation and machine parameters [1], [2], [3].

In this paper, a simple and more accurate initial rotor position estimation method is proposed, and starting jerk at standstill condition is mainly focused. An incremental encoder is used for the reason of system reliability. The proposed method is analyzed and experimentally investigated on a 1.5 kW 6/4 pole SRM which is designed for small electric vehicles. A Basic principle about the relation between the inductance, winding current and rotor angle at the standstill condition is analytically mentioned. The principle of the proposed method is described, and some information on the test system and its result are shown.

II. BASIC PRINCIPLE

Figure 1 shows the outline of the tested motor at different rotor position. When the rotor rotates into any direction, the inductance of the winding is varied. The relationship between the rotor position and the phase inductance can be drawn as in Figure 2. Under normal running condition and starting condition, the excitation signal for each phase must be properly synchronized to the phase inductance values within torque development zone (i.e., when the inductance profile has a positive slope) in order to generate large positive torque. Therefore, to rotate the motor into the specified direction correctly, the rotor position is required to be known.

For a SRM drive system, even though the widely used incremental encoder can provide the rotor position data, still the rotor position at the initial stage cannot be accessed before the real position has been known. When the motor begins to rotate, some undesirable events could happen, for examples: the motor temporarily rotates into the wrong direction; the motor starts to jerk back and forth before it can run smoothly. The starting jerk problem as shown in Figure 3 and Figure 4 can occur in the situation where the motor with inaccurate initial rotor-position data is attempting to immediately adjust to the true position after the encoder index has been detected. Therefore, a more accurate initial rotor-position estimation technique has been developed in this paper. This improved technique will be described in the next section.



a) Rotor at 0°(aligned position), b) Rotor at 73°

Figure 1. Cross section of a 6/4 pole 3 phase SRM.

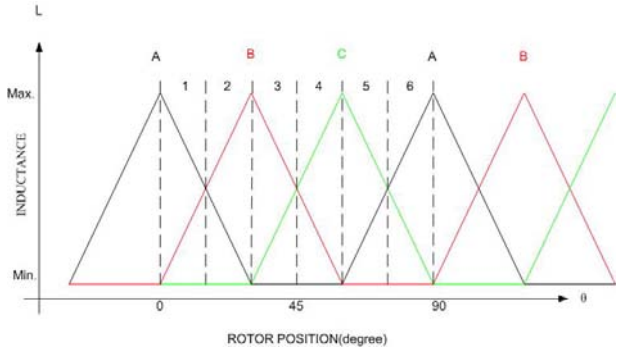


Figure 2. Idealized unsaturated inductance versus the rotor position.

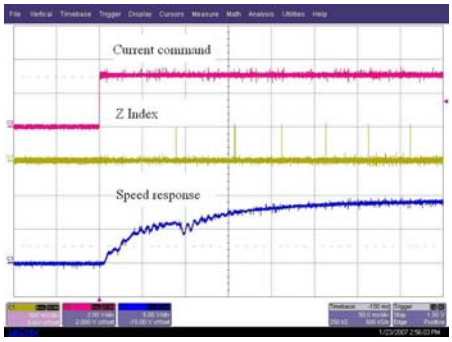

Figure 3. Current command, Z Index and speed response for estimated position = 68°, rotor position = 73° with load 2 Nm.

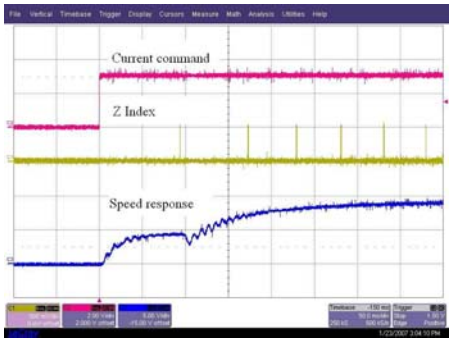

Figure 4. Current command, Z Index and speed response for estimated position = 83°, rotor position = 93° with load 2 Nm.

III. ROTOR POSITION ESTIMATION

A. *Previous methods*

In recent years, several rotor position estimation methods have been studied for SRMs [1]-[5]. In [1], [2] the phase winding at the motor stator is first excited. Then the rotor pole can be aligned in the same direction as the excited stator pole. With this method, the rotor position can be accessed but the rotor has to move. Therefore, there is a possibility that the rotor move to the wrong direction.

In [1], [2], [3] the rotor position estimation method can be done by motor testing. Firstly, the excited voltage has been applied to the stator pole; next the phase current has been measured and calculated for flux linkage. Then the measurement result is compared to the data that has been collected during the motor is working properly.

TABLE I
The relation between the current amplitude and the rotor position

Section No.	Rotor position	Current	Rotor estimation
1	0°<θ<15°	Ia<Ic<Ib	7.5°
1	θ=15°	Ia=Ic<Ib	15°
2	15°<θ<30°	Ic<Ia<Ib	22.5°
2	θ=30°	Ic<Ia=Ib	30°
3	30°<θ<45°	Ic<Ib<Ia	37.5°
3	θ=45°	Ic=Ib<Ia	45°
4	45°<θ<60°	Ib<Ic<Ia	52.5°
4	θ=60°	Ib<Ic=Ia	60°
5	60°<θ<75°	Ib<Ia<Ic	67.5°
5	θ=75°	Ib=Ia<Ic	75°
6	75°≤θ<90°	Ia<Ib<Ic	82.5°
6	θ=90°	Ia<Ib=Ic	90°

Therefore with this method, the necessary data of the motor during the working is needed and this could lead to the mistaken if the voltage period is too small or the measurement instrument is not accurate enough to separate the rotor angles if the voltage period is getting bigger. This also could lead to the undesirable moving of shaft similar to the first method [1], [2], [3].

In [4], [5] the rotor position estimation method is applying the small testing signal and measuring the phase current of the motor. The phase current can estimate the rotor position in some interval and the appropriated phase can be selected for exciting the winding at starting condition. However, this method is only an approximation for the rotor position and is not accurate enough. For applying to the 6/4 pole 3 phase of SRM, the rotor position can be estimated for the interval of 15 degrees only.

Therefore, in order to apply this method in our work, the rotor position could be estimated as in table 1. But the precision was not satisfied and cause the problem in the real application. Therefore the new technique has been developed to solve this kind of problem.

B. *Proposed method*

This estimation method used each phase current data based on the assumptions that the resistive voltage drop is negligible and there is no mutual coupling between two phases, the voltage equation of one SRM phase can be simplified as (1). Using inject the short duration about few hundred microseconds of gate drive signal to each phase simultaneously, each phase winding current will increase as a straight line from zero and have peak value at the end of excitation as shown in Figure 5. The period of the pulse is short enough and do not produce enough torque to move the rotor. That means the relation in (2) is valid and the slope of the current waveform directly depend on the value of V/L.

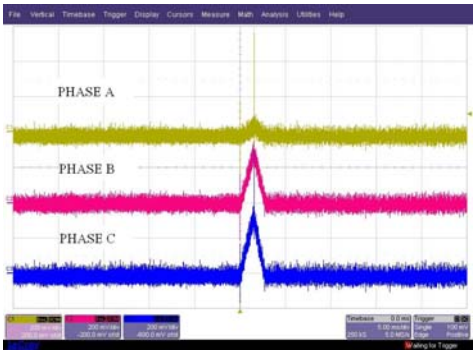

Figure 5. Current from test signal using the proposed method at rotor = 0°.

Where V is the supply voltage and L is the phase inductance, respectively. (1), (2)

$$V = L\frac{di}{dt} \tag{1}$$

$$\Delta i = \frac{V}{L} \times \Delta t \tag{2}$$

Figure 6 indicates the measured winding peak current at every one degree of rotor position. The apply voltage about 600 microsecond is applied and the current is measured by three hall- effect current sensors (HX50-P) and 8-bit A/D converters.

From Figure 6 the current waveform can be also divided in 6 sections similarly to the inductance profile in Figure 2. Each section has one phase that amplitude is nearly zero. The currents in other two phases are used for rotor position calculation in that section. Also, it always has cross section point at 0°, 30°, 60° and 90°. In the proposed method, for example between 15° to 45°, phase C current has minimum value and phase A and B are symmetrical around 30° point. For analysis, the current-profiles are approximated by straight line as shown in Figure 7. The relation between measured current and rotor position can be solved by the following (3).

$$\theta est = 30 + [(Ia - Ib)\frac{\theta base}{(Ia + Ib)}] \tag{3}$$

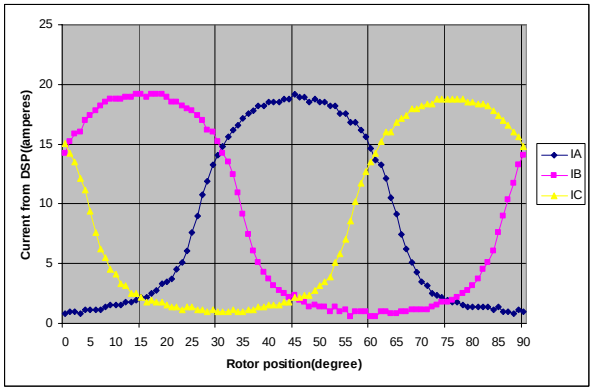

Figure 6. Phase currents obtained from DSP with A/D 8 bits versus the rotor position.

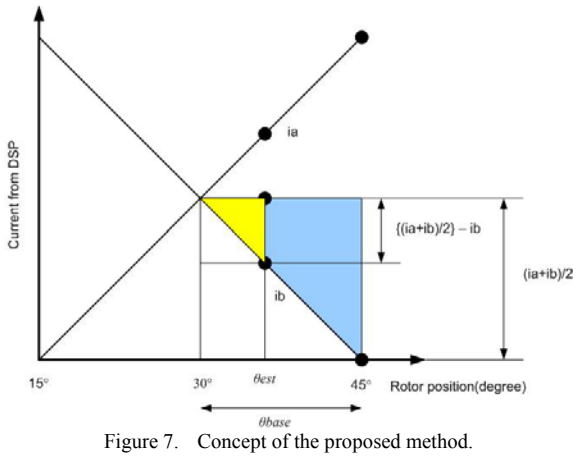

Figure 7. Concept of the proposed method.

Where

θest = Estimate rotor position
Ia = maximum phase current
Ib = second maximum phase current
$\theta base$ = base of section (15°)

It is assumed that the minimum current in each section is very small, therefore its value can be set to zero. With the same concept, the rotor position in the other section can be calculated as below:

Section 1: Rotor position during 0° to 15°, calculate from (4)

$$\theta est = (Ib - Ic)\frac{15}{(Ib + Ic)} \tag{4}$$

Section 2: Rotor position during 16° to 30°, calculate from (5)

$$\theta est = 30 - [(Ib - Ia)\frac{15}{(Ib + Ia)}] \tag{5}$$

Section 3: Rotor position during 31° to 45°, calculate from (6)

$$\theta est = 30 + [(Ia - Ib)\frac{15}{(Ia + Ib)}] \tag{6}$$

Section 4: Rotor position during 46° to 60°, calculate from (7)

$$\theta est = 60 - [(Ia - Ic)\frac{15}{(Ia + Ic)}] \tag{7}$$

Section 5: Rotor position during 61° to 75°, calculate from (8)

$$\theta est = 60 + [(Ic - Ia)\frac{15}{(Ic + Ia)}] \tag{8}$$

And Section 6: Rotor position during 76° to 90°, from (9)

$$\theta est = 90 - [(Ic - Ib)\frac{15}{(Ic + Ib)}] \tag{9}$$

IV. EXPERIMENTAL RESULTS

Figure 8 shows the experiment setup which consists of SRM, torque meter and DC motor. SRM is coupled to the torque meter while the DC motor is used as a load for 2 Nm.

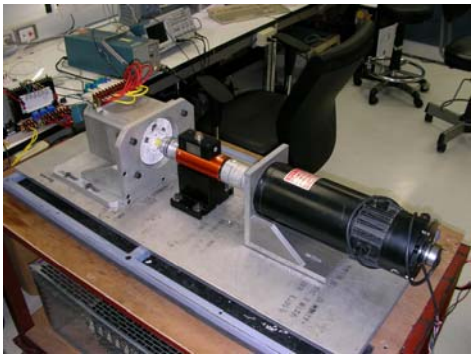

Figure 8. Experimental setup for testing the SRM.

The result of the estimated rotor position using the proposed method is shown and compared to the actual rotor position in Figure 9.

In this experiment, the actual rotor positions were measured after the first index has been detected using an external circuit to detect the rotor position.

Figure 10, 11 show the experimental result by using our technique at the rotor position = 73° and 93° near aligned position with load 2 Nm.

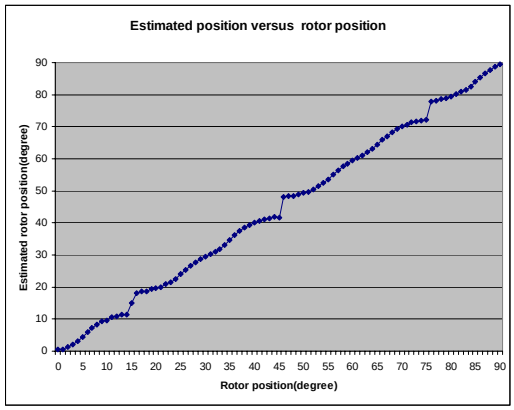

Figure 9. Estimated position versus rotor position.

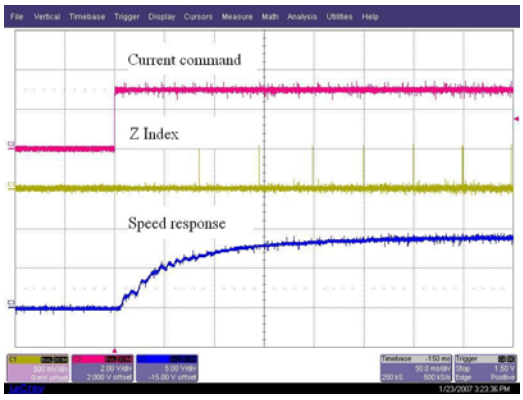

Figure 10. Current command, Z Index and speed response for rotor position estimation from the purposed method at rotor position = 73° with load 2 Nm.

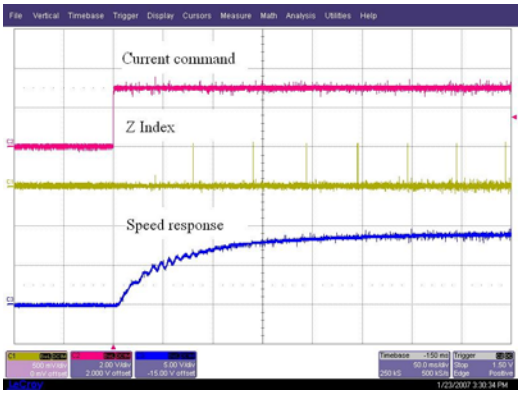

Figure 11. Current command, Z Index and speed response for rotor position estimation from the purposed method at rotor position = 93° with load 2 Nm.

V. CONCLUSIONS

The starting jerk reduction method based on improvement of the initial rotor position method for the SRM had been proposed. The effectiveness of the method is evidently shown by the experimental results. It has been shown that, position errors within 3.5degrees can be achieved whereas the previous method gives position errors within 7.5degrees. Consequently the starting jerk can be significantly reduced. Moreover, the proposed method can be easily implemented using a low-cost DSP without any motor parameter.

***Abstract*- This paper proposes a simple linear model of a switched Reluctance Machine (SRM). The permeability of the core is set to be infinity. The equipotential flux at the air gap is obtained from the Finite Element Analysis (FEA). The approximated permeance or reluctance profile are generated by using flux tube analysis at various rotor positions. The validity of the proposed model is confirmed by the FEA. This linear model is a function of the motor geometry so the designer can choose the estimated sizes of the machine easily.**

I. INTRODUCTION

The magnetic property of the SRM depends on the machine's geometry especially the rotor and the stator poles. They define the characteristic of the pole flux [1]. To design the SRM, if the designer knows the equipotential flux path then the permeance can be calculated [2]. For this paper, the flux tube analysis is used to analyze the permeance profile of the candidate machine. Sine we know the permeance profile or reluctance profile, the magnetizing curve is known and the static torque profile can be estimated. The permeance profile definitely depends on the machine geometry. By developing the linear model, the designer can initially estimate the sizes of the machines. The detail of the design is finally done by the FEA program.

This paper proposes the permeance models at different rotor positions from 0% alignment to 100% alignment with 10% increment. Figure 1 depicts the equipotential flux path obtained from the FEA and the estimated flux path. This estimated flux path is used for the flux tube analysis [3].

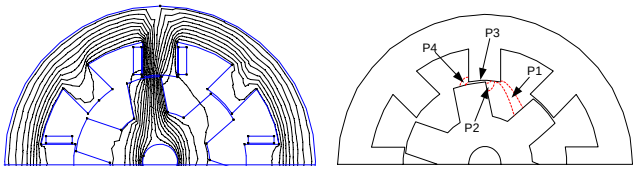

Figure 1. The equipotential flux path (left) obtained from the FEA and the estimated flux path for flux tube analysis (right).

II. FLUX TUBE ANALYSIS

The geometry of the rotor pole defines the inductance profile of the machine. Once the flux paths are known, then the permeance can be calculated. The method used for this calculation is called "flux tube analysis". For this proposal, flux paths are assumed to follow straight line segments as shown in Figure 2 and circular arcs as shown in Figure 3 as an approximation of their actual path. In deriving a model, the permeability of the iron is set to infinity, and saturation effects are neglected, as is fringing flux at the end of the core. A flux tube analysis is performed at different rotor positions from unaligned position to fully aligned position.

A. Straight line section.

Figure 2 shows the straight flux lines flowing from one ferromagnetic surface to another. The permeance is

$$\wp = \mu_0 l \frac{s}{g} \tag{1}$$

where s is the width of a ferromagnetic material, l is the depth of a ferromagnetic material, and g is the air gap between the two ferromagnetic surfaces.

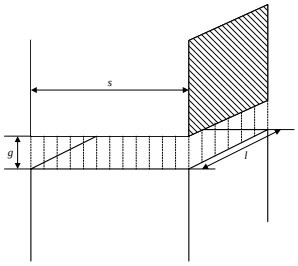

Figure 2. The two ferromagnetic surfaces showing the straight flux path.

B. Circular Arc section.

Figure 3 shows two surfaces that are not parallel and the resulting curved lines that are about a single center point for each equipotential line. The permeance is

$$\wp_3 = \frac{\mu_0 l}{\theta} \ln \frac{x_2}{x_1} \tag{2}$$

where x_1 and x_2 are radii, l is the depth of a ferromagnetic material, and θ is the angle between two ferromagnetic surfaces.

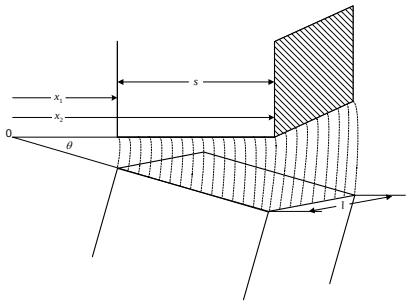

Figure 3. The two ferromagnetic surfaces showing the circular arc flux path.

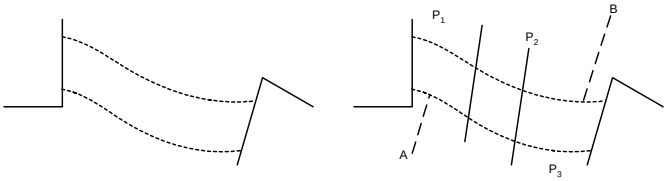

Figure 4. The arbitrary flux path can be divided into 3 basic sections.

For the example shown in Figure 4, the equipotential flux path can be separated into three basic paths. $\wp_1$ is a curved line with a center of rotation at point A. $\wp_2$ is a straight line and $\wp_3$ is a curved line with a center of rotation at point B. The total permeance of Figure 4 is shown as follow:

$$\wp_{total} = \left[\frac{1}{\wp_1} + \frac{1}{\wp_2} + \frac{1}{\wp_3}\right]^{-1} \quad (3)$$

III. Equipotential Flux Path

A finite element analysis program [4] is used to simulate the flux path. The geometry of the candidate machine is shown in Table I. Figure 5 depicts the cross-sectional of the machine in the FEA program. To simulate the linear property of the core, the permeability of the core material is set to be infinity, parameter in the program is set to 10^{12} as shown in Figure 6.

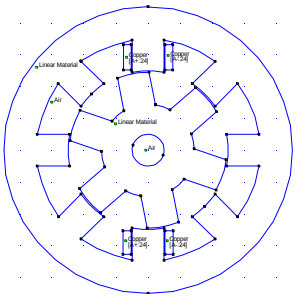

Figure 5. The cross-sectional of the candidate machine.

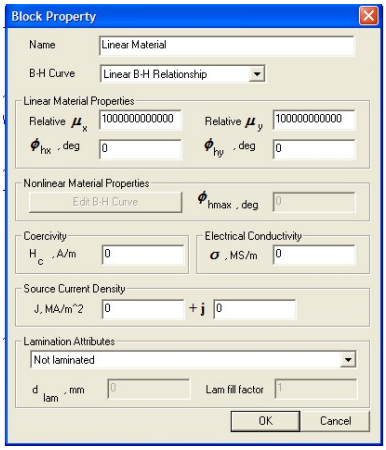

Figure 6. The permeability of the core material is set to 10^{12} in FEA program.

TABLE I
THE DIMENSIONS OF CANIDATE SRM

Stator outer diameter	90.00 mm
Internal stator diameter	34.50 mm
Internal rotor diameter	13.50 mm
Shaft diameter	10.00 mm
Stack length	50.00 mm
Airgap	0.50 mm
Winding turn per pole	24 turns

The results from FEA show the equipotential flux path as depicted in Figure 7. This is used to create the estimated flux path for further analysis.

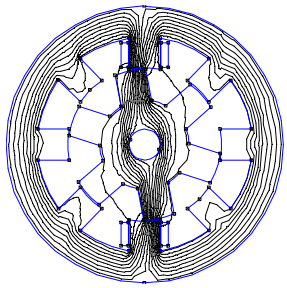

Figure 7. The equipotential flux paths of the exampled rotor position obtained from the FEA program.

IV. Example of the Proposed Method

From the FEA results, the equipotential flux path at different rotor positions is generated. The example is shown in Figure 8. The rest of the rotor positions are shown in the appendix.

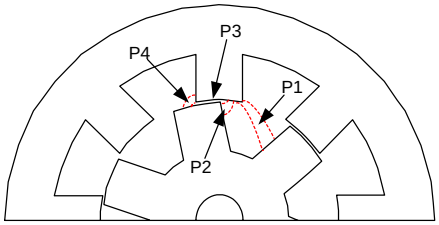

Figure 8. Estimated flux path from the exampled rotor position.

The estimated flux path in Figure 8 is divided into 4 permeance sections. Figure 9 – 12 show the flux path and the parameters for flux tube calculation for each basic section.

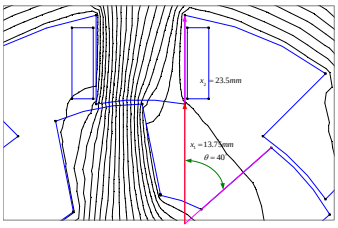

Figure 9. The equipotential flux path of section P1 and its dimension.

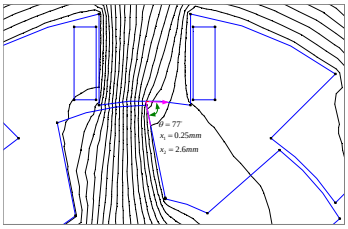

Figure 10. The equipotential flux path of section P2 and its dimension.

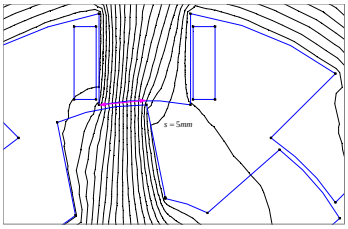

Figure 11. The equipotential flux path of section P3 and its dimension.

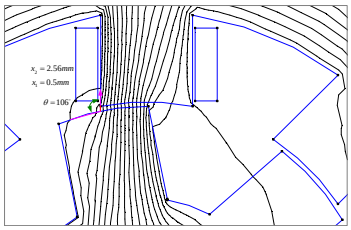

Figure 12. The equipotential flux path of section P4 and its dimension.

Once the permeance of each section is combined, the pole flux is calculated by using Equation 4.

$$\phi = \wp_{total} \times Ni \tag{4}$$

where ϕ is the pole flux, $\wp_{total}$ is the total permeance at considered pole, N is the number of turns and i is the phase current.

From the Figure 13 reveals that the results from FEA and the proposed model are acceptably close. The phase current is set to 1A.

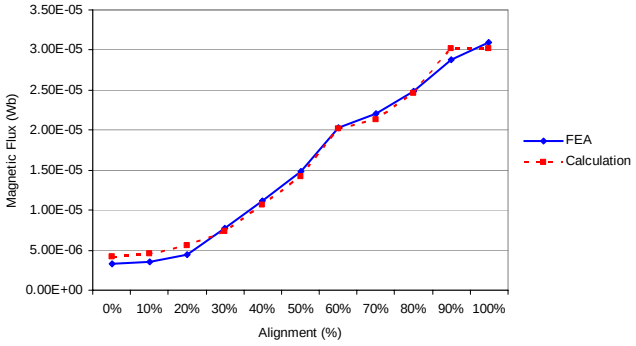

Figure 13. The comparison of the pole flux between FEA and the proposed linear model.

V. CONCLUSION

Flux tube analysis is used to develop a linear model of the SRM. The linear model provides a simple and quick solution of how to determine the machine geometry initially. The results of the proposed model are accurate by comparing with the FEA results. This method can be applied with any numbers of phases of SRM. The non linear model will be discussed in the near future.

Field Efficiency Estimation Technique for Inverter-Fed Induction Motor

T. Phumiphak* and C. Chat-uthai**

* Department of Electrical Power Engineering, Faculty of Engineering, Mahanakorn University of Technology, Bangkok 10530, Thailand (e-mail: kcthanaphiwat@yahoo.com)

** Department of Electrical Engineering, Faculty of Engineering, King Mongkut's Institute of Technology Ladkrabang, Bangkok 10520, Thailand (e-mail: kcchaiwu@kmitl.ac.th)

***Abstract*-This paper presents a technique for estimating the field efficiency of inverter-fed induction motor at various operating frequencies and loads using only a set of data from field measurement without the need for measuring output of motor which is highly intrusive task. The field performances of motor such as output power and torque, and efficiency can be estimated by using the measurement data coupled with the use of genetic algorithms based on motor equivalent circuit concept. The 2.2 kW and 5.5 kW three-phase induction motors fed by inverter were tested under operating frequencies of 40, 45, 50 Hz at various loads. The estimated results of proposed technique are presented and then compared to the measured values obtained from laboratory test and found to give a better correlation over a wide range of speeds and loads. This efficiency technique expects to be useful in assisting decisions of replacement of motors in industry because of its acceptable accuracy and non-intrusive operation.**

I. INTRODUCTION

In power system, the largest component of the loads is three-phase induction motors and they are extensively used in industrial and commercial applications. The ac frequency-controlled variable-speed drives have recently shown a growing number of applications in the process industries. The most common configuration is a pulse-width-modulation (PWM) frequency converter. When induction motors are driven by inverters for variable speed, the waveforms become distorted and contain several higher order harmonics. In regard to efficiency considerations, for the motors operating with variable speed, there are two major differences that need to be considered. First, as the cooling fan is attached to the motor shaft, when the operating speed goes down, the fan rotates at lower speed; therefore the air impelled by the fan is then reduced. Secondly, for the motor fed from frequency converter, the core losses change at different operating frequencies affecting the internal losses and temperatures. In addition, current harmonics circulating in the windings produce additional heating.

As far as energy consumption is concerned, reducing induction motor efficiency means that the increase of the induction motor losses. If the rated output of an induction motor is maintained, motor input power will be increased. In other words, when a motor is operating at rated power output with variable speed, the utility has to supply more input power to accomplish the same work. As for the customers, if an induction motor efficiency is reduced (higher total losses), the electricity charge on the customers will be increased. Many research papers have been reported regarding the performance prediction of induction motors under distorted supply systems [1-3]. The predicted performance figures are obtained from the solution of the equivalent circuits whose parameters are different for fundamental and for different harmonics. Some authors have assumed the parameters to be constant irrespective of the presence of harmonic contents in the supply voltage but in practice some of the parameters vary considerably depending upon the order of harmonic. Thus, the predicted performances using such models are quite different from the measurements. Obviously, this is an unacceptable condition.

In this paper, the focus is put on how field efficiency of inverter-fed induction motor can be determined by minimum intrusion. A technique for estimating efficiency of such motor using only a set of accessible data from field measurement without the need for measuring motor output is then proposed. The appropriate value of motor parameters at any operating load (variable speed) can be evaluated by the use of measured data such as frequency, rms voltage, rms current, input power, and speed coupled with the numerical optimization technique called genetic algorithms (GAs) [4]. The GAs are a heuristic technique based on the evolutionary processes similar to natural selection, mutation, and reproduction observed in biological systems that may be used to solve a system of nonlinear equation.

II. INVERTER-FED INDUCTION MOTOR

Induction motor efficiency characterizes the energetic behavior during the conversion of the electrical power in mechanical power. Comparison of motor efficiencies is certainly a valid tool to justify the use of one motor over another. The motor field efficiency is mainly a function of operating output load and speed which is defined as

$$\text{Field Efficiency} = \frac{P_{mechanical}}{P_{electrical}} \cdot 100 \qquad (1)$$

where $P_{mechanical}$ is the output power at motor shaft and $P_{electrical}$ is the electrical power absorbed from supply.

The difference of these two powers is the total operating losses which can be subdivided into the core, windings, and mechanical losses. As stated in [1], the operation of inverter-fed induction motor drive with variable voltage, variable frequency and variable rotational speed has an effect on these operating losses.

The core losses (hysteresis and eddy-current) are highly dependent on frequency and the maximum flux density per pole. For the drive operating in the range of speeds up to the base speed, the maximum flux density is kept constant at different frequencies; therefore the ratio voltage per frequency has to be kept constant. For speeds above the base speed, voltage is constant and frequency is increased. In this range, eddy-current losses become constants, and hysteresis losses reduce slightly with the increase of frequency. Copper losses in windings and rotor bars depend on the rms current squared, and on the resistances. Fundamental frequency current components depend on the motor load, while harmonic components depend on the specific PWM pattern at the operating point, and motor parameters. The effects of current harmonics are mainly two. First, they produce additional vibrations and noise. Secondly these current harmonics produce the extra heating that will affect the steady temperatures reached in the windings. Mechanical losses depend on the operating motor speed, and are related to friction in bearing and windage (rotor blades).

III. FIELD EFFICIENCY ESTIMATION

This paper proposes a non-intrusive technique for estimating the field efficiency of inverter-fed induction motor operating at any load (variable speed) without costly testing procedure. The estimated field efficiency is based on the concept of equivalent circuit parameters [5]. From the equivalent circuit, the motor performances can be defined as follows

$$\mathbf{Z}_1 = R_1 + j\omega L_1 \tag{2}$$

$$\mathbf{Z}_2 = \frac{R_c\, j\omega L_m}{R_c + j\omega L_m} \tag{3}$$

$$\mathbf{Z}_3 = R_{SLL} + j\omega L_2 + \frac{R_2}{s} \tag{4}$$

$$\mathbf{Z}_{total} = \mathbf{Z}_1 + \frac{\mathbf{Z}_2\mathbf{Z}_3}{\mathbf{Z}_2 + \mathbf{Z}_3} \tag{5}$$

the motor power factor can be expressed as

$$PF = \cos\left(\tan^{-1}\left(\frac{\mathrm{Im}(\mathbf{Z}_{total})}{\mathrm{Re}(\mathbf{Z}_{total})}\right)\right) \tag{6}$$

$$\mathbf{I}_1 = \frac{\mathbf{V}_1}{\mathbf{Z}_{total}} \tag{7}$$

$$\text{input power} \quad P_{input} = 3V_1 I_1 (PF) \tag{8}$$

$$\mathbf{I}_2 = \frac{\mathbf{I}_1\mathbf{Z}_2}{\mathbf{Z}_2 + \mathbf{Z}_3} \tag{9}$$

then, the estimated motor performances are obtained from

$$\text{output power} \quad P_{output} = \frac{3I_2^2 R_2 (1-s)}{s} \tag{10}$$

$$\text{output torque} \quad T_{output} = \frac{P_{output}}{\omega_r} \tag{11}$$

$$\text{Efficiency} = \frac{P_{output}}{P_{input}} \cdot 100 \tag{12}$$

where V_1, I_1, R_1 and L_1 denote stator voltage, current, resistance and leakage inductance respectively, I_2, R_2 and L_2 stand for rotor current, resistance and leakage inductance referred to stator respectively, R_c is core loss resistance, L_m is magnetizing inductance, R_{SLL} is the proposed stray load loss parameter [5], s denotes slip and ω denotes angular velocity ($2\pi f$).

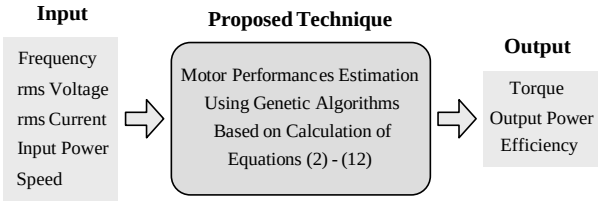

Figure 1. Flowchart of Field Efficiency Estimation

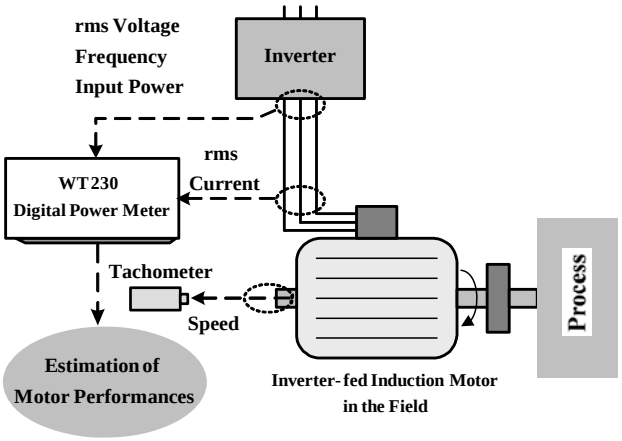

Figure 2. Implementation for Proposed Technique

The appropriate parameters of motor at any condition can be estimated by using a set of measured data coupled with the use of genetic algorithms as shown in Fig. 1. The field data which rely on measuring input frequency, rms voltage (V_1), rms current (I_1), electrical power (P_{input}) and speed of motor are obtained from field measurement as shown in Fig. 2. Then, the motor parameters can be evaluated by using Eq. (7) and (8)

coupled with the GAs in order to minimize the error of Eq. (13).

$$\text{Min.} \quad F_{objective} = \left|\frac{I_{1,cal}}{I_{1,mea}} - 1\right|^2 + \left|\frac{P_{input,cal}}{P_{input,mea}} - 1\right|^2 \qquad (13)$$

where $I_{1,cal}$ and $P_{input,cal}$ are the calculated values using Eq. (7) and (8). $I_{1,mea}$ and $P_{input,mea}$ are the measured values obtained from the operating motor.

IV. EXPERIMENTAL RESULTS

The non-intrusive technique described above was applied to two different sizes of three-phase induction motors. Table 1 shows the nameplate information of the motors. These motors were tested in the laboratory using standard electrical instrumentation. The motors under test were supplied with power from the three-phase inverter (380-480 V, 50/60 Hz, 27.9A, switch frequency 1 kHz, Fuji FRENIC 5000G11, Type FRN7.5G11S-4JE). For input electrical power a three-phase digital power meter (model WT230, Yokogawa) provided data on frequency, voltage, current and power. The values of both voltage and current were measured in mode rms obtained by

$$\sqrt{\frac{1}{T}\int_0^T f(t)^2 dt} \qquad (14)$$

where $f(t)$ denotes input signal (voltage or current) and T is one period of the input signal.

TABEL I
NAMEPLATE INFORMATION OF INDUCTION MOTORS

	2.2 kW (3 hp)	5.5 kW (7.5 hp)
Hz	50	50
V	220/380	220/380
A	8.7/5.0	20.4/11.8
rpm	1420	1430
Pole	4	4

The motors were loaded by a dynamometer with rotating shaft-mounted torque sensor and tachometer for measuring motor output torque and speed. The load test of motors was performed at three different operating frequencies (40, 45 and 50 Hz) under various loads. The load test results (T) of 2.2 kW and 5.5 kW motors were shown in Fig 3 and 4 respectively. To illustrate the use of this proposed technique, assume that an inverter-fed induction motor is operating in the process at a given frequency and load. For example, the 2.2 kW motor is operating at frequency of 40 Hz, the set of data obtained from field measurement is 226.6 V (rms), 5.12 A (rms), 2371 W, 1104.5 rpm as illustrated in Table 2. By using Eq. (13), the appropriate motor parameters under this condition are evaluated and the motor performances can be estimated. The result shows that the estimated (E) output torque and power are 14.56 N-m and 1684.7 W while the actual torque and power obtained from test are 14.86 N-m and 1719.7 W, and the estimated efficiency is 71.06 % while the actual is 72.53 %. From Table 3, the 5.5 kW motor is operating at 45 Hz, the measurement data is 240.3 V, 10.36 A, 5335 W, 1292.6 rpm. The estimated efficiency is 83.46 % while the test is 82.67 %.

	T	80.32	81.84	82.50

Notice that the estimated values in Table 2 and 3 are not much different from the test. For comparison, the example results of torque and efficiency estimations of the motors at any operating frequency and load using this proposed technique are listed with the test data as shown in Fig 3 and 4. It can be observed that the correlation of proposed technique and actual is remarkably good, and the performance results also show the good agreement; many of the errors are obviously less than 2 %. From Fig. 3 and 4 together with Table 2 and 3, it is evident that the efficiency of motors are reduced when they are operating with variable speed under either fixed output power or fixed output torque conditions.

V. CONCLUSION

The proposed non-intrusive technique for estimating field efficiency of inverter-fed induction motor based on field measurement has been described. This technique relies on the available information of measured voltage, current, electrical power and speed of actual motor in the field without conducting motor tests. These field data coupled with the GAs are used for estimating the motor performances. The performance graphs in Fig.3 and 4 clearly illustrate that agreement between the proposed and the actual is good (within 2 %). The attractiveness of this proposed technique is that it is a simple procedure; it is possible to estimate the efficiency of inverter-fed induction motor operated under variable speed at any load in a short time while the motor is in service without the removal of motor. Thus, this non-intrusive technique is suitable for conducting on-site energy audits of motors.

***Abstract*-This paper presents a technique for designing small transformers (EI structure) to have minimum cost while at the same time insuring the satisfaction of design constraint (defined temperature rise). The technique is based on an optimization problem which is the minimum cost design using the genetic algorithms (GAs), and coupled with the neural networks for the evaluation of winding temperature rise. Various samples of small low-frequency transformers (less than 240 V and 250 VA) have been designed and tested in order to illustrate how well the appropriate evaluated steady state temperature rise of winding at full-load using this proposed technique match those of the measured values (error less than 5°C). This procedure is suitable for the economical transformer design having the defined winding temperature rise which is considerable flexibility for a particular purpose.**

I. INTRODUCTION

Many computer-aided design procedures relevant to design optimization for small transformers have appeared in the literature [1-3]. As the cost of energy is growing at a high rate, the energy issue has recently resulted in an increase interest in the small transformer efficiency. It is important to consider the economic (low-cost) impact of transformer efficiency (low-loss) on the manufacturer's perspective. For small low-frequency transformers, a standard set of EI structures are often recommended for use in the applications characterized by low operating frequencies and moderate output power. In conventional design, consideration is given to the layout of the core and windings. The laminated core occupies the central space. The windings are wrapped around the core, with the low voltage and high voltage windings. For shell type cores, the core laminations usually come in discrete sizes. They may be fabricated to eliminate waste from stamping from rolled strip, thus the EI cores have specific ratios for their window dimensions and magnetic path sizes [4] as shown in Fig.1. The rms value of sinusoidal source voltage (V) can be expressed in term of frequency (f in hertz), number of turns (N), peak flux density (B in tesla), and effective core cross-sectional area (A_c in m^2) as the relation of volt per turn

Conventional transformer design always starts from determining required frequency, voltage and VA rating, and estimating a number of factors for core and winding arrangement. Such factors are obtained by using values that are generally only known to experienced design engineers [5]. Moreover, this is done while assuming that the flux density, current density (J in A/mm^2), and other electrical or magnetic parameters are fixed. In reality, this design may result in a transformer which does not meet temperature rise requirements. This miserable situation arises because the ultimate design is critically dependent on the electrical and magnetic parameters. For example, a designer may intend to minimize losses or cost or weight of transformer. As a result of these problems, it may imply that transformer design cannot be unique for a given set of ratings and specifications.

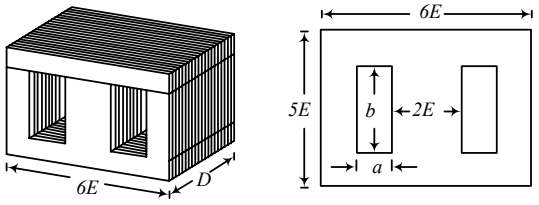

Figure 1. EI Core Geometry and Dimension Ratio (a = E, b = 3E)

$$\frac{V}{N} = \sqrt{2}\,\pi\, f\, B\, A_c\, F_s \tag{1}$$

where F_s denotes the stacking factor and $A_c = 2ED$.

This paper explores the optimal design of low-cost small low-frequency transformers (i.e. how to choose the optimum values for electrical and magnetic parameters) having the constraint of defined temperature rise value. The total cost of transformer (C_t) can be determined by the sum of core cost (C_{core}) and windings cost (C_{cu}) as

$$C_t = C_{core} + C_{cu} = \gamma_{core} W_{core} + \gamma_{cu} W_{cu} \tag{2}$$

where γ_{core} and γ_{cu} denote price of core and winding in Baht per kilogram respectively, W_{core} and W_{cu} are weight of core and winding in kilogram respectively.

The design objective is to minimize the total cost of transformer (C_t) subject to the desired temperature rise value constraint. The flux density (B) and core thickness (D) are set to be the design variables while the core laminations size ($2E$) and current density (J) are the design parameters. This proposed design allows for the exploration in the design of an economical transformer having temperature rise options which is considerable flexibility for a particular application.

II. TEMPERATURE RISE EVALUATION

The losses in a small transformer consist of the core loss (P_{core}) and winding loss (P_{cu}). The core loss at any flux densities below the saturation is a sum of two loss mechanisms; the hysteresis loss and the eddy current loss. The core loss determination employed in this paper is obtained from the interpolation of the test data curves. By definition, P_{cu} in a conductor carrying ac current with a value I_{rms} is

$$P_{cu}(D,B) = \frac{\rho_{cu}\, l_{cu}}{a_{cu}} I_{rms}^2 \tag{3}$$

where ρ_{cu}, l_{cu} and a_{cu} denote the resistivity, effective length and cross-sectional area of conductor respectively. The effective length l_{cu} is estimated by calculating the length of conductor on each layer of the winding, and then summing over all layers, taking into account the increasing diameter of each layer wound around the previous one. The total copper loss is the sum of primary winding and secondary winding losses. To achieve this copper loss practically, hence the effect of temperature rise is then considered in the design in order to improve the accuracy of copper loss calculation.

Consider a body with two parallel faces within which heat is generated uniformly. The two faces extend indefinitely and are exposed to the same ambient temperature. Then, heat is transferred uniformly and equally from both faces. The maximum temperature rise (θ_m) will occur at the midpoint between the two faces as [4]

$$\theta_m = \frac{q_v}{2h_o} L^2 \tag{4}$$

where h_o is coefficient of material thermal conductivity in watt per area-$^\circ$C, L is length between the faces to mid-point of body, and q_v is time rate of heat generation per unit volume. In this work, q_v can be defined by

$$q_v = \frac{P_{cu}(D,B)}{V_{cu}(D,B)} \tag{5}$$

where V_{cu} is winding volume. Note that P_{cu} and V_{cu} are dependent on the design of transformer structure. The average temperature rise through the body is given by

$$\theta_{av} = \frac{2}{3}\theta_m \tag{6}$$

As mentioned above, it is revealed that q_v depends on P_{cu} and V_{cu} , while h_o depends on the material property and exposed coil area of material. Moreover, a coil with laminated structure of several different coefficients of thermal conductivity will have an average coefficient of thermal conductivity normal to laminated structure [4-5]. Thus, it can be seen that the temperature rise is mainly dependent on P_{cu}, V_{cu} and A_{cu} .

In case of winding temperature rise problem, there is no simple relationship among the parameters involved in the solution. In this work, neural networks are proposed to evaluate the appropriate winding temperature rise that results in the design of an economical small transformer. The neural network methodology is a computer information processing system that is capable of sufficiently representing any nonlinear function. The neural network techniques are composed of the elements operating in parallel. The network function is mainly determined by the connections between elements. Generally, the neural networks are trained so that a particular input leads to a specific target output based on a comparison of the output and the target until the network output matches the target. Batch training of a network proceeds by making weight and bias changes based on an entire set (batch) of input vectors [6]. The feed-forward network as shown in Fig. 2 is selected, where **p** is a vector of R input elements, s is number of neurons in layer, **W** is weighting vector, **a** and **b** denote the output vector (temperature rise, Δ_T) and bias vector respectively.

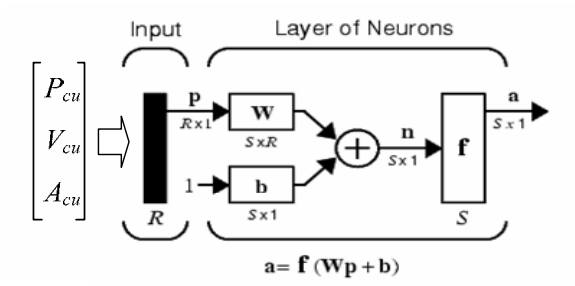

Figure 2. Structure of Feed-forward Network Architecture

Fifteen small transformers having different structures were built and tested. At the training stage, the input elements were defined as P_{cu}, V_{cu} and A_{cu}. The steady state temperature rise data at full-load of the primary and secondary windings were recorded by using analyzing recorder (Yogokawa: AR1100A). Then, the feed- forward network was trained by using those input data (**p** =15) obtained from the laboratory test. Two different rating transformers (TR A and TR B) were designed, built and tested in order to verify this proposed procedure. In this design, the winding temperature rise evaluation using the

neural network which has already been trained was implemented using the data of P_{cu}, V_{cu} and A_{cu}. The design results are illustrated in Table 1. The comparisons of winding temperature rise results obtained from the proposed evaluation and laboratory test which show a good agreement are presented in Fig. 3.

III. Design Of Economical Transformer

This section presents the use of optimal design of small transformer. As mentioned above, a designer may intend to minimize total transformer cost for particular purpose. Thus, the determination of optimal transformer parameters can be accomplished more economically with the help of an optimization technique called the genetic algorithms (GAs) [7] coupled with the neural networks for the winding temperature rise evaluation.

The choice of which parameters are fixed and which are free is made by the designer. One approach used previously is to fix the electrical and magnetic parameters and then choose the transformer geometry parameters to minimize cost. An alternate approach is to start with assumed core geometry and then find values for the electrical and magnetic parameters which minimize the design objective. The approach used in this paper, is preferred for practical reasons. First, transformer cores are generally available only in discrete sizes. Second, all core materials saturate at some maximum flux density (B_m). Therefore, the flux density (B) and core thickness (D) are set to be the design variables while the core laminations size ($2E$) and current density (J) are then set to be the design parameters in the optimization process. Note that once the design value for flux density has been settled during the optimization process (GAs), the side constraint of B must always be restricted that $B \le B_m$. Moreover, the updated winding temperature rise using the proposed procedure is also included as shown in Fig. 4.

The optimization task is to minimize the total cost in Eq. (2) subject to temperature rise constraint as follows

$$\textit{Minimize} \qquad C_t(D,B) = C_{core}(D,B) + C_{cu}(D,B) \qquad (7)$$

Subject to

$$\frac{N_p A_p \times N_s A_s}{F_w} - ab \le 0 \qquad (8)$$

$$\Delta_T - \Delta_{Td} \le 0 \qquad (9)$$

where A_p and A_s are conductor cross-sectional area of primary and secondary windings respectively, N_p and N_s are number of turns of primary and secondary windings respectively, F_w denotes window utilization factor of core, Δ_T and Δ_{Td} stand for the value of evaluated and defined temperature rise respectively.

IV. Experimental Results

This section explores the proposed procedure for optimal design of economical small transformers which can help the designer make more intelligent decisions in order to project the production cost of transformer having the temperature rise within desired value. The minimum cost designs with the temperature rise constraint (within 20°C) of two 24 VA, 220/12 V, 50 Hz transformers using different size of S-14 core ($2E$) are implemented. The cost of core and winding are defined as 50 and 400 Baht/kg respectively, and $B \le 1.4$ tesla.

$\Delta_{T,sec}$ ($^\circ$C)	18.12	19.08

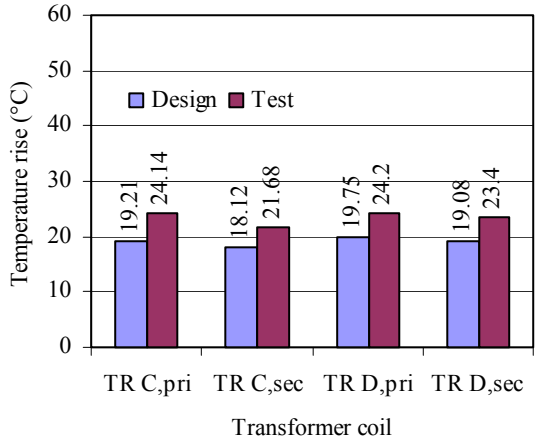

Figure 6. Comparisons of design temperature rise and laboratory test using proposed procedure

The two prototype transformers as shown in Fig. 5 are constructed and the design results are illustrated in Table 2. From Fig. 6, it can be seen that the evaluated values of temperature rise obtained from the design are in agreement with the measured values from test (error less than 5°C).

V. CONCLUSION

The design of economical small transformers using the GAs coupled with neural networks have been presented in which the total cost of transformers were minimized by choosing the flux density and core thickness to be design variables while the core laminations size and current density are set to be the design parameters. In this paper, the proposed temperature rise evaluation procedure is implemented in which the temperature of windings will be updated based on the temperature rise evaluation using neural networks in each iteration. The results of winding temperature rise in Fig. 6 indicate that the differences between evaluated values using this proposed procedure and the measured values from laboratory test are in good agreement (error less than 5°C). The main advantage of this design is that it can be many solutions for the minimum cost design of the same rating transformer having different defined temperature rise values. These solutions can be useful for the use in manufacturers in order to make more intelligent decisions for economical design such as the design of small transformer having low cost with the determination of total losses for the desired efficiency while the temperature rise of windings must be within the insulation class.

***Abstract*-This paper presents steady state and dynamic models of doubly fed induction machines operated as generators in wind energy conversion systems. Both models are based on the stator voltage synchronous reference frame. The first model investigates steady state operating point and stability on the torque-slip curve, whereas the second model determines transient response. The operation of DFIG can be categorized into two modes: constant power and maximum power. The objective of the constant power mode is to keep output power at a reference value to avoid disturbance owning to power fluctuation. The objective of the maximum power mode is to extract power from wind energy as much as possible. In this mode, the output power may not be constant depending on wind speed. The mathematical steady state and dynamic models are verified by a case study. The results show that both models provide a good representation of the behavior of DFIG in the two modes of operation.**

I. INTRODUCTION

The doubly fed induction generator (DFIG) is often used in medium and large wind turbines. The main advantages of these machines are that a small size of converter is required compared to the machine rating and stator active and reactive power with variable speed range can be controlled independently.

The mathematic models of DFIM and a control method were detailed in [1, 2]. In the stator-field-oriented reference frame, stator active power and reactive power can be directly controlled by the quadrature and direct components of the rotor current, respectively. Alternatively, in the stator synchronous reference frame, the stator active and reactive powers are independently controlled by d-q axis of stator current. The steady state performance of DFIG was described in [4].

When connected to the grid, a DFIG can be operated with two modes of operation: maximum and constant output power. In the maximum power mode, the DFIG is operated to extract output power as much as possible, whereas in the constant power mode, the generator is operated to maintain output power at any specified value.

In this paper, both dynamic and steady state models based on the stator voltage oriented reference frame are proposed to investigate both modes of operation. The steady state behavior of DFIG can be effectively investigated by the torque-slip characteristic curve and an operating point on the curve, the dynamic behavior by transient performance. Both two modes are explained and verified by steady state and dynamic models.

II. Doubly Fed Induction Generator Model

The nonlinear voltage equations of DFIG in synchronously rotating reference frame are

$$v_{Sd} = (R_S + L_S \frac{d}{dt}) i_{Sd} - \omega_0 L_S i_{Sq} + L_0 \frac{d}{dt} i_{Rd} - \omega_0 L_0 i_{Rq} \quad (1)$$

$$v_{Sq} = \omega_0 L_S i_{Sd} + (R_S + L_S \frac{d}{dt}) i_{Sq} + \omega_0 L_0 i_{Rd} + L_0 \frac{d}{dt} i_{Rq} \quad (2)$$

$$v_{Rd} = L_0 \frac{d}{dt} i_{Sd} - (\omega_0 - \omega_m) L_0 i_{Sq} + (R_R + L_R \frac{d}{dt}) i_{Rd} - (\omega_0 - \omega_m) L_R i_{Rq} \quad (3)$$

$$v_{Rq} = (\omega_0 - \omega_m) L_0 i_{Sd} + L_0 \frac{d}{dt} i_{Sq} + (\omega_0 - \omega_m) L_R i_{Rd} + (R_R + L_R \frac{d}{dt}) i_{Rq} \quad (4)$$

In this frame, the electrical torque is

$$T_e = \frac{2}{3} \frac{P}{2} L_0 \left(i_{Sq} i_{Rd} - i_{Sd} i_{Rq} \right) \quad (5)$$

When the d-axis of the reference frame aligns to the stator voltage as shown in Fig 1,

$$v_{Sq} = 0$$
$$v_{Sd} = \frac{3}{2} \sqrt{2} U_S$$

In this frame, the stator active power and reactive power can be calculated as in (6) and (7).

$$P_S = \frac{2}{3} v_{Sd} i_{Sd} \quad (6)$$

$$Q_S = -\frac{2}{3} v_{Sd} i_{Sq} \quad (7)$$

For the steady state model, the stator and rotor voltage phasors can be derived from (1) – (4) in terms of reactance.

$$V_S = (R_S + jX_S) I_S + jX_0 I_R \quad (8)$$

$$V_R \angle \phi^o = jsX_0 I_S + (R_R + jsX_R) I_R \quad (9)$$

The electrical torque is given by

$$T_e = \frac{2}{3} \frac{P}{2} \frac{X_0}{\omega_0} \mathrm{Im}(I_S I_R^*) \quad (10)$$

Obviously from (8) - (10), the torque-slip characteristic curve of DFIG at any rotor voltage can be directly determined.

III. Wind Turbine Characteristic

The power converted, $P_{turbine}$, by a wind turbine is related to the power coefficient, C_p, given for a wind speed, V, is

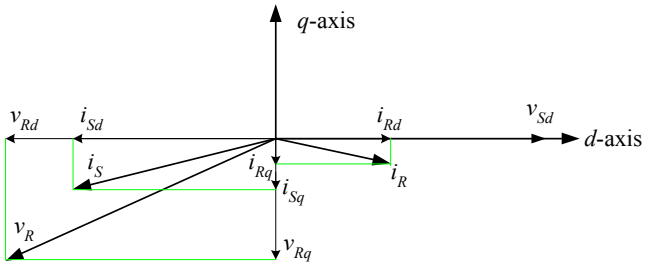

Figure 1. Vector diagram of DFIG in synchronous reference frame.

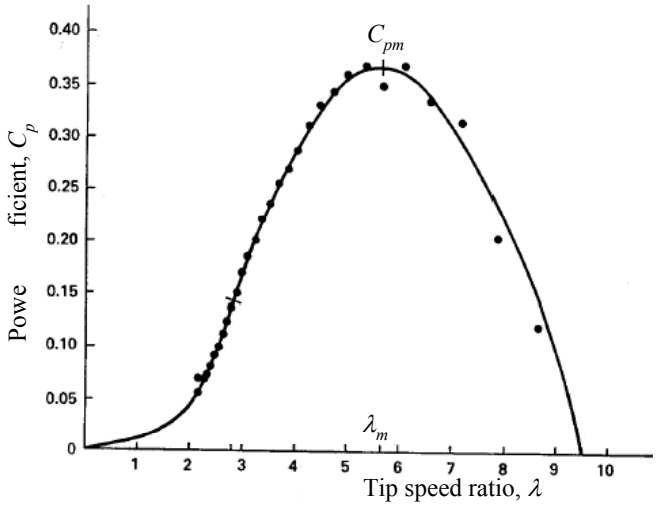

Figure 2. Typical power coefficient versus tip speed ratio curve.

$$P_{turbine} = 0.5 C_p \rho A V^3 \quad (11)$$

where ρ and A are the air density and the swept area by the rotor blades, respectively.

For a variable-speed turbine, the objective is to operate near maximum efficiency, where the resulting maximum power can be expressed by

$$P_{turbine,m} = 0.5 \rho A C_{pm} (R / \lambda_m)^3 \omega^3 \quad (12)$$

where R and ω are the rotor radius measured at the blade tip and the rotation speed of the blade, respectively. The optimum tip speed ratio, λ_m, is defined as a ratio between the rectilinear speed of the blade tip and the wind speed at the maximum power coefficient, as shown in Fig. 2 [5], [6].

It is apparent from (12) and Fig. 2 that as wind speed changes, the rotor speed will change to obtain the maximum power from the wind.

IV. Steady State Behaviors and Torque-slip Curves

As any desired output power, P_W, from the wind turbine, the relation of wind turbine power and electrical power are

$$P_W = P_S + P_R + P_l \quad (13)$$

For small power loss ($P_l \approx 0$), the air gap power is equal to stator power. The stator power and wind turbine output power can then be calculated as a function of slip.

$$P_W \approx (1-s)P_S \quad (14)$$

Therefore, at any given output power, P_W , and reactive power, Q_S, the stator current can be determined from (6) and (7). The rotor current and voltage are found from (8) and (9), respectively. From the calculated rotor voltage, the torque-slip curve can be investigated directly as function of slip.

For examples, the torque-slip curve for various rotor voltages amplitudes and phase angles are shown in Fig. 3 and 4. In Fig. 3 and 4, it can be seen that the pull-out torque depends on the rotor voltage and phase angle. Therefore, at any given torque and speed, the DFIG can be operated in relation to the command by varying the rotor voltage. Likewise, at any fixed given torque, the speed can be varied by controlling the rotor voltage.

V. Verification of Steady State Behavior

For constant output power operation, the stator power is assigned by reference output power as in (15).

$$P_S = P_{ref} /(1-s) \quad (15)$$

Therefore, the rotor voltage can be calculated as described in Section IV for desired P_S and Q_S. When P_{ref} is kept constant at –0.5 p.u. with unity power factor, the result is shown in Fig. 5. The intersection between the electrical torque and torque-slip curve determines an operating point. In this mode of operation, the rotor speed is not constant because the torque is not equal to wind turbine torque. Note that in this mode the output power is nearly constant. Therefore, the rotor speed can be controlled by other methods such as pitch control, stall regulation [7]. For the maximum power mode, an operating point (rotor speed) is determined from the power coefficient curve.

In Fig. 6, the DFIG is assigned to operate at its rated electrical torque, 1 p.u. at slip = -0.4. As can be seen at this point, the operating point is closed to the pull-out torque. Therefore in practice, this point can be avoided for stable operation. In this mode, the rotor speed is constant at steady state when the electrical torque and wind turbine torque are

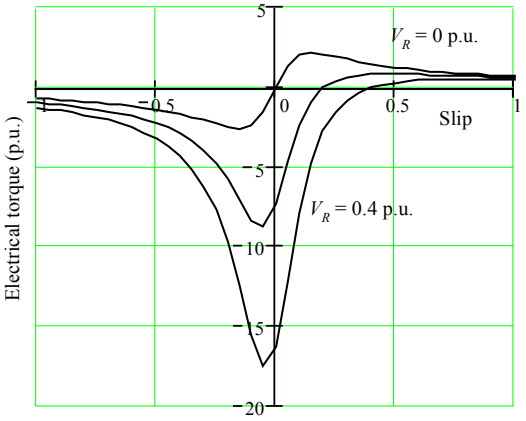

Figure 3. Torque-slip curve as function of V_R = 0, 0.2 and 0.4 p.u. at ϕ = 0.

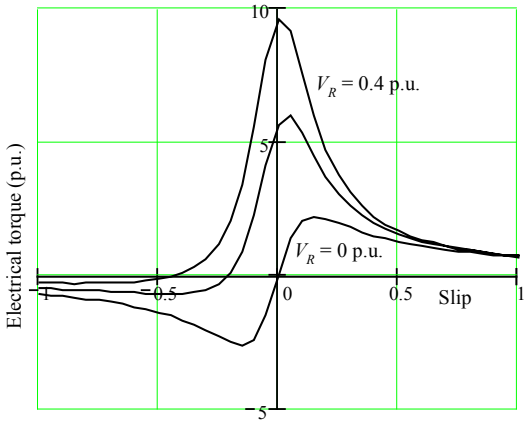

Figure 4. Torque-slip curve as function of v_R = 0, 0.2 and 0.4 p.u at $\phi = \pi$.

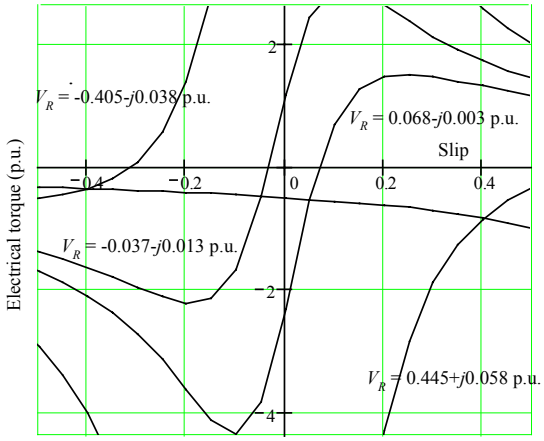

Figure 5. Operating points for constant output power.

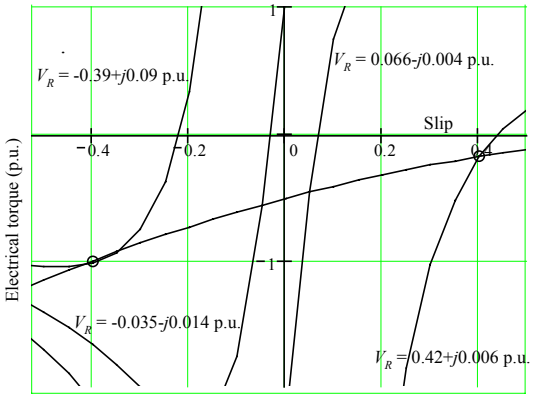

Figure 6. Operating points for maximum output power.

equal. However, if speed command is varied because of inconstant wind speed, the output power will fluctuate.

VI. Verification of Dynamic Behavior

Both modes of operation are verified in a dynamic model simulation to investigate their transient responses and behaviors. In the constant output power operation, a total power of –0.5 p.u is kept constant. while the mechanical torque is varied from –0.4 to –0.6 p.u. The result is shown in Fig. 7 and can be seen that the output power tries to stay constant at –0.5 p.u. or P_{ref} , although the mechanical torque is not constant and fluctuates. However, the rotor speed either increases or decreases depending on which torque is higher. This could lead to DFIG operated in unstable region. For the maximum power operation, the commands for this mode are the desired reactive power and rotor speed that is related to the maximum power coefficient and wind speed.

For the same mechanical torque as in Fig. 7, the results are shown in Fig. 8 and 9. Obviously, the rotor speed response (solid line) is tracked to the speed command (dash line) to keep output power at maximum. When the electrical and mechanical torques are equal, the rotor speed is constant. If the mechanical torque is increased, the electrical torque will reduce to increase the rotor speed until it goes constant at a constant mechanical torque again. The output power of Fig. 9 sees more fluctuation than that of Fig. 7 but can extract more power than the other for the maximum power operation.

VII. Conclusion

Both steady state and dynamic model equations of DFIG are presented based on the stator synchronous frame. In this frame, stator active power and reactive power can be independently controlled by direct and quadrature axis components of stator current, respectively. In the steady state model, the pull-out torque is a complex form represented by a function of rotor voltage. Furthermore, the operating point can be directly seen from the torque-slip curve to determine a steady state stability margin.

DFIG can be operated in two modes of operation: constant power and maximum power. In the first mode, its output power is kept constant at a reference value regardless of input power. In the maximum power operation, the speed command is obtained from the power coefficient-tip speed ratio curve for maximum power extraction. The results reveal that a DFIG can be effectively controlled in both modes of operation.

***Abstract*- A power transformer with internal winding faults is designed to study the magnitude of fault current for protecting transformer. There are two types of the winding fault: turn to ground and turn to turn faults. The paper presents the design and results of a power transformer winding faults by using PSCAD/EMTDC program. The simulation results show the magnitude of earth fault current and differential current and the comparison of primary and secondary fault of the transformer.**

Keywords: power transformer, internal fault, winding fault

I. INTRODUCTION

A power transformer is an important equipment on the power system. It is used to step up and down voltage levels on the transmission and distribution system. If a fault occurs in power transformer, the power system will be interrupted for a long time. There are two types of the faults in power transformer: the external fault and the internal fault [1]. The external fault is the outside zone protection of transformer. This causes mechanical stress in transformer winding and increasing temperature in the transformer. Unlike the external fault, the internal fault directly affects on power transformer winding. Faults of power transformer winding consist of turn to ground and turn to turn faults. In the occurrence of the fault, the differential relay must operate to protect power transformer hence decrease cost of the system maintenance [2].

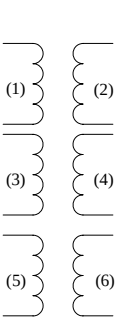
The objective of this paper is to study earth fault current and differential current which occur at the primary and secondary side of a transformer. Therefore, the power transformer with internal faults model is proposed. They are simulated under following conditions:

1. Turn to ground and turn to turn faults at primary winding
2. Turn to ground and turn to turn faults at secondary winding

The models are implemented on PSCAD/EMTDC program.

II. MODEL OF POWER TRANSFORMER

The beginning of the study is to build a model of a three-phase, two winding, six coils transformer which obtains the transformer data from [3]. It starts with inputting the transformer data in BCTRAN's transformer model in ATP/EMTP program to calculate six of the resistance (R) and inductance (L) parameters. A normal transformer has a 6x6 matrix of the R and L parameters as shown in Fig. 1 [9].



$$[R] = \begin{bmatrix} R_1 & 0 & 0 & 0 & 0 & 0 \\ 0 & R_2 & 0 & 0 & 0 & 0 \\ 0 & 0 & R_3 & 0 & 0 & 0 \\ 0 & 0 & 0 & R_4 & 0 & 0 \\ 0 & 0 & 0 & 0 & R_5 & 0 \\ 0 & 0 & 0 & 0 & 0 & R_6 \end{bmatrix}$$

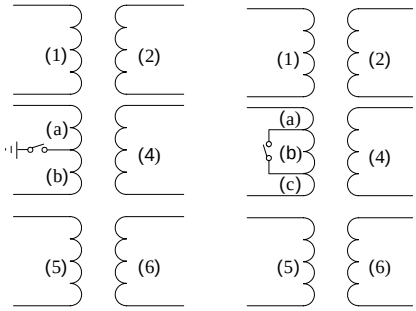
$$[L] = \begin{bmatrix} L_1 & M_{12} & M_{13} & M_{14} & M_{15} & M_{16} \\ M_{21} & L_2 & M_{23} & M_{24} & M_{25} & M_{26} \\ M_{31} & M_{32} & L_3 & M_{34} & M_{35} & M_{36} \\ M_{41} & M_{42} & M_{43} & L_4 & M_{45} & M_{46} \\ M_{51} & M_{52} & M_{53} & M_{54} & L_5 & M_{56} \\ M_{61} & M_{62} & M_{63} & M_{64} & M_{65} & L_6 \end{bmatrix}$$

Figure 1.. R and L parameters of the 3 phase 2-winding power transformer

Where R_i and L_i is a resistance and self inductance of winding respectively which are represented in diagonal matrices. M_{ij} is the mutual inductance between winding i and j. They are represented in upper and lower matrix.

III. INTERNAL WINDING FAULTS

The internal winding faults occur in two cases. These consist of turn-to-ground and turn-to-turn faults as shown in Fig. 2 [5-8].



a) turn-to-ground fault b) turn-to-turn fault

Figure 2. Winding faults in power transformer

If a turn-to-ground fault occurs at coil 3 of primary side which is separated into two sub-coil *a* and *b* as shown in Fig. 2a), the matrix of [R] and [L] are modified into 7x7 matrix as shown in Fig 3.

$$[R] = \begin{bmatrix} R_1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & R_2 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & R_a & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & R_b & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & R_4 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & R_5 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & R_6 \end{bmatrix}$$

$$[L] = \begin{bmatrix} L_1 & M_{12} & M_{1a} & M_{1b} & M_{14} & M_{15} & M_{16} \\ M_{21} & L_2 & M_{2a} & M_{2b} & M_{24} & M_{25} & M_{26} \\ M_{a1} & M_{a2} & L_a & M_{ab} & M_{a4} & M_{a5} & M_{a6} \\ M_{b1} & M_{b2} & M_{ba} & L_b & M_{b4} & M_{b5} & M_{b6} \\ M_{41} & M_{42} & M_{4a} & M_{4b} & L_4 & M_{45} & M_{46} \\ M_{51} & M_{52} & M_{5a} & M_{5b} & M_{54} & L_5 & M_{56} \\ M_{61} & M_{62} & M_{6a} & M_{6b} & M_{64} & M_{65} & L_6 \end{bmatrix}$$

Figure 3. R and L parameters of the 3 phase 2-winding power transformer

The fault position along the coil is defined by n_a and n_b

Then $n_a + n_b = n_3$

Where n_3 is the number of coil turns

n_a and n_b are the number of sub-coil turns *a* and *b*

Resistance and inductance between sub-coil *a* and *b* are calculated in (1)-(11).

$$R_a = \frac{n_a}{n_3} R_3 \; ; \; R_b = \frac{n_b}{n_3} R_3 \; ; \; k = \frac{n_a}{n_b} \qquad (1)$$

When the variable k is the voltage ratio between sub-coil *a* and *b* which varies with fault position along the coil. This method is to calculate the self and mutual inductance between sub-coil *a* and *b*. Then the method solves the element of fault in terms of L_a, L_b, M_{ab}, M_{ai} and M_{bi} as in (2)-(11).

Consistency $$L_a + 2M_{ab} + L_b = L_3 \qquad (2)$$

Leakage factor $$\sigma_{ab} = 1 - \frac{{M_{ab}}^2}{L_a L_b} \qquad (3)$$

Proportionality $$\frac{L_a}{L_b} = \left(\frac{n_a}{n_b}\right)^2 \qquad (4)$$

The leakage factor between sub-coil is assumed to be zero $(\sigma_{ab} = 0)$. Therefore, L_a, L_b and M_{ab} can be found from (5)-(7).

$$L_a = \frac{L_3}{\frac{1}{k^2} + \frac{2\sqrt{1-\sigma ab}}{k} + 1} \qquad (5)$$

$$L_b = \frac{L_3}{k^2 + 2k\sqrt{1-\sigma ab} + 1} \qquad (6)$$

$$M_{ab} = \frac{L_3\sqrt{1-\sigma ab}}{\left(k + \frac{1}{k}\right) + 2\sqrt{1-\sigma ab}} \qquad (7)$$

The mutual inductance between sub-coil *a* (M_{ai}) and *b* (M_{bi}) in the other coils can be divided to two cases [5].

Case A: the coil i is wound on the same leg as sub-coil *a* and *b*. M_{ai} and M_{bi} can be solved by equation (8)-(9).

$$M_{ai} = M_{3i}\sqrt{\varepsilon}\sqrt{\frac{L_a}{L_3}}\sqrt{1 + \frac{1-\varepsilon}{\varepsilon}\frac{L_3 L_i}{{M_{3i}}^2}} \qquad (8)$$

$$M_{bi} = M_{3i} - M_{ai} \qquad (9)$$

where $\varepsilon = \frac{\sigma_{ai}}{\sigma_{3i}}$

Case B: the coil i is not wound on the same leg as sub-coil *a* and *b*. M_{ai} and M_{bi} can be solved by equation (10)-(11).

$$M_{ai} = M_{ia} = \frac{k}{1+k} M_{3i} \qquad (10)$$

$$M_{bi} = M_{ib} = \frac{1}{1+k} M_{3i} \qquad (11)$$

Fig. 2b) illustrates that the turn-to-turn faults have three sub-coil consist of *a*, *b* and *c*. The [R] and [L] are both 8x8 matrices. The unknown variables in sub-coil *a*, *b* and *c* of turn to turn faults can be calculated by using relations of consistency, leakage factor and proportionality. M_{ab}, M_{ac}, M_{bc}, L_a, L_b and L_c and mutual inductance between sub-coil *a*, *b* and *c* of the other coils can be solved in [5-9].

IV. IMPLEMENTATION

A three-phase two-winding transformer modeled with internal winding faults is implemented on PSCAD/EMTDC program as following steps by using the data of test report obtained from [3].

Step 1: Input the transformer data on short circuit and open circuit test to calculate matrix [R] and ω[L] by BCTRAN. This results in the output file (*.pch file) as shown in Table I. Table I contains elements of [R] and ω[L] without internal winding faults.

Step 2: Calculating the matrix [R] and [L] with internal winding faults and build the model by programming with Fortran in EMTDC as shown in Fig. 4**.**

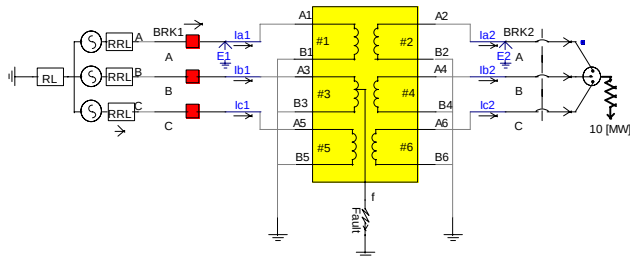
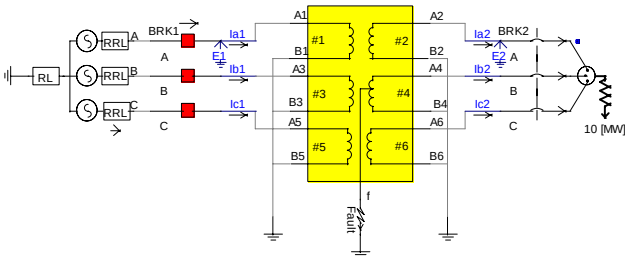
V. SIMULATION RESULT

In this research, the power transformer three-phase two winding 50 MVA 115/23kV 50 Hz Yy0 primary and secondary side, star connected winding with neutral point solidly earthed, was modeled. V_{base} is the transformer voltage. MVA_{base} is 100 MVA



a) The turn to ground fault at primary side Phase B



b) The turn to ground fault at secondary side Phase B

Figure 5. The system simulation for turn-to-ground faults

Source: Z_1=0.01192+j0.04378 pu.
Z_0=0.04237+j0.17426 pu.

Fig. 5 shows the models of turn to ground faults at phase B on both sides of the transformer. The fault position will be moved along the winding of transformer which varies between 10% to 90% by starting from terminal to neutral point. The fault current from each fault position is measured to obtain the magnitude. Fig. 6 shows the relation between the magnitude of fault current and distance of turn to ground fault at the winding on the primary side. The fault current rapidly increases when the fault position is close to neutral point. This is because the reactance decreases near the neutral point [1,2].

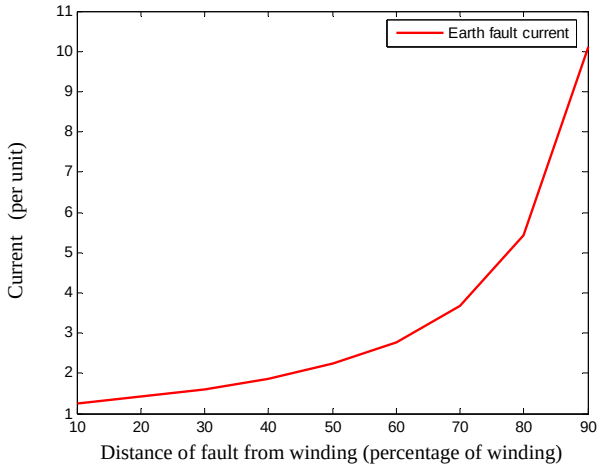


Figure 6. Turn-to-ground fault current on primary side

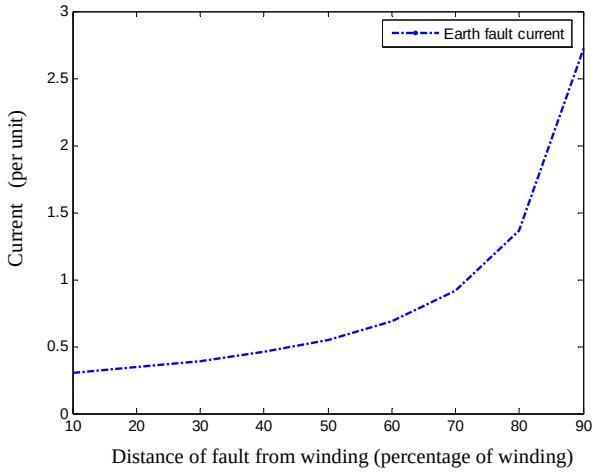

Figure 7. Turn-to-ground fault current on secondary side

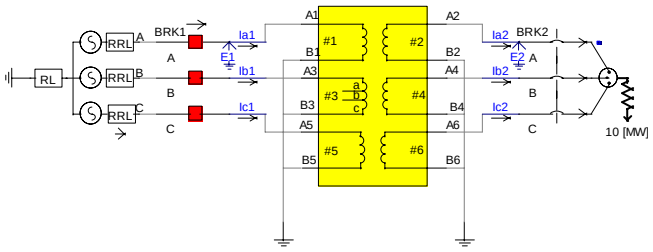
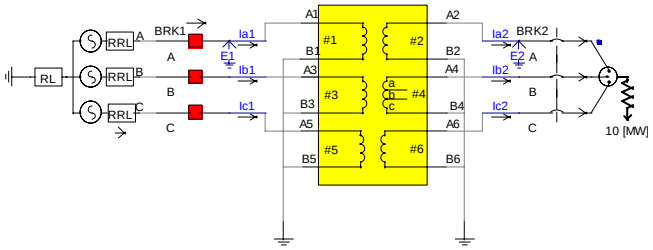
Fig. 7 shows the relation between the magnitude of fault current and distance of turn to ground fault at winding on secondary side. The fault current rapidly increases when the fault position is close to neutral point. This is because the reactance decreases near the neutral point [1,2].



a) The turn to turn fault at primary side Phase B



b) The turn to turn fault at secondary side Phase B

Figure 8. The system simulation for turn-to-turn faults

Fig. 8 shows the model of turn to turn faults on both sides of transformer at phase B. The sub-coil *b* is represented turn to turn faults by using midpoint of winding as the reference and expanding to both end of the winding. It will be raised at 10% each step until 90% of winding length. The fault current from each fault positions is measured to obtain the current magnitude.

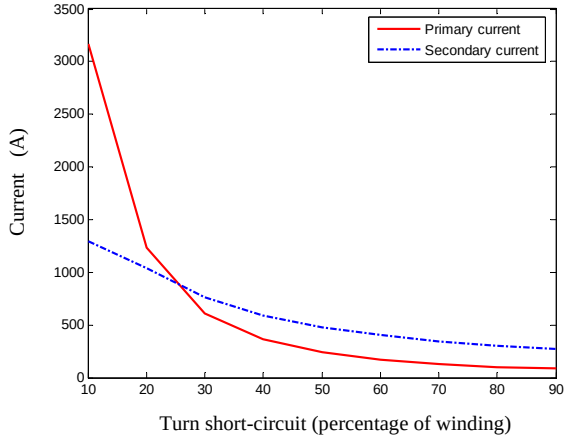


Figure 9. Turn-to-turn fault at primary side

Fig. 9 shows the comparison of the primary and secondary side currents during a turn to turn fault occurred on primary winding. It shows that the terminal fault current rapidly decreases when the range of sub-coil *b* increases. In a few turns of the winding, the primary current is higher than the secondary current. In a greater turns the secondary current is higher than the primary current.

Fig. 10 shows the comparison of the primary and the secondary currents during a turn to turn fault occurred on secondary side winding. The fault current increases proportionally when the range of sub-coil *b* increases [10]. The secondary current has greater slope higher than of the primary current.

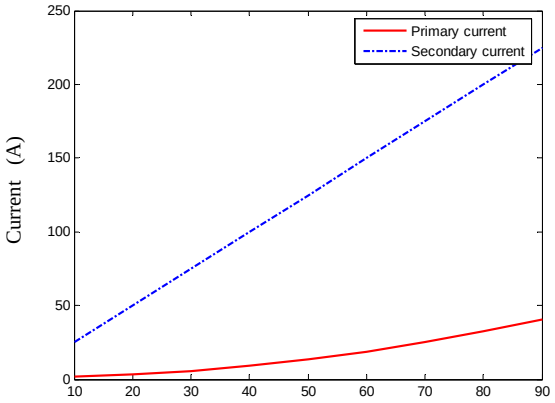

Figure 10. Turn-to-turn fault at secondary side

VI. CONCLUSION

The method of modeling a transformer with internal winding faults is presented. The internal winding faults in a transformer are also studied by PSCAD/EMTDC program in both cases: turn to ground and turn to turn fault. The result indicates that the fault current is higher when fault position close to neutral point in case of turn to ground fault. In case of turn to turn fault at primary side, the difference between the primary and secondary current is slight when compares with the fault at secondary side.

The model provides correct simulation results. This is beneficial to power system protection study. The power transformer winding faults can be modeled then used to test differential relay algorithm.

Abstract **This paper deals with the design and experimental implementation of a maximum power point tracking (MPPT) for photovoltaic system , which is a DC-DC boost converter operating in continuous conduction mode(CCM). The converter is able to draw maximum power from the PV system for a given irradiation level by adjusting the duty cycle of converter. Analytical models are built for the PV system and converter on the basis of the data sheet of manufacturer and the principle of energy conservation. The control technique, implement with a single-chip microcontroller ADMC331, is based on the Hill-climbing / P&O method. From the result obtained it can be concluded that , the MPPT can increase the overall efficiency of the system 87 % under different atmospheric condition.**

Key Words: Photovoltaic, Maximum Power Point Tracking , PI controller, Hill – climbing / Perturbation and Observation Algorithm

I. INTRODUCTION

Photovoltaic(PV) generation assumes increased importance as a renewable source due to advantages such as the absence of fuel cost, little maintenance and no noise and wear due to absence of moving parts. However, Two important factors limit the implementation of photovoltaic systems i.e. high cost and low efficiency in energy conversion. In photovoltaic systems, the PV panel represents 57% of the total cost of the system, and the battery storage system corresponds to 30% of the cost. Other system components such as inverters and maximum power point tracker contribute only with 7% (Hua and Lin, 2003). Due to the high cost of solar cells. Therefore, controlling maximum power point tracking (MPPT) for the photovoltaic system is essential in a PV system. The amount of power generated by a PV system depends on the operating voltage of the array. While a maximum power point (MPP) of PV system varies with solar insulation and temperature. Its V-I and V-P characteristic curves specify a unique operating point at which maximum possible power is delivered. At the MPP, the PV operates at its highest efficiency. Therefore, many methods have been developed to determine MPPT. Three popular tracking methods based on power feedback are widely adopted in PV power systems. They are the perturbation and observation method(P&O) [2], the incremental conductance method (IncCond) [3] and the hill climbing method (HC). Both P&O and InCond are based on the same technology by regulating the PV array's voltage to follow an optimal set point, which represents the voltage of maximum power operating point . This point is continuously tracked and updated to satisfy a simple mathematical equation: dP/dV = 0, where P represents the PV module's output power and V represents the PV voltage., the maximum power points can always be tracked if we keep dP/dV equal to zero., MPP-trackers have been widely implemented with several techniques and power conditioners. In the work developed by Maheshappa et al., the PV array voltage is compared with a constant reference voltage, which corresponds to the PV voltage at the maximum power point, under specific atmospheric conditions, as MPP will depend on the chosen reference. In the work proposed by Medeiros and Antunes, the neural network requires a new training at each change of the system size. The incremental conductance method (Solodovnik et al., 2004) leads to good accuracy in tracking the MPP even under rapidly changing weather, but a digital signal processor (DSP) is necessary in the implementation. Within this text, this work presents the design and experimental implementation of a real time maximum power point tracker for photovoltaic systems. The MPP-tracker proposed in the paper is a study DC-DC converter operating in continuous conduction mode(CCM).The Hill- climbing /P&O algorithm searches the maximum power pint according to irradiation. The algorithm is implemented using microcontroller ADMC 331,whose output signal set the duty cycle of pulse width modulation (PWM) boost converter.

II. Characteristics of Photovoltaic Cell

Fig.1. shows the typical equivalent circuit of PV-cell. The typical I-V output characteristics of PV-cell are represented as following (1).

$$I = I_{ph} - I_{rs} \{e^{q/AKTc}(V+IR_S) - 1\} - (V+IR_S) / R_{sh} \quad (1)$$

Where,

$I_{ph} = \{I_{sc} + K_I (T_C - 25)\}\lambda$, $I_{rs} = [\, T_C / T_r]^3 e^{\{(qE_{gap}/BK)(1/T_r T_C)\}}$

I and V_O : cell output current and voltage
I_{ph} : light generated current
I_{SC} : short circuit current
I_{re} : reverse saturation current
I_{or} : cell saturation current at T_r
TC : cell temperature
T_r = 301.18 ^oK : reference Temperature
q = electron charge
K =1.38e-23 : Boltzmann's constant
K_I = 0.0017 : Temperature coefficient at ISC
Egap : energy gap [eV]
λ : percentage irradiation
R_S : series resistance ,R_{Sh} : shut resistance
A,B : ideality constants

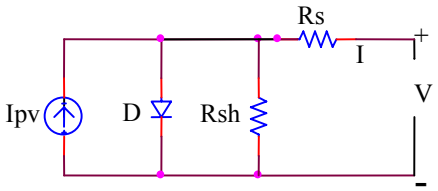

Figure 1. The equivalent model of photovoltaic.

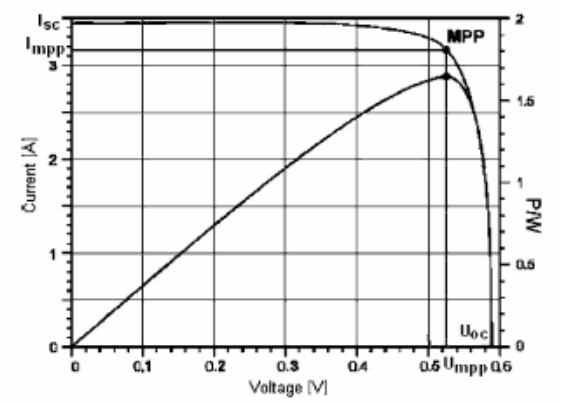
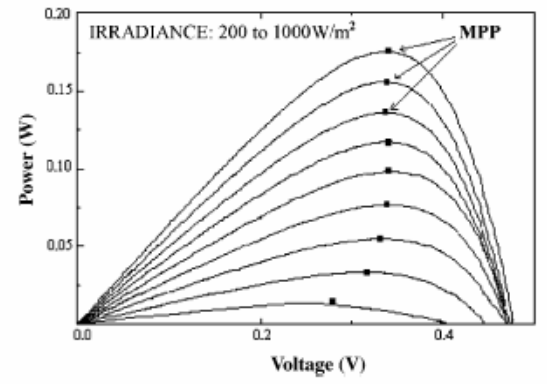
Figure. 2(a) shows the typical I-V and P-V output characteristic curve of PV- module. Fig. 2(b) show the typical P-V output characteristic curves of P-V module in the case that the irradiance is varied.

From Fig.2(b). we know that the output characteristic of PV-module are nonlinear and each curve only has one maximum power point (MPP) . Additionally , the output current of PV- module is mainly affected by irradiation variation , whereas the output voltage of PV-module is mainly affected by temperature variation . therefore, to efficiently use PV-module, in case the atmospheric condition are varied, the maximum power point tracking of PV- module should be implemented.



(a) Type characteristic curve



(b) Irradiation variations

Figure 2. The output characteristic curves of PV-cell

III. Boost type DC-DC Converter

In Fig. 3, the schematic of the boost converter power stage is given. It consists of the power switch T, boost inductor L, filter capacitor C, output diode D, and load resistance R. Here, the DC input source voltage Vpv is supplies by PV module. The Boost converter operates in the continuous conduction mode(CCM) where the inductor current flows continuously (i_l>0) are used. When the switch T is in the on state, the current in the boost inductor increases linearly, and at the time, the diode is in off state. When the switch T is turned off, the energy stored in the inductor is released through the diode to the output RC circuit. The pulsating current produced by the switching is smoothed by capacitor filter and DC voltage is provide to the load The boost converter transfer function is obtained by considering its steady state operation . The DC voltage transfer function is

$$\frac{Vout}{V_{PV}} = \frac{1}{1-D} \qquad (2)$$

Assuming a lossless circuit, P_{PV} = Pout

$$V_{out}.I_{out} = V_{PV}.I_{in} = I_{out} / I_{in} = (1- D) \qquad (3)$$

Where V_{PV} and I_{PV} is converter input voltage and current or the output voltage and current of the PV module, respectively, Vout and Iout is the output voltage and current , respectively, and D is the duty ratio of the controllable switch. The boost converter operates in the CCM for L >Lmin Where function is obtained by considering its steady state operation. The DC voltage transfer function is

$$L_{min} = \frac{V_{PV} D}{2\Delta i_L f} \quad (4)$$

Here, f is the switching frequency. And then ,this expression can be to calculated the inductor current ripple value Δi_L such that a given value of inductor is obtained. The minimum value of the filter capacitance that results in voltage ripple is given by

$$C_{min} = \frac{V_{out} D}{2R\Delta v_c f} \quad (5)$$

IV. Characterization of PI controller

PI controllers are in most cases analyzed and tuned in the continuous time domain. The corresponding transfer function is given as following

$$U(S) = K_p\left(1 + \frac{K_I}{K_p} \times \frac{1}{I(S)}\right) \quad (6)$$

Where I and U denote the input error signal and controller's output, s is the Laplace variable and K_p and K_I are the two parameter of the PI controller associated with the proportional (P) and integral (I) part. Equation (6), the transition from the continuous to the discrete time domain entail that the integral operation has to be by Zero order hold (ZOH). Such as can now be shown in the following.

$$U(k+1) = K_p I_{k+1} + K_p\left(\omega_{PI} T_{sample} - 1\right) I_k + I_k \quad (7)$$

Equation (7) , the signal is sampled at the instant k and held constant until the next sampling instant k+1.

V. Maximum Power Point Tracking (MPPT)

Maximum power point tracking means that PV module is always supposed to operate at maximum output voltage rating. A MPPT is a DC/DC converter that sets the PV module to operate at MPP independently of the load. The diagram of the MPP- tracking proposed in this work is shown in Fig.3., Using a power MOSFET is PWM controller, operating with switching frequency equal to 10 KHz. Adjusting the duty cycle of switching. The MPP-tracking control circuit is implemented with microcontroller ADMC 331.

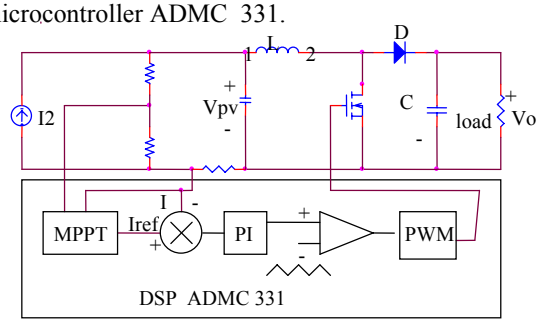


Figure 3. The diagram of the implemented system

VI. Control algorithm

A simple algorithm based on Hill- climbing and Perturbation and observation (P&O) method has been developed for real time track., and then it can fail under rapidly changing atmospheric condition. In the method described in [2], the power converter is controlled using the PV module output power. Figure.4. is based on the calculation of the PV output power and of the power change by sampling voltage and current values. The power change is detected by comparing the present and previous voltage levels, in order to calculate a reference voltage which is used to produce the PWM control signal. The DC/DC converter is driven by a DSP-based controller for fast-response and the overall system stability is improved by including a PI controller which is also used to match the array and reference voltage levels. However, the DSP-based control unit increases the implementation cost of the system.

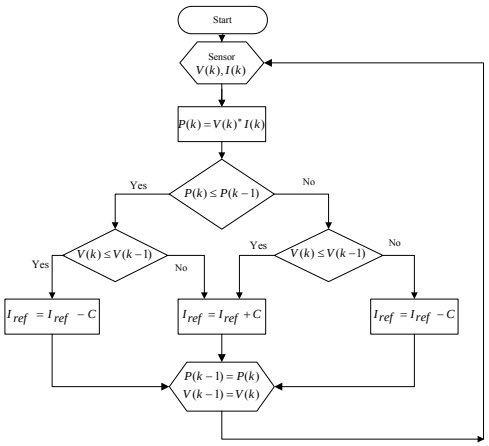

Figure 4. Algorithm flowchart

VII. Experimental Results

The proposed photovoltaic system was implemented using a DSP-based control with microcontroller ADMC 331. The system consists of a nonlinear current source as the power source, the PV-module ,s electrical characteristic ware Voc = 21.6 V, Isc = 3.3 A, IMPP = 3.1 A , VMPP = 17.3 V; there are the manufacturer rated values under standard operating condition., a resistor set as the load is 60 ohmic load. Such as design of inductor and capacitor of DC-DC converter., that the inductor value is calculated as 0.40 mH. The output capacitor value is calculated as 17 µF., Taking into account that the ripple of the PV output current must be less than 2%. The switching frequency is 10 KHz. The simulation was implemented under real time changing irradiation condition. For testing the MPP tracking, the performance of the PV system is studied for a clear sunny day with various radiation level on 15th

January 2007 at King Mongkuk' s University of Technology Thonburi (KMUTT) in Bangkok. All measurements ware recorded by a data logger every 5 second from 10 A.M to 2.30 P.M time. A lot of measurements have been made different sky condition. Figure.5. show of the experiment results gathered using the algorithm. Which refers to different irradiation., As can be observed, the system is stable and operates successfully even in cases of changing atmospheric condition., PV system output power(W) and input power (W) has been plotted, in Fig.6, versus time to show how well the device tracked. Figure.7 has been plotted to show efficiency versus time. Thus , experiment result confirm the method proposed.

VIII. CONCLUSION

The purpose of maximum power tracking is to transfer the maximum available power to the resistance load form the PV system. The MPP- Tracking is a boost converter , The use of microcontroller allows simple modification of the system, controlled by a single chip microcontroller that employs the Hill- climbing / P&O algorithm. Experiment results describe the performance of the designed MPP-tracking . The MPP-tracking increased about 24 % the energy transfer from the PV system to load and the overall efficiency of the MPP-tracking system about 87 % . The results show that proposed MPP- tracking algorithm has successful tracked the MPP in changing illumination condition.

***Abstract*- Nowadays, the goals of electrical supply utilities are to reduce equipment failures, to extend service life, to increase equipment reliability and to reduce their related operating and maintenance costs. High voltage circuit breaker is also an important element in the electrical network. In order to determine or to detect the abnormal conditions inside the circuit breakers, the powerful vibration techniques have been proposed for many years. Thus, vibration technique by analyzing the signal in time-frequency-domain was performed in this work under no-load switching operations with a commercially available high-voltage puffer-type circuit breaker without opening its major parts. Vibration of circuit breaker poles and operating mechanism as well as various monitored parameters were recorded under normal and variable operating conditions, which were the variations of auxiliary supply voltage, hydraulic oil pressure and SF_6 gas pressure. After that, a sensitivity of vibration method to the variable operating conditions was evaluated**.

I. INTRODUCTION

Up till now, the preventive maintenance is predominantly used to maintain circuit breakers after specific time interval or after specific number of operations. Even though nowadays, the reliability of the circuit breaker has been continuously improved by various measures in design and construction of the circuit breakers [1], [2], failures still exist and sometimes cause costly consequences. Therefore, maintenance is inevitably needed. However, this task is very costly, time-consuming and sometimes can incorporate unintentional defects due to excessively invasive maintenance.

The condition monitoring and diagnostic tests, especially with non-invasive techniques, have been developed with aiming to facilitate maintenance activity. Some techniques have been developed so far by many researchers, such as measurement of enclosure vibration to detect abnormal contact condition inside GIS [3], development of acoustic analysis by measuring vibration signals of circuit breaker in laboratory and in field test [4], [5], [6]. The idea is that mechanical malfunctions and abnormal behaviors should be detected as changes in the vibration signatures of the circuit breakers.

In this paper, the diagnostic method by analyzing the vibration signatures in time-frequency domain was presented. The tests were performed with a commercial 110kV SF_6 puffer-type circuit breaker, which is a free-standing pole model with 3-pole operating mechanism. At first, the vibration signature was recorded during no-load switching operations under normal operating condition as a reference fingerprint. After that, the signatures under variable auxiliary supply voltage, variable hydraulic oil pressure and SF_6 gas pressure variation were recorded. After comparison with the reference fingerprint, these intentionally variable operating conditions could be detected as changes in the analyzed vibration signatures.

II. EXPERIMENTAL SETUP

This experiment was performed with a 110kV SF_6 puffer-type circuit breaker with hydraulic operating mechanism as shown in Fig. 1 for the experimental setup. The investigation was performed under no-load switching operations. The vibration signals of the free-standing poles and of operating mechanism were recorded under normal and variable operating conditions that could probably occur in service, e.g. variation of control voltage supplied from station service power source or battery from the secondary circuit, SF_6 pressure change due to leakage or over-filling and hydraulic oil pressure change caused by seal and gasket aging.

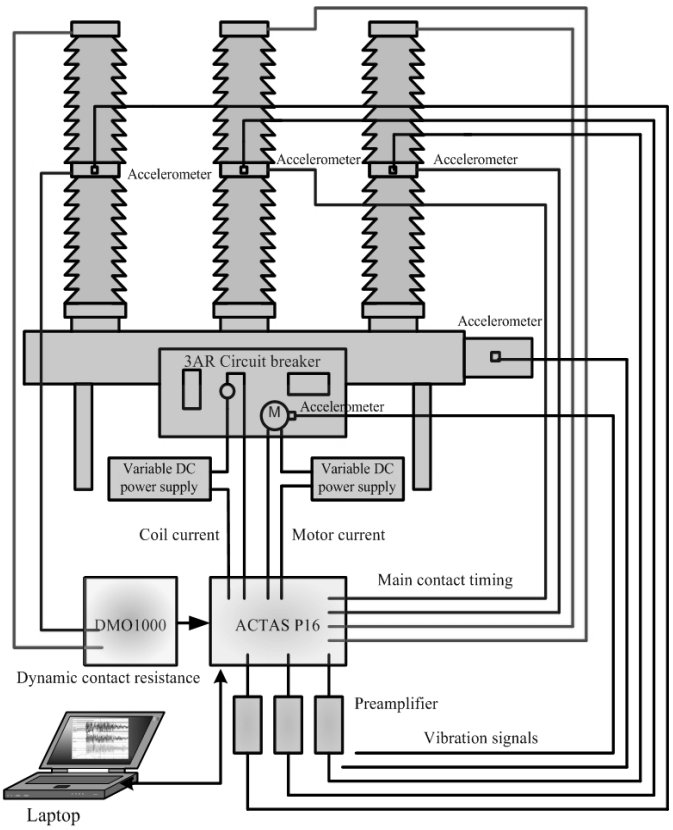

Figure 1. Experimental setup

During each no-load switching operation, other parameters such as close and trip coil current, hydraulic pumping motor current and time, main contact timing, dynamic contact resistance, were also measured as shown in Fig. 2. The measured vibration signatures under normal operating condition were used as a reference base line. The signatures under variable operating conditions summarized in Table I were compared with the reference signature. The tests and measurements were performed in a laboratory because of the readily controlled testing conditions.

The main components of the test system and their details were described as follows:

- A 110kV, 1250A, and 31.5kA puffer-type SF_6 circuit breakers with three-pole-operated hydraulic operating mechanism
- 5 accelerometers type 4501 (B&K) mounted externally at the middle of each pole, hydraulic operating mechanism and pumping motor of the circuit breaker
- 3 preamplifiers type 2626 (B&K) for vibration signal conditioning with optical cable connection to accelerometer
- 1 circuit breaker testing device ACTAS P16[1].
- 1 dynamic contact resistance measurement device DMO1000[1]
- Measurement cables and coaxial cable for serial connection between notebook and measurement device
- 1 notebook as a control unit with ACTAS software program
- 2 variable DC or AC power supply for control circuit and pumping motor
- SF_6 storage and filling unit.

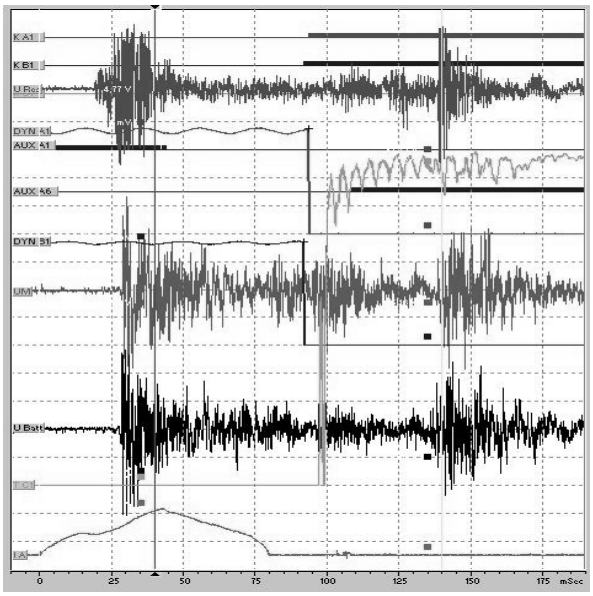

Figure 2. Vibration signals and other measured parameters recorded during closing operation

[1] KoCoS Meßtechnik AG, Südring 42, D-34497 Korbach, Germany

TABLE I
SUMMARY OF TESTING CONDITIONS

Test conditions	Voltage	Oil Pressure (bar)	SF_6 (bar)	Nr. of SW per test
Normal or rated operation	100%	320	6.5	15
Variable supply voltage	115%	320	6.5	15
	70%	320	6.5	15
Variable oil pressure	100%	280	6.5	15
	100%	250	6.5	15
Variable SF_6 pressure	100%	280	8	15
	100%	250	5.5	15

The vibration signals during closing and opening operations were recorded by using accelerometers and a data acquisition system. The vibration measurement consists of the following components:

1. Sensors: The piezoelectric accelerometer is used to measure the vibration signal propagating to the external structure via various parts of the internal mechanism and insulating medium. They were temporarily mounted with adhesive glue on circuit breaker enclosure surface. It produces a charge in proportional to the acceleration (pC/ms^{-2}).
2. Preamplifier and signal conditioner: These devices are needed in order to match the impedance and amplify the signal from accelerometer to reasonable value.
3. Data acquisition: The sampling rate was set at 10kHz. The total record time was set at 200ms for closing operation and 150ms for opening operation.

III. VIBRATION SIGNAL ANALYSIS

A. Circuit breaker's Vibration Signal

Vibration signal monitoring can refer to the movement of moving parts inside circuit breaker. The use of vibration signal can be compared with the hearth beating sound. Doctor can analyze the body health by the rhythm of beating. Like in circuit breaker condition assessment, the circuit breaker conditions can be acquired by vibration signal. Fig. 3 shows example signals of circuit breaker during opening and closing operations.

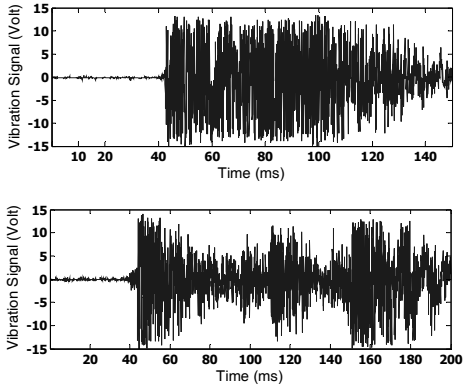

Figure 3. Opening (upper) and closing (lower) vibration signal.

Many sources of acoustic vibration are detected during the closing or opening operation such as the instant of solenoid coins, the impacted of arcing and main contacts. Each source of vibration will generate different vibration signature.

B. Wavelet transform

Wavelet Transform (WT) is a mathematical tool that transforms the signal in time domain to time-frequency domain. Its concept is similar to Short Time Fourier Transform (STFT). The STFT decomposes the original signal to a set of 'sinusoidal signals' with different frequencies. The coefficients of STFT are proportional to the correlation coefficients of the original signal with the unit complex sinusoidal in each frequency.

WT decomposes the original signal to a set of wave like signals, called 'wavelet'. These wavelet signals are the scaled (dilated) and shifted forms of the mother wavelet, as shown in Fig. 4.

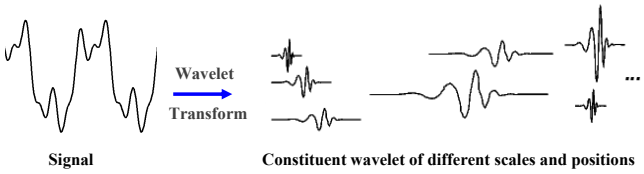

Figure 4. Signal decomposition using wavelet transformation [2]

The WT coefficient can be calculated by using the following expression.

$$C(a,b) = \int_{-\infty}^{\infty} f(t)\frac{1}{\sqrt{a}}\psi(\frac{t-b}{a})\,dt \qquad (1)$$

Where, ψ is the wavelet function and its shape varied by variables **a** (dilation) and **b** (position). Fig. 5 shows the example of the mother wavelet, dilated wavelet (a = 2) and position shifted wavelet (b = 10). The observation can be made that the smaller the dilation means the higher the frequency. The greater the position shifted means the longer the delay.

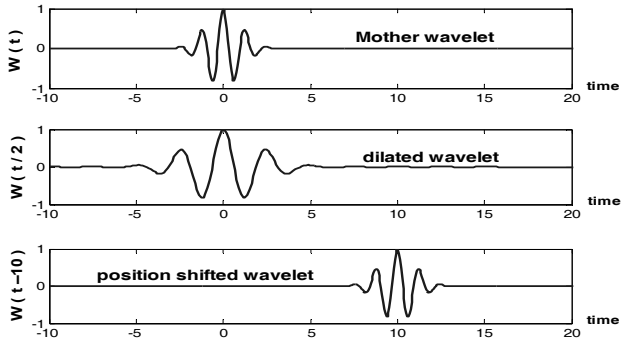

Figure 5. Mother wavelet, dilated wave*let (a=2) and position shifted wavelet (b= 10)*

The great advantage of WT is the ability to decompose the selected frequency component at any time. Therefore it is suitable to analyze instant transient signals. Even a barely visible small discontinuity can still be detected [7].

The event extraction of time domain vibration signal as in Fig. 6 is not easy to perform by human eye, especially opening vibration signal. The Wavelet transform is applied to enhance the event detection. Wavelet transform is a mathematical tool that transforms a signal in time domain to time-frequency domain. For this resource, the complex morlet with 1 bandwidth parameter and 1.5 wavelet center frequencies is selected. Fig. 6 shows the comparison between opening vibration signal and its transformed signal.

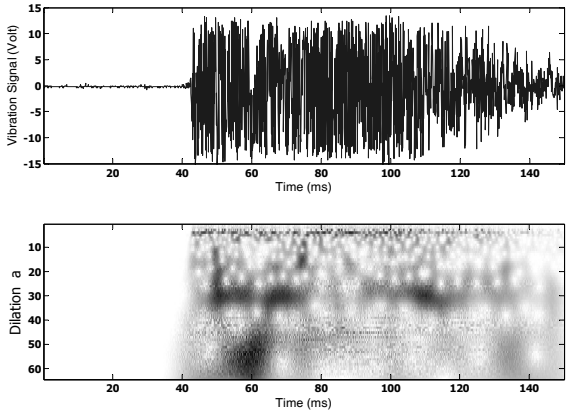

Figure 6. Time domain opening vibration signal (upper) and its wavelet transformed spectrogram (lower)

The wavelet transformed spectrogram in Fig. 6 shows the magnitude of signal in each frequency. At the vertical axis, the higher number of **a** (dilation) refers to the lower frequency signal. The value of horizontal axis is time in millisecond. Moreover, the darker color means the higher magnitude, e.g. the large magnitude low frequency signal (**a**=60) appears at 60ms.

C. Information Extraction from wavelet spectrogram

The wavelet transformed spectrogram contains a lot of information such as moving instant of solenoid armature and its speed, moving instant of moving contact. Fig. 7 shows the wavelet spectrogram of opening operation at normal operation as in table I compared with dynamic resistance (solid line) and delayed solenoid coil current signal (dash line).

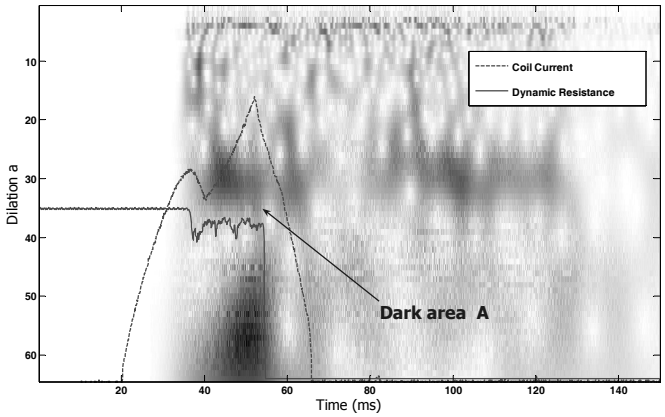

Figure 7. Spectrogram of normal condition closing operation compared with coil current (dash line) and dynamic resistance signal (solid line)

There are a lot of event signatures in the wavelet spectrogram shown in Fig. 7. The starting of shaded area of high frequency scale, at dilation = 1, relates to the starting movement of moving parts. The dark area A at scale of 30 refers to the scratching of arcing contact, and the arcing contact is fully separated at the end of this dark area. This result is confirmed by the comparison with dynamic resistance signal.

IV. RESULTS

A. *Effect of control voltage to vibration signal*

Practically, the dedicate power supply is used to supply the power to every control device including trip circuit. The variation of this control voltage affects to electromechanical mechanism. Fig. 8 shows the comparison between transformed vibration signal of closing operations at 70%, 100% and 115% control voltage.

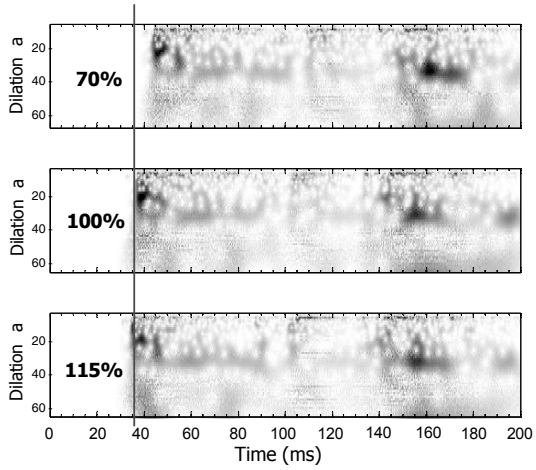

Figure 8. Spectrogram of vibration signal of circuit breaker closing operation which different control voltage

The higher the control voltage, the earlier appearance of the shaded zone of spectrograms occurs. However, the distance between signatures is still similar. Thus, there is no change of contact moving speed.

B. *Effect of hydraulic pressure to vibration signal*

Because the operation of puffer-type circuit break requires extremely high power and high speed, the hydraulic operating mechanism is selected. In the experiment, the hydraulic oil pressure is reduced from 320bar to 280bar and 250bar. The transformed signal is presented in Fig. 9. Each signature shows the same position of starting movement. For the higher hydraulic oil pressure, the faster moving occurs. Therefore, the event signature in this case occurs earlier and the signature becomes shorter, e.g. in Fig. 8, the arcing contact signature of closing operation at 320bar hydraulic oil pressure is much shorter than the others at 280bar and at 250bar.

C. *Effect of SF_6 pressure to vibration signal*

There is no significant effect of SF_6 pressure to the vibration signal. It is not easy to explicitly identify the event signature in the wavelet spectrogram.

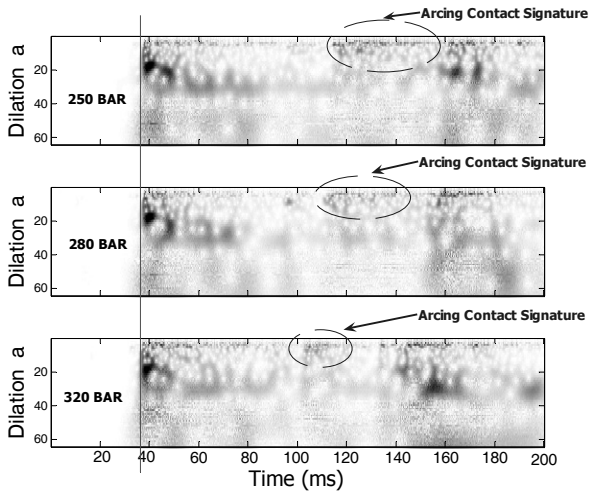

Figure 9. Spectrogram of closing vibration signal which different hydraulic oil pressure

V. CONCLUSION

The vibration signal analysis was performed in this work by using the wavelet transform in order to investigate the sensitivity of this method according to the variations of circuit breaker operating conditions. The variation of auxiliary supply voltage and hydraulic oil pressure results in reasonable changes in the transformed vibration signature. The variation of SF_6 gas pressure can not be detected by this method.

The changes in the transformed vibration signatures according to the variation of its operating conditions have been verified in this work. Thus, this vibration analysis can be used to observe the significant events occurring inside the circuit breaker. Therefore, further development of this method is recommended to use this as circuit breaker diagnostic tool.

Abstract- **This paper presents a utilization of generator participating factors for sensitivity analysis in a new electricity environment. In this study, the sensitivity index is referred to the effect of power generation on the use of transmission network facilities. The high sensitivity index means the high usage portion of the network. The generator participating factor is proposed to reduce a strong sensitivity at generation buses by distributing power generations, reducing system loss, and producing high benefit of system-wide usage. The results send incentive signals to generators for power-generation allocation based on system usage. To demonstrate its effectiveness, the proposed method is applied to the IEEE 30-bus system and 118-bus system.**

I. INTRODUCTION

Conventional Electricity Supply Industry (ESI) has been structured as a monopoly business that brings a high price of electricity, less efficiency in operation and management, etc. Therefore, many countries has restructured their ESIs by expecting that the new models will result in the higher efficiency, lower investment including operation and management costs, cheaper electricity price to customers, and higher electricity supply security. In a modern power system as deregulated or partial deregulated structure, the power producers do not have an obligation to serve the electricity. However, they play a roll regarding their costs not only the cost of power generation but also the other costs as transmission charge based on system usage and congestion management. It is important to send the incentive signal to users aiming at utilizing the system-wide facilities. The sensitivity method [1] was proposed to analyze the effects of nodal power injection on the use of transmission facilities. It means that the users with high sensitivity indices use high portions of transmission network. Consequently, the system might not be optimally used and transmission users, both generator and load, might pay high transmission charges. In addition, new participants, who need to install new capacity and find out the suitable location, where the lowest transmission charge is provided, can use the indices as a decision factor. Generator participating factors in [2] was suggested for solving the optimum power flow and finding the minimum cost of power generation [3] in a deregulated ESI.

This paper presents a generator participating factors for sensitivity analysis. The objective of sensitivity method is considered as sending the incentive signal to the generators, while the objectives of the generator participating factors are considered as distributing the power generation agreed by the generation companies in a deregulated environment, reducing system congestion and losses. The IEEE 30-bus system and IEEE 118-bus system are demonstrated for illustration purposes.

II. POWER FLOW MODEL

The problem formulation is originated from power flow analysis by using the decoupled Newton-Raphson method. The power flow model is formulated that power generation at a bus is firstly considered as:

$$P_{G\,i}=P_{Gset\,i}+P_{Gc\,i} \tag{1}$$

where:
i = 1, 2,…, NG, NG+1,…, NB.
$P_{Gi\,max} \geq P_{Gi} \geq P_{Gi\,min}$
$P_{Gc\,i}= \alpha_i \Delta G$
$\Delta G=\Delta P_T$, $\Delta P_T=P_T-P_{T0}$
$\sum \alpha_i = 1.00$

The parameters α_i is the grid's own generator participating factor agreed by the generation companies. Both active and reactive power loads are modeled as function of voltage at the bus. The considered functions are:

$$P_{Li}=P_{Loi}(A_1+A_2V+A_3V^2+A_4V^{ep}) \tag{2}$$

$$Q_{Li}=Q_{Loi}(R_1+R_2V+R_3V^2+R_4V^{eq}) \tag{3}$$

where:
P_{Gi} : p.u. active power generation at bus i
P_{Gseti} : p.u. active power schedule at bus i
P_{Gci} : p.u. active power generation due to primary and secondary controls at bus i
P_T : p.u. active power schedule at tie-line
NG : number of generator connected bus
NB : total number of buses in the system
α_i : participation factor of generator connected to bus i
ΔG : static area control error
P_{Li}, Q_{Li} : actual active and reactive load at bus i
P_{Loi}, Q_{Loi}: scheduled active and reactive load at bus i.
$A_1, A_2, A_3, A_4, R_1, R_2, R_3, R_4, ep, eq$ are constants while $A_1+A_2+A_3+A_4 = 1.0$ and $R_1+R_2+R_3+R_4 = 1.0$.

The power mismatch matrix can be written as:

$$\begin{bmatrix} dP \\ dQ \end{bmatrix} = \begin{bmatrix} Jpd & Jpv \\ Jqd & Jqv \end{bmatrix} \begin{bmatrix} d\delta \\ dV \end{bmatrix} \quad (4)$$

To calculate power flow, bus 1 is assumed as the reference for the purpose of voltage phase angle calculations of the other buses. The decoupled Newton-Raphson iterative solution is used. The example of linear equations for real power can be written as in (5). However, only *Jpd* and *Jqv* are taken into consideration for the power flow calculation.

$$\begin{bmatrix} \Delta P_1 \\ \Delta P_2 \\ \vdots \\ \vdots \\ \Delta P_{NB} \end{bmatrix} = \begin{bmatrix} \frac{\partial P_1}{\partial X} & \frac{\partial P_1}{\partial \delta_2} & \cdots & \frac{\partial P_1}{\partial \delta_{NB}} \\ \frac{\partial P_2}{\partial X} & \frac{\partial P_2}{\partial \delta_2} & \cdots & \frac{\partial P_2}{\partial \delta_{NB}} \\ \vdots & \vdots & \cdots & \vdots \\ \frac{\partial P_{NB}}{\partial X} & \frac{\partial P_{NB}}{\partial \delta_2} & \cdots & \frac{\partial P_{NB}}{\partial \delta_{NB}} \end{bmatrix} \begin{bmatrix} \Delta X \\ \Delta \delta_2 \\ \vdots \\ \Delta \delta_{NB} \end{bmatrix} \quad (5)$$

where:

$$\Delta P^k = P_{specified} - P_{calculated} \quad (6)$$

$$\Delta Q^k = Q_{specified} - Q_{calculated} \quad (7)$$

$$X^{k+1} = X^k + \Delta X \,,\; \delta^{k+1} = \delta^k + \Delta\delta \,,\; V^{k+1} = V^k + \Delta V \quad (8)$$

ΔX is referred to ΔG as unknown. k is iteration of computation. We can solve for ΔX, $\Delta\delta$ and ΔV by iterative process. The power flow solution is used later for sensitivity calculation. The computational procedure is shown in Fig. 1.

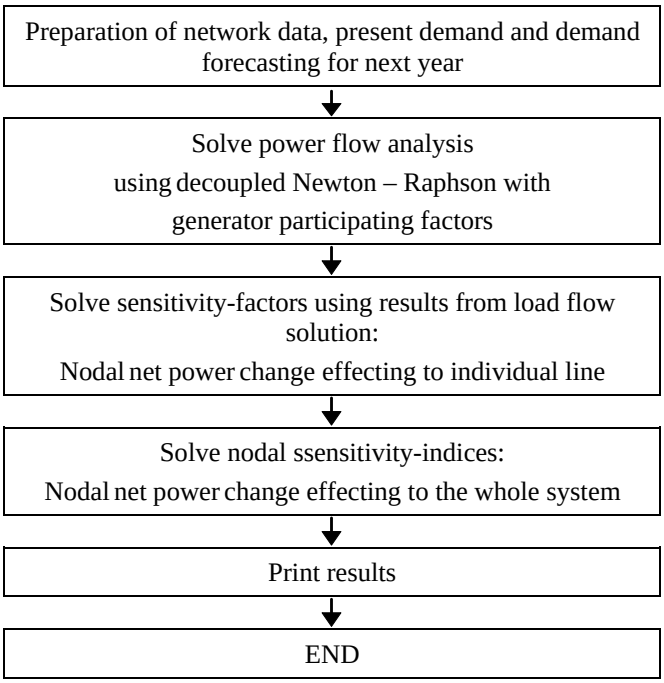

Figure 1. Computational procedure.

III. Sensitivity Indices Calculation

The computation of the sensitivity indices consists of three main steps. Firstly, the sensitivity factors are calculated. They represent an influence of the incremental generation or demand at each bus to the tie-line flows. Secondly, the sensitivity matrix is formed in terms of sensitivity factors. Lastly, the nodal sensitivity indices based on the use of system are determined. These results are used to calculate nodal transmission tariffs.

A. Sensitivity factor calculation

The calculation of sensitivity factors starts from the determination of the Jacobian matrix J which contains the derivatives of the bus power injection with respect to the voltage amounts V_i and angles δ_i of a base load flow case (index 0).

$$J_0 = \begin{bmatrix} J1 & J2 \\ J3 & J4 \end{bmatrix} = \begin{bmatrix} Jpd & Jpv \\ Jqd & Jqv \end{bmatrix}_{(2NBx2NB)} \quad (9)$$

$$J_1 = \begin{bmatrix} \frac{\partial P_1}{\partial X} & \frac{\partial P_1}{\partial \delta_2} & \cdots & \frac{\partial P_1}{\partial \delta_{NB}} \\ \frac{\partial P_2}{\partial X} & \frac{\partial P_2}{\partial \delta_2} & \cdots & \frac{\partial P_2}{\partial \delta_{NB}} \\ \vdots & \vdots & \cdots & \vdots \\ \frac{\partial P_{NB}}{\partial X} & \frac{\partial P_{NB}}{\partial \delta_2} & \cdots & \frac{\partial P_{NB}}{\partial \delta_{NB}} \end{bmatrix}_{(NBxNB)} \quad (10)$$

The matrix J has ($2NB$x$2NB$) dimension as shown in (9) where NB indicates the numbers of buses. To calculate sensitivity factor, the matrix J needs to be inversed. Thus, we get the new matrix L which contains the derivatives of the bus voltage and angle with respect to the bus active power P and reactive power Q injection.

$$L = J^{-1} = \begin{bmatrix} Jpd & Jpv \\ Jqd & Jqv \end{bmatrix}^{-1} = \begin{bmatrix} \frac{\partial \delta}{\delta P} & \frac{\partial \delta}{\delta Q} \\ \frac{\partial V}{\delta P} & \frac{\partial V}{\delta Q} \end{bmatrix} \quad (11)$$

The branch flow equation given in term of voltages and impedances can be written as:

$$S_{i-j} = 3V_i^2 \left(Y_{0ij}^* + Y_{ij}^*\right) - 3V_i V_j^* Y_{ij}^* \quad (12)$$

where Y_{0ij}, Y_{ij} are elements of the π equivalent and *i*, *j* are terminal buses of the considered branch *i-j*. By deriving (12) with respect to V_i, V_j, δ_i and δ_j, the sensitivity factor of line *i-j* due to power injection changes at bus *k* can be determined.

$$K_{i-j,k}^{PP} = \frac{dP_{i-j}}{dP_k} = \frac{\partial P_{i-j}}{\partial \delta_i} \cdot \frac{\partial \delta_i}{\partial P_k} + \frac{\partial P_{i-j}}{\partial \delta_j} \cdot \frac{\partial \delta_j}{\partial P_k} + \frac{\partial P_{i-j}}{\partial V_i} \cdot \frac{\partial V_i}{\partial P_k} + \frac{\partial P_{i-j}}{\partial V_j} \cdot \frac{\partial V_j}{\partial P_k} \quad (13)$$

and

$$K_{i-j,k}^{QP} = \frac{dQ_{i-j}}{dP_k} = \frac{\partial Q_{i-j}}{\partial \delta_i}\cdot\frac{\partial \delta_i}{\partial P_k} + \frac{\partial Q_{i-j}}{\partial \delta_j}\cdot\frac{\partial \delta_j}{\partial P_k} + \frac{\partial Q_{i-j}}{\partial V_i}\cdot\frac{\partial V_i}{\partial P_k} + \frac{\partial Q_{i-j}}{\partial V_j}\cdot\frac{\partial V_j}{\partial P_k} \quad (14)$$

where $\frac{\partial \delta_i}{\partial P_k}, \frac{\partial \delta_j}{\partial P_k}, \frac{\partial V_i}{\partial P_k}, \frac{\partial V_j}{\partial P_k}$ are elements of *L*.

The sensitivity factors can be applied to all branches and affect all buses in the system. The matrix can also be spitted into four sub-matrices by separating active and reactive power as following:

$$[\Delta S_{branch}] = [K][\Delta S_{bus}] \quad (15)$$

$$\begin{bmatrix} \Delta P_{branch} \\ \Delta Q_{branch} \end{bmatrix} = \begin{bmatrix} K^{PP} & K^{PQ} \\ K^{QP} & K^{QQ} \end{bmatrix} \begin{bmatrix} \Delta P_{bus} \\ \Delta Q_{bus} \end{bmatrix} \quad (16)$$

From (16), both incremental active and reactive power flows in any transmission line can be determined. In this paper, only the active and reactive powers influenced by bus real power are considered. It means that the applications of sub-matrix K^{PP} and K^{QP} are applied to form the sensitivity matrix.

B. Sensitivity Matrix and Incremental Flow Calculation

In this step, the sensitivity matrix is performed as shown in Table I. It shows real power sensitivity factors influencing lines L_1 to L_4 due to the power injection of countries A to D. The positive sign of sensitivity factor means that bus power injection increases power flows over the transmission lines. Similarly, the negative sign means that bus power injection reduces power flows over the transmission lines while the zero value means that there is no power injection or absorption to the network at the bus.

Table II presents the net balance injection in MW. T1 represents the time reference (base-case). T2 represents the forecast of the peak bus injection. Then, the expected changes of the flows are calculated based on sensitivity factors in Table I and incremental injection in Table II.

TABLE I
EXAMPLE OF SENSITIVITY MATRIX

Lines / Buses/Nodes	L_1	L_2	L_3	L_4
A	+0.3	+0.2	+0.4	-0.7
B	-0.1	-0.5	-0.3	+0.3
C	+0.5	+0.3	+0.2	-0.1
D	-0.1	-0.3	-0.1	+0.6

TABLE II
NET BALANCES OF SAMPLE NODE (MW)
(+) NET INJECTION, (-) NET ABSORPTION

Nodes / Time	A	B	C	D
T_1 (measured)	+2000	+800	-2300	-500
T_2 (forecasted)	+1300	-200	-1000	-100
Changes	-700	-1000	+1300	+400

For example, the incremental flow on line L1 is equal to (+0.3)x(-700)+(-0.1)x(-1000)+(+0.5)x(+1300)+(-0.1)x(+400) =(-210) + (-100) + (650) + (-40) = 300 MW. The nodes A, B, C, and D cause the incremental flow on L1 as amount of -210, -100, +650, and -40 MW. Similarly, incremental flows in line L2, L3 and L4 can also be determined. The incremental flows are used to calculate the sensitivity indices in the next section.

C. Sensitivity Indices Calculation

To send the correct economic signal based on a system usage and congestion to all users, the sensitivity indices should be determined. The sensitivity index is the nodal factor multiplied with a uniform postage stamp tariff. As a result, the nodal tariffs are computed. The users at each node or country will be charged in the different rates due to their network usages. The nodal sensitivity index is calculated as:

$$SI_k = 1 + \frac{\prod_{i-j} SF_{k,i-j}}{\sum_{k=1}^{n}\left(\prod_{i-j} SF_{k,i-j}\right)} \quad (17)$$

where

$$SF_{i-j,k} = 1 + \frac{\left|\Delta S_{i-j,k}\right|}{\sum_{k=1}^{n}\left|\Delta S_{i-j,k}\right|}\cdot\left|\Delta S_{i-j}\right| \quad (18)$$

SI_k is the sensitivity index at bus *k*. $\left|\Delta S_{i-j,k}\right|$ is the incremental magnitude of power flow of line *i-j* due to the injection change of bus *k*. $\left|\Delta S_{i-j}\right|$ is the total incremental magnitude of complex power of line *i-j*.

IV. SIMULATION RESULTS AND DISCUSSIONS

The IEEE 30-bus system is firstly used as a testing system. It comprises six generation buses and twenty-four lines. To calculate the sensitivity matrix in the year N, load flow data based on the measurement of the base case at the end of the year N-1 and forecasted data of the present year N must be defined. By analyzing the load flow and solving (1)-(16), the sensitivity factors can be calculated. Then, the incremental flow on transmission lines as portions of bus injection is determined. By solving (17)-(18), the sensitivity index of each bus with and without generator participating factor is determined as shown in Table III. However, only generation-buses are demonstrated.

TABLE III

TABLE VI

LOAD, GENERATION AND SYSTEM LOSSES WITH AND WITHOUT GENERATOR PARTICIPATING FACTORS FOR THE IEEE 118-BUS SYSTEM

(MW)	with GPF	without GPF
Load	3667.99	3668.00
Power Losses	140.91	184.73
Generation	3808.90	3801.21

Consideration without generator participating factors, bus No. 1 is the slack bus. It has a function to generate the electricity supporting the load mismatch. In this case, the slack bus is forced to produce the largest amount of power generation. The sensitivity of this bus as shown in Table III is the highest value as 0.060099 because of its system usage. The other generators show different sensitivity-values. For example, bus No. 5 has 0.0298085 as the lowest value because produce the less net power injection. The other buses can be explained in the same way. The total system loss is 173.60MW as shown in Table IV. Comparing with using generator participating factors, the total power generation is distributed. The power generation and sensitivity index of the slack bus are reduced and while the indices of the other buses are increased due to the participating factors. The system loss is reduced to 48MW. It implies that the factors distribute total power generation to beneficially utilize network facilities and reduce total system loss.

Next, the IEEE 118-bus system is demonstrated as a larger system. It comprises fifty-four generators with nine transformers and hundred seventy-seven lines. Because of a limitation of space, only important generation buses are presented. Thus the summation of sensitivity indices is not equal to one. In this system, the bus No. 89 is represented as the slack bus. The simulation results without using of generator participating factors are used as a reference. The total power loss is equal to 184.73MW. The highest sensitivity index is 0.2278 at the bus No. 26, which is not the slack bus. It can be explained that even through the bus injects low power generation, transmission capacity is increased, which results in capacity loading and congestion problem. This produces high index value. The slack bus has a second highest index as 0.1102. It can be simply described that the high power generation causes high sensitivity because of using high system portion.

With using generator participating factors, bus Nos. 12, 66, 69, 80, and 103 show results as expected, the higher power generation get the higher sensitivity indices. The slack bus is not changed much in sensitivity index value because it still produces a huge amount of electricity comparing to other generators and uses a high portion of the system. However, the system loss is reduced to 140.91MW. Moreover, there are significantly important results of the bus Nos. 10, 25, 100 and 111. They increase power generations by sharing the total generation amount from the slack bus but their sensitivity indices are reduced. It can be explained that by increasing the power generation of these buses, it removes the stress of system usage, capacity loading and congestion. On the other hand, it can be explained that a use of generation participation factor to analyze system sensitivity sends signals based on system usage to optimize power generation and transmission capacity. In additional, the system loss can be also reduced.

V. CONCLUSION

This paper presents a utilization of generator participating factors for sensitivity analyses of bus injections to system. The sensitivity indices send signal regarding the system usage and congestion. The higher sensitivity index means higher usage portion of the network. The generator participating factors are proposed to distribute power generations, remove the stress on sensitivities of the generation buses, make beneficially system usage and reduce transmission loss. The IEEE 30-bus system and 118-bus system are demonstrated.

***Abstract* – The state estimation presented in this paper includes a detection step for the possible presence of a topology error. Upon the detection of a possible error, the topology error identification step is invoked to locate its potential location. The suspicious node is then represented by the full bus-section model after which a generalized DC state estimation step capable of identifying the error in the status measurements is applied. This results in an accurate network topology that is used in the subsequent full AC state estimation. The proposed method has been successfully applied to a test system.**

I. INTRODUCTION

Nowadays, state estimation plays an important role in providing the reliable system states from measurements for a power system. The network topology or the information on how the buses and branches of the power system are connected is an important input to the state estimation and is provided by the well-known function called network topology processor.

Conventional network topology processor has the ability to provide system topology by processing the statuses of circuit breakers assuming that they are correct. The resulting system topology is used in later stages of power system analysis, especially state estimation.

When generalized state estimation was proposed in [1], a generalized approach for network topology processing was also proposed as an integral part of the state estimation. By generalized approach, network topology processor is supposed to be able to provide reliable system topology by using a blend of methods to indicate topology error (topology error processing) or to estimate possible topology (topology estimation).

Normally, the conventional state estimation can be performed properly in the environment of gross measurement errors by efficient bad data detection. However, topology errors can have a substantial impact on the results of state estimation. In serious cases, topology error can adversely affect the convergence of state estimation solution [2]. It is therefore desirable for the generalized state estimation to be able to detect not only measurement errors, but also other types of errors, especially topology errors.

Many researchers have proposed ways to carry out the topology error detection as a post-processing or preprocessing step of state estimation [3] and two-stage estimation [4,5]. The generalized state estimation technique is an efficient way to carry out the topology error detection by means of topology estimation [6,7].

The occurrence of topology errors is seldom and not widespread in a practical environment. The full-step and system-wide execution of topology error processing or topology estimation in every pass of state estimation analysis is therefore expensive and unnecessary. Topology error detection based on power transfer distribution factors has been proposed to detect suspected cases affected by topology errors [8,9]. This step is useful to determine whether the full step of topology error processing or topology estimation should be performed or not.

In this paper a generalized approach for network topology processing to provide reliable topology as a preprocessing step of the full ac state estimation for improved accuracy of the estimated states is presented.

II. BACKGROUND

A. Network Topology Processing

Network topology processor (NTP) is a function that determines the system topology from the information on the statuses of circuit breakers. Automatic NTP was first proposed in reference [10]. In a conventional approach, NTP only processes circuit breaker statuses by using graph search technique [10,11], rule-based technique [12], or connectivity matrix technique [13], to provide the system topology that is used in forming the bus admittance matrix (Y_{bus}).

The efficient and simple way for network topology processing is the graph search technique because it avoids calculations and can be applied to any bus configurations.

Topology error will directly affect Y_{bus} that is used in state estimation in terms of the measurement functions of bus injections. The accuracy of state estimation results therefore depends on the system topology obtained from NTP.

In the generalized approach, a process for rejecting topology errors called topology error processing is incorporated in the NTP so that it provides the accurate system topology. Although topology error processing can be performed after state estimation, the use of accurate system topology in state estimation will increase the possibility to provide accurate state estimates without serious problem during the operation.

B. Conventional State Estimation

The state estimation provides the estimates of the power system state variables based on a combination of measurements and virtual measurements. It can be formulated mathematically using the constrained optimization problem:

Minimize $f(z - h(x))$ (1)

Subject to $g(x) = 0$ and $c(x) \le 0$

Where: z is the vector of measurements

x is the vector of state variables

$h(.)$ is the vector functions relating measurements to state variables

$f(.)$ is the objective function

$g(.)$ and $c(.)$ are vectors of functions representing power flow quantities.

In the weighted least-squares method the following quadratic objective function is used:

$$f(z - h(x)) = [z - h(x)]^T W[z - h(x)] \quad (2)$$

Where W is a diagonal matrix of weights (For telemetry, the inverse of measurement variances are normally used as weights)

C. Generalized State Estimation

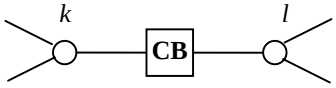

Figure 1. Zero impedance branch or branch of circuit breaker

The generalized state estimation is performed on a model in which part of the network is represented at the physical level, i.e. modeled in terms of bus sections and circuit breakers. This allows the inclusion of measurements made on zero impedance branches or branches of circuit breakers. The conventional states are augmented with new state variables.

The measurements made on zero impedance branches and circuit breakers called pseudo-measurements can be formed by considering the known branch status.

When the branch status is closed:

$$\Delta\theta_{kl} = \theta_k - \theta_l = 0 \quad \text{and} \quad \Delta V_{kl} = V_k - V_l = 0 \quad (3)$$

When the branch status is open :

$$P_{kl} = 0 \quad \text{and} \quad Q_{kl} = 0 \quad (4)$$

The new state variables are the states corresponding to the zero impedance branches or circuit breakers, e.g. power flows and node voltage angles at both ends of the branches.

D. Topology Error

There are 2 types of topology errors.

1. Branch status error:

- Inclusion error: Including a branch outage into the system topology.

- Exclusion error: Excluding an active branch from the system topology.

2. Substation configuration error:

- Bus-split error: Splitting a single bus to multiple electrical nodes.

- Bus-merge error: Merging two bus sections or more into a single electrical node.

III. PROPOSED NETWORK TOPOLOGY PROCESSOR

The proposed NTP consists of main 4 steps:

Step 1. Topology determination: Determine a bus to branch model of the power system.

Step 2. Topology error detection: Check the consistency between the topology and the measurements.

Step 3. Topology error identification: Find the indicator for suspicious area of topology error.

Step 4. Topology estimation: Estimate the statuses of circuit breaker to indicate the possible topology.

The topology error detection step (step 2) has been proposed to detect a suspected case which may be affected by a topology error. This step is useful in determining whether the full step of topology processing should be performed or not. By the approach of two-stage estimation, step 3 and step 4 can be called the first and the second stages of the approach, respectively.

After the system topology is noticed that it may contain a topology error, the topology identification and estimation will be performed consequently and the processing steps may be iteratively repeated for a multiple error case.

A. Topology Determination

For determining system topology the conventional NTP may be applied. The steps in topology determination are:

1. Bus-section processing (substation-level processing): In this step the substation presented in the details of bus-configuration will be changed to electrical nodes by using the statuses of circuit breakers and switching devices.

2. Network connectivity analysis (network-level processing): In this step all electrical nodes will be linked together by transmission lines.

The two popular graph search techniques applied to determine topology are breadth-first search and depth-first search[14]. The breadth-first search is selected to performed topology determination for the proposed NTP because it is a fast and simple way for connectivity analysis.

After all the steps are completed, the resulting network topology will be used to form the bus admittance matrix (Y_{bus}) for later analysis.

B. Topology Error Detection

Power transfer distribution factors (PTDFs) are applied in order to estimate power flow from power injection data. This allows the agreement between the topology and the measurements to be checked [8,9].

The PTDFs are derived from the sensitivities of line flows with respect to bus injections [15]. By assuming that all the per unit bus voltage magnitudes are approximately unity the calculation involves only Y_{bus}:

$$PTDFs(i,k) = conj[(Z_{bus})_{ik} - (Z_{bus})_{jk}] / conj(z_{ij}) \quad (5)$$

The approximated branch power flows can be calculated using:

$$\overline{S}_{branch} \approx PTDFs \times S_{bus} \quad (6)$$

Where i = sending bus , j = receiving bus, k = bus number

$\bar{S}_{branch}$ = a vector of branch power flow
S_{bus} = a vector of bus injection
z_{ij} = the impedance of branch *ij*
Z_{bus} = Bus Impedance Matrix = $(Y_{bus})^{-1}$

When the estimated power flows are obtained, the hypothesis testing is used to decide whether topology is correct or not. The following performance index (*J(r)*) used for the hypothesis testing with chi-square is

$$J(r) = \sum_{i=1}^{N} (r_i^{\,2} / \bar{S}_{branch,i}) \qquad (7)$$

Where: N = the number of power flow measurements
r_i = the residual between the measured and estimated power flows.

C. Topology Error Identification

After the topology error has been detected in the previous step, the specific suspected area will be identified by estimating topology error in terms of the topology index (TI) [16].

For the calculation of the topology index, conventional state estimation will be run to calculate the sensitivity matrix by discarding the accuracy of state variables therefore the less accurate model such as the dc model or fast decouple model may be used.

If the measurements have redundancy, the topology error will directly affect the residuals of all the incidence measurements especially the corresponding node injection [17]. The topology index (TI) used to represent the topology error can be calculated from the equation below:

$$\mathrm{TI} \approx \left(S_{node}^{T} S_{node}\right)^{-1} S_{node}^{T} r \qquad (8)$$

Where S_{node} = Sensitivity Matrix corresponding to node measurements

In the case of a branch status error (exclusion and inclusion error), the two TI values of the two nodes that belong to the error branch often have close values.

In the case of bus configuration error (bus split and merge error), the TI values of the node corresponding to error bus are always the largest and the next largest.

D. Topology Estimation

When the suspicious buses are identified using the hypothesis testing in the previous step, the generalized state estimation will be performed with the expansion of the suspicious buses represented in details to estimate possible statuses of the circuit breakers. To avoid complexity of the state estimation process, only the real power measurements are used in this step [7]. The augment state variables of this step are real power flows through circuit breakers and nodal voltage magnitudes. These state variables are used to indicate the possible corresponding statuses of the circuit breakers.

IV. ILLUSTRATIVE EXAMPLE

The bus-branch model of a 4-bus 4-line test system is shown in Fig.1. The flow measurements of all branches (both ends of the branch), injections and voltage magnitudes of all buses are obtained from power flow calculation with 0.01 MVA power mismatch and then a random error is applied to each measurement. The per-unit values are on the system base of 100MVA.

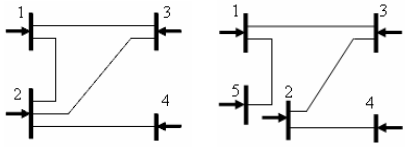

Figure 2. Base Case(A) and Bus split case (B)

For the topology error detection, the number of measurements (N) = 8, thus the threshold of *J(r)* is C = $\chi^2(\alpha, N-1)$=18.5.

For the topology error identification, the standard deviation of the measurements (σ) of 0.01 is used, and the confidence interval α = 0.01. The conventional state estimation with 16 measurements (i.e. bus voltage magnitudes, real power flows at both ends of all branches and real power injections of all buses) is used.

Example 1: Correct topology with normal error of analog measurements

This example is referenced to the power system in the Figures 1, 2 and 3. The real power flow and reactive power flow measurements are used to compare with approximated power flows calculated from the bus injections using the PTDFs. In the cases 4–6, the errors are applied to all the power flows in the percentage of the base MVA.

TABLE 1
TOPOLOGY ERROR DETECTION RESULTS OF EXAMPLE 1

No.	Topology	Measurement	*J(r)*
1	Base case	Base case	5.53

5	Base case	15% error	189.17
6	Base case	20% error	331.11

From the results in table 1, cases 1-3 will pass the test with assumption of correct topology, but case 4-6 will be detected with having a suspicious topology error, thus topology error identification should be invoked for case 4-6. The error of case 4 may be accepted due to slightly difference from threshold.

After topology error identification and estimation of case 4-6, the results will depict that topology is the same as that of previous.

Example 2: Error Topology with normal error of analog measurements

In the case of topology error, the results are shown in Table. 2. Topology error detection determines the presence of a topology error for each case on the criterion that *J(r)* exceeds the threshold (i.e. C > 18.5). After the topology error detection is performed for each suspicious case, the node with the maximum TI is identified as suspicious.

In the case of branch status error (exclusion and inclusion error), the two TI values of the two nodes that belong to the error branch often have close values. The two nodes should thus be considered together in the topology determination step or in a simpler way by reversing the branch status and perform topology detection and identification again.

In the case of bus configuration error (bus split and merge error, Figures 2(B), the TI values of the nodes corresponding the split bus 2 (node 2 and node 5) always have the largest and next largest values. The topology estimation should be performed with the suspicious bus represented in full details.

TABLE 2
TOPOLOGY ERROR DETECTION AND IDENTIFICATION RESULTS OF EXAMPLE 2.

no	topology	measurement	*J(r)*	J(x)	TI max1	TI max 2	node
Exclusion Error							
7	L1-2 outage	Base case	$7x10^4$	$3x10^4$	1.00	0.98	1,2
8	L1-3 outage	Base case	$6x10^4$	7838	0.51	0.47	1,3
Inclusion Error							
9	Base case	L1-2 outage	78	$2x10^5$	9.65	9.24	1,2
10	Base case	L1-3 outage	186	$2x10^4$	1.00	0.94	1,3
Bus-Split Error							
11	Bus split	Base case	$3x10^4$	3276	0.55	0.53	5,2
Bus-Merge Error							
12	Base case	Bus split	118	$5x10^4$	0.80	0.15	2,4

V. CONCLUSIONS

The proposed network topology processor is supposed to be a preprocessing step of the full ac state estimation to provide the reliable topology information for accurate state estimation results. The topology processor consists of two main parts, the first part performing the topology determination which provides the topology information and the second part performing the topology correction which checks and rejects topology errors. In practical environment the topology error is rare and not widespread. In some cases the topology errors do not alter the network configuration therefore their identification is not necessary. The proposed simple error detection by means of the compromise of topology and measurements, and the fast approximation of power flows using PTDFs, is useful for detecting non-serious cases, i.e. the case of acceptable measurement error, to avoid the full steps of the topology processor.

The limitations of the proposed topology processor are :

1. Considerable computational time is needed due to the blends of numerical techniques applied in the topology processor. This may not be suitable for real-time environments.

2. In the some difficult cases (e.g. topology error and gross measurement error occurring at same time, near zero flows in lines, and interacting and conforming measurement errors), the topology correction may be unable to detect and identify the reliable topology information therefore an efficient state estimation and bad data detection may be used to cope with such cases.

3. For the error processing, the measurements are assumed to have redundancy, so the observability analysis is not considered here.

The proposed network topology processor has been successfully applied to simplified test systems and is being extended to apply to more practical and complex systems.

***Abstract* –This paper presents a method of topology error detection using approximate branch power flows calculated from power transfer distribution factors. The correlation between the approximate flow and measurements is used to indicate the presence of possible topology errors. The method has been satisfactorily tested using data from test systems.**

I. INTRODUCTION

Nowadays, state estimation plays an important role in providing the reliable system states from measurements for a power system. The network topology or the information on how the buses and branches of the power system are connected is an important input to the state estimation and is provided by the well-known function called network topology processor.

Conventional network topology processor has the ability to provide system topology by processing the statuses of circuit breakers assuming that they are correct. The resulting system topology is used in later stages of power system analysis, especially state estimation.

When generalized state estimation was proposed in [1], a generalized approach for network topology processing was also proposed as an integral part of the state estimation. By generalized approach, network topology processor is supposed to be able to provide reliable system topology by using a blend of methods to indicate topology error (topology error processing) or to estimate possible topology (topology estimation).

Normally, the conventional state estimation can be performed properly in the environment of gross measurement errors by efficient bad data detection. However, topology errors can have a substantial impact on the results of state estimation. In serious cases, topology error can adversely affect the convergence of state estimation solution [2]. It is therefore desirable for the generalized state estimation to be able to detect not only measurement errors, but also other types of errors, especially topology errors.

Many researchers have proposed ways to carry out the topology error as a post-processing or preprocessing step of state estimation [3] and two-stage estimation [4]. The generalized state estimation technique is an efficient way to carry out the topology error detection by means of topology estimation [5,6].

The occurrence of topology errors is seldom and not widespread in a practical environment. The full-step and system-wide execution of topology error processing or topology estimation in every pass of state estimation analysis is therefore expensive and unnecessary. Topology error detection based on power transfer distribution factors has been proposed to detect suspected cases affected by topology errors [7].

In this paper, topology error detection based on power transfer distribution factors will be simplified and applied to data from the test systems containing typical topology errors. The topology error detection step is useful to determine whether the full step of topology error processing or topology estimation should be performed or not.

II. BACKGROUND

A. *Power Transfer Distribution Factors*

The method of distribution factors is based on the approximate linear behavior of branch flows with bus injections. The Power Transfer Distribution Factors (PTDFs) are derived from the sensitivities of line flows with respect to bus injections [8]. By assuming that all the per unit bus voltage magnitudes are approximately unity the calculation involves only Y_{bus}:

$$PTDFs(i,k) = conj[(Z_{bus})_{ik} - (Z_{bus})_{jk}] / conj(z_{ij}) \quad (1)$$

With the further approximation of DC load flow [9], the following relation results:

$$PTDFs = B^f B^{-1} \quad (2)$$

Where i = sending bus, j = receiving bus
l = branch number, k = bus number
z_{ij} = the impedance of branch ij
Z_{bus} = Bus Impedance Matrix = $(Y_{bus})^{-1}$
B = the matrix of imaginary part of Y_{bus}
B^f = the branch to bus susceptance matrix
Where the admittance of branch ij = g + jb
$B^f_{lk} = b$ *when* $k = i$, $B^f_{lk} = -b$ *when* $k = j$
$B^f_{lk} = 0$ *otherwise*

B. *Topology Error Processing*

Topology Error Processing (TEP) is used to carry out the topology error problem that may occur in the power system network. There are 2 types of topology errors.

1. Branch status error:

- Inclusion error: Including of a branch outage into the system topology.

- Exclusion error: Excluding an active branch from the system topology.

2. Substation (Bus) configuration error:

- Bus-split error: Splitting a single bus to multiple electrical nodes.

- Bus-merge error: Merging two bus sections or more into a single electrical node.

The methods of topology error detection reviewed in [3] have 2 different approaches. The first approach always requires the execution of conventional state estimation and relies on its. Topology error detection will be performed as a post-processing step of state estimation. The alternative approach relies on the consistency check and the critical branch flow discrepancy by using SCADA measurement. The rule-based technique was proposed in [10] for consistency check of the network topology in online power system. This approach is based on many of rules that are suitable for particular systems and therefore practical experiences are needed to set the rules. The approach of critical branch flow discrepancy is the efficient way to detect topology error but it needs the multiple scan of SCADA measurements. The approximated power flow by using PTDFs was proposed in [7] to detect topology error by matching the scenario of topology with the measurement until the lowest residual error is obtained. The matching approach will be more complicated when the system is large and bus configuration errors are presented.

By the approach of topology estimation [5,6], it will be assumed that topology is inaccurate therefore the TEP will be performed by means of topology error identification and estimation. The reliable network topology will be obtained by this approach for later analysis. If the assumption of inaccurate topology is tested and depicted that it is wrong, the full step of topology can be avoided.

III. PROPOSED TOPOLOGY ERROR DETECTION

In this paper the topology error detection is proposed as a preprocessing step of topology error processing (topology error identification and estimation) to detect the suspicious topology error case by using the simple assumption and statistical test. The proposed method consists of main 4 steps as shown in Figure 1:

Step 1. Approximation of power flow by using Power Transfer Distribution Factors (PTDFs)

Step 2. Branch status error detection

Step 3. Bus configuration error detection

Step 4. Hypothesis Testing with Chi-Square

The steps 2-4 have been proposed to detect a suspected case which may be affected by a topology error. This step is useful in determining whether the full step of topology processing should be performed or not. After the system topology is noticed that it may contain a topology error, the topology identification and estimation will be performed consequently and the processing steps may be iteratively repeated for a multiple error case.

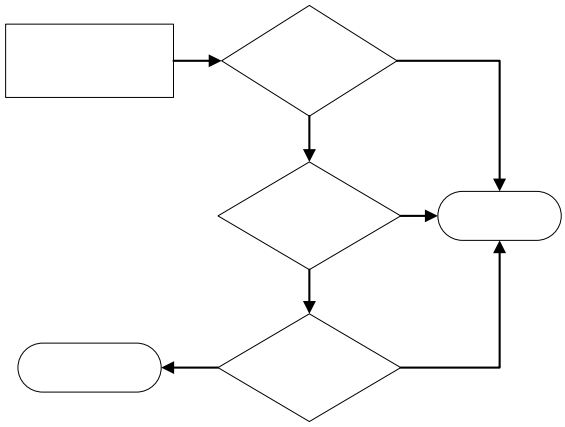

Figure 1. Flow Chart of the Proposed Method

A. Approximate power flow by using Power Transfer Distribution Factors (PTDFs)

Power transfer distribution factors (PTDFs) are applied in order to estimate power flow from power injection data. This allows the agreements between the topology and the measurements to be checked [7,8].

The approximated branch power flows can be calculated using:

$$\overline{S}_{branch} \approx PTDFs \times S_{bus} \quad (3)$$

Where S_{bus} = a vector of bus injection

$\overline{S}_{branch}$ = a vector of branch power flow

B. Branch status error detection

In this step, the agreement between branch status and branch measurement will be checked by the following simple assumptions:

1) When topology information depicts that branch *i* outages, the power flow measurement of branch *i* should be zero or near zero.

2) When the power flow measurement of branch *i* is zero or a very small value, the branch *i* will be suspected that it outages.

To check the assumptions the estimated power flow from the previous step will be used by the following step.

Step 1. Determine the zero threshold which will be used to decide which the power flow should be zero flow (e.g.10^{-5} p.u.)

Step 2. The exclusion error is supposed to be checked in this step by the following condition.

if estimated power of branch *i* = 0, i.e. branch *i* outage, and measured power of branch *i* < threshold then the status of branch *i* is correct.

Step 3. The exclusion error is supposed to be checked in this step by the following condition.

if measured power of branch *i* < threshold and estimated power of branch *i* < threshold then the status of branch *i* is correct.

When some suspicious branch status errors are found, the full step of topology correction will be performed consequently. In the other hand, bus configuration error detection will be performed.

C. *Bus configuration error detection*

In this step, it assumed that when the bus configuration is changed, all power flows corresponding to the bus will be considerably changed correspondingly. Therefore different bus configurations will give the different power flow sets. The correlation between the bus configuration and its corresponding power flows is exploited.

The correlation coefficient (R^2) which represents how two data sets correlate [11] is applied to observe the correlation between the topology information and measurement. The correlation coefficient (R^2) can be calculated by the following equation.

$$R^2 = \frac{\left(\sum_{i=1}^{N}(x_i-\bar{x})(y_i-\bar{y})\right)^2}{\sum_{i=1}^{N}(x_i-\bar{x})^2\sum_{i=1}^{N}(y_i-\bar{y})^2} \quad , \; 0 \le R^2 \le 1 \qquad (4)$$

Where x and y are two data set that have the same number of elements. $\bar{x}$ is the mean value of x and $\bar{y}$ is the mean value of y

The correlation coefficient of the measurements and estimates can be used to represent how well the agreement between measurements and topology is. In the case of branch status error, the correlation coefficient always fail to detect the error therefore the branch status error detection is needed to avoid the failure of topology error detection.

D. *Hypothesis Testing with Chi-Square*

In this step, the hypothesis testing with chi-square [11] will be performed to make sure that the result of the bus configuration error detection is reasonable. The following hypothesis testing is used to decide whether topology is correct or not:

Step1. Define null and alternative hypothesis

H_0 : Topology is erroneous.

H_1 : Topology is correct.

Step2. Calculate the performance index:

$$J(r) = \sum_{i=1}^{N}(r_i^2 / \bar{S}_{branch,i}) \qquad (5)$$

Where: $r_i = S_{branch,i} - \bar{S}_{branch,i}$

N = the number of power flow measurements

Assumption: The residual is assumed to have a normal distribution hence $J(r)$ has the Chi-square distribution.

Step3. if $J(r) \ge C$ then H_0 will be accepted.

if $J(r) < C$ then H_0 will be rejected.

$C = \chi^2(\alpha,\nu)$ where α = confidence interval

ν = degree of freedom = N-1

Because of the inaccurate model used to estimate power flow, the error due to the model will be included in the residual. The threshold should be set to an appropriate value by using C as the minimum and then the threshold can be increased by considering the residual of base case.

IV. ILLUSTRATIVE EXAMPLE

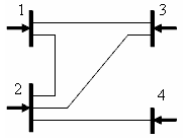

Figure 2. Base Case

The bus-branch model of a 4-bus 4-line test system is shown in Fig.2. The flow measurements of all branches (both ends of the branch), injections and voltage magnitudes of all buses are obtained from power flow calculation with 0.01 MVA power mismatch and then a random error is applied to each measurement. The per-unit values are on the system base of 100MVA.

- For branch status error detection, the zero threshold of 10^{-5} p.u. is used for the zero power flow.
- For bus configuration error detection, the threshold of $R^2 = 0.9$
- For Chi-Square test, the confidence interval $\alpha = 0.01$. 8 measurements (i.e. real and reactive power flows at one end of all branches) is used. The minimum threshold is $C = \chi^2(0.99,7) = 18.5$

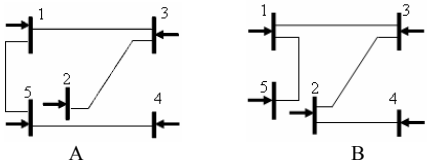

Figure 3. Bus 2 split (configuration A and B)

Example 1: Small test system

This example is referenced to the power system in the Figures 2, 3A and 3B. The real power flow and reactive power flow measurements are used to compare with approximate power flows calculated from the bus injections using the PTDFs.

TABLE 1
TOPOLOGY ERROR DETECTION RESULTS OF EXAMPLE 1

Case	Topology	Measurement	BSE	R^2	J(r)
1.	Fig.1	Base case	-	0.9996	0.55
2.	Fig.1	5 %Error	-	0.9701	23.89
Branch status error					
3.	B 1-2 outage	Base case	B 1-2	0.0245	-
4.	B 2-4 outage	Base case	B 2-4	0.7224	-
5.	Fig.1	B 1-3 outage	B 1-3	0.6523	186
6.	Fig.1	B 2-4 outage	-	0.9984	9.27
Bus configuration error					
7.	Fig.2 (A)	Base case fig.1	-	0.1476	322
8.	Fig.1	Base case Fig.2(B)	-	0.3596	118

From the results in table 1, case 1 will pass the test as having a correct topology. In the case 2, the errors are applied to all the power flows in the percentage of the base MVA, i.e. error is 0.05 p.u. Case 2 will be detected with having a

suspicious topology error or may be accepted if the threshold is adjusted for acceptable measurement error.

In the case of branch status error (case 3-6), the branch with erroneous status will be detected, except for case 6 because the error has no effect on the system.

In the case of bus configuration error (case 7-8), the very low R^2 will depict that the error has a large effect on the system.

Example 2: Topology error detection applied with the larger system

When the larger system is tested, the threshold of topology error detection should be adjusted for each case by considering result of base case.

In table 2 the estimate power flow (real power flow) are compared with the power flow of base case of IEEE test case. From the results, the threshold of R^2 and the Chi-Square test may be selected for the topology error detection e.g. 0.9 and 2C for the threshold, respectively.

TABLE 2.
THE COMPARISON OF ESTIMATED POWER FLOW AND BASE CASE POWER FLOW OF IEEE TEST CASE

Test Case	R^2	$J(r)$	C
IEEE 14 bus	0.9935	56.125	36.19
IEEE 30 bus	0.9951	64.328	63.69
IEEE 57 bus	0.9924	52.063	111.14
IEEE 118 bus	0.9926	349.62	232.67

For large systems, the effect of branch status error will be so little that the R^2 and chi-square test fail. Therefore the branch status error detection must always be performed before the statistical test.

V. COMMENTS

In the practice, the threshold value for the test of the proposed method should be adjusted for accurate results by considering the base case. The most important thing that must be considered for selecting the threshold is the correct topology may be detected that it is error, but the error topology should not be detected that it is correct.

VI. CONCLUSIONS

The topology error detection described above is proposed to be a preprocessing step of the full topology error processing. The topology error detection consists of two main parts, the first part checking the branch status error and the second part checking the bus configuration error. In practical environment the topology error is rare and not widespread. In some cases the topology errors do not alter the network configuration therefore their identification is not necessary. The proposed simple error detection by means of the compromise of topology and measurements, and the fast approximation of power flows using PTDFs, is useful for detecting non-serious cases, i.e. the case of acceptable measurement error, to avoid the full steps of the topology error processing.

The limitations of the proposed topology error detection are:

1. The simple statistical method and assumptions may allow certain types of errors not related to the assumptions to slip through.

2. In the some difficult cases (e.g. topology error and gross measurement error occurring at same time, near zero flows in lines, and interacting and conforming measurement errors), the topology correction may be unable to detect and identify the reliable topology information therefore an efficient topology error processing and bad data detection may be used to cope with such cases.

3. For the error processing with statistical test, the measurements are assumed to have redundancy and the appropriate threshold should be selected for the reliable result.

The proposed topology error detection has been successfully applied to simplified test systems and is being extended to apply to more practical and complex systems.

***Abstract*- This paper describes a successful adaptation of the ant colony optimization (ACO) approach to solve the economic dispatch (ED) problem in power system. The practical ED problem have nonsmooth cost functions with equality and inequality constraints that make the problem of finding the global or near global optimum difficult. To show its efficiency and effectiveness, ACO is applied to test two ED problems. The first one is ED problem with valve-point loading effects and other one is ED problem considering the multiple fuels. Additionally, the results of ACO are compared with the conventional approaches, such as genetic algorithm (GA), tabu search (TS) algorithm and particle swarm optimization (PSO). The experimental results showed that the proposed ACO approach was indeed capable to obtaining higher quality solution efficiently and computational time.**

Keywords: Ant colony optimization, Economic dispatch problem, Genetic algorithm, Particle swarm optimization, Tabu search algorithm

I. INTRODUCTION

The economic dispatch (ED) problem is one of the optimization problems in power system operation. The objective of ED problem is to schedule the optimal combination of outputs of all generating units to minimize the operating cost while satisfying the load demand and system equality and inequality constraints. Improvements in scheduling of the unit power outputs can lead to significant cost savings.

In the past decades, a number of approaches have been developed for solving this problem using mathematical programming, such as lambda iteration method, gradient method, and linear programming, etc. Unfortunately, the input-output characteristics of modern power generating units are inherently highly nonlinear because of valve-point loading effects, multi-fuel effects, etc. Therefore, they may lead to multiple local minimum points of the cost functions and this makes the problem of finding the global or near global optimum difficult.

Recently, modern heuristic optimization techniques such as simulated annealing (SA) [1], genetic algorithm (GA) [2,3], evolutionary programming (EP) [4,5], Tabu search (TS) algorithm [6], neural network approaches, and particle swarm optimization (PSO) [7,8] have been given much attention by many researches due to their ability to find an almost global optimal solution. From the past literature review, we believed that the ED problem with nonsmooth cost functions not yet applied by ant colony optimization (ACO).

For the last few years, the algorithms inspired by the observation of natural phenomena to help solving combinatorial problems have been increasing interest. One of these algorithms is ACO, which has become a candidate for many optimization applications. The first ACO was introduced by Dorigo [9], which can only be used to solve different combinatorial optimization problem. It was inspired by the behaviors of real ant colonies. In analyzing the behaviors of real ants, it was found that the ants are capable of finding shortest path from food sources to the nest without using cues.

The feasibility study of the ACO is demonstrated for solving the ED problem with nonsmooth cost functions. The results optimized by the ACO are compared to those obtained by the conventional approaches such as GA, TS and PSO in terms of solution quality and computational efficiency.

II. PROBLEM FORMULATION

The objective of ED problem is to find the optimal combination of power generation that minimizes the total generation cost while satisfying an equality constraint and inequality constraints.

A Objective Function

In reality, the objective function of an ED problem has non-differentiable points according to valve-point effects and multiple fuels. Therefore, the objective function should be composed of a set of nonsmooth cost functions.

(i) Nonsmooth cost functions with valve point effects :

To take account for the valve-point effects, sinusoidal functions are added to the quadratic cost functions as follows:

$$F_t = F_i(P_i) = a_i + b_i P_i + c_i P_i^2 + \left| e_i \times \sin(f_i \times (P_i^{\min} - P_i)) \right| \quad (1)$$

where F_t is the total generation cost; F_i is the generation cost function of i^{th} generator is usually expressed as a quadratic polynomial; a_i , b_i , and c_i are the cost coefficients of the i^{th} generator; e_i and f_i are the coefficients of generator reflecting valve-point effects. P_i is the power output of the i^{th} generator and n is the number of generators committed to the operating system.

(ii) Nonsmooth cost functions with multiple fuels:

Generally, a piecewise quadratic function is used to represent the input-output curve of a generator with multiple fuels. The piecewise quadratic function is described as follows:

$$F_i(P_i) = \begin{cases} a_{i1} + b_{i1}P_i + c_{i1}P_i^2 & P_i^{\min} \le P_i \le P_{i1} \\ a_{i2} + b_{i2}P_i + c_{i2}P_i^2 & P_{i1} \le P_i \le P_{i2} \\ \vdots & \vdots \\ a_{ik} + b_{ik}P_i + c_{ik}P_i^2 & P_{ik-1} \le P_i \le P_i^{\max} \end{cases} \quad (2)$$

where a_{ij}, b_{ij}, and c_{ij} are the cost coefficients of generator i for the j^{th} power level.

B) Constraints

(i) Equality constraint

While minimizing the total generation cost, the total generation should be equal to the total system demand plus the transmission network loss. However, the network loss is not considered in this paper for simplicity. This gives the equality constraint

$$\sum_{i=1}^{m} P_i = P_D \quad (3)$$

where P_D is load demand

(ii) Inequality constraint

The generation output of each unit should be between its minimum and maximum limits. That is, the following inequality constraint for each generator should be satisfied

$$P_i^{\min} \le P_i \le P_i^{\max} \quad (4)$$

where $P_i^{\min}$, $P_i^{\max}$: minimum, maximum output of i^{th} generator.

III. Ant Colony Optimization

A) Basic principle of ant colony

ACO is an evolutionary meta-heuristic algorithm based on a graph representation that has been applied successfully to solve various hard combinatorial optimization problems [9]. The main idea of ACO is to model the problem as the search for a minimum cost path in a graph. Artificial ants walk through this graph, looking for good paths. Each ant has a rather simple behavior so that it will typically only find rather poor-quality paths on its own. Better paths are found as the emergent result of the global cooperation among ants in the colony.

B) The ACO algorithm for solving ED problem

To apply the ACO algorithm to solve the ED problem, it is convenient to represent the problem by a graph $G = (N, E)$, where N are the nodes and E is the set of links. Ants cooperate by using indirect form of communication mediated by pheromone they deposit on the links of the graph G while building solutions. For example, 3 units power system as showed in Fig. 1. The ED problem can be represented as a graph of the routes between the nest and food source shown in Fig. 2.

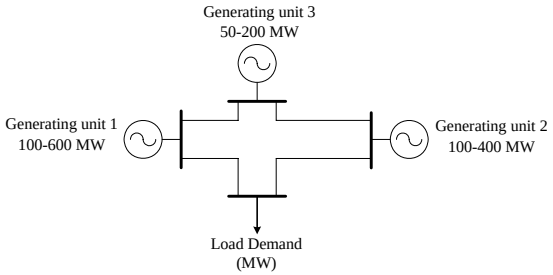

Fig. 1 The power system consists of 3 generating units.

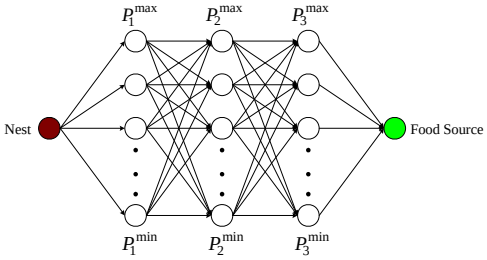

Fig. 2 Routes of ants between nest and food source for ED problem

In this example, each generation output (P_1, P_2, and P_3) is coded by number of nodes depend on resolution. Thus, a large number of nodes, the more accuracy trials are updated only after having constructed a complete path and the solution found. If choose number of node equal to 4,500 for the first generating units yield the resolution is 0.1 MW ($P_1^{\max} - P_1^{\min} = 600 - 150 = 450$ MW)

Informally, the ACO algorithm works as follows: m ants are initially positioned on the node representing the first link. Each ant will construct one possible structure of the entire system. In fact, each ant builds a feasible solution (called a tour) by repeatedly applying a stochastic greedy search, called, *the state transition rule*.

The amount of pheromone is modified by applying the *global updating rule*. Ants are guided, in building their tours, by both heuristic information and by pheromone information. Naturally, a link with a high amount of pheromone is a very desirable choice. The pheromone updating rules are designed so that they tend to give more pheromone to edges, which should be visited by ants.

(i) State Transition Rule

The state transition rule used by the ant colony is given in equation (5). This represents the probability with which ant k selects a link connects node i and node j:

$$p_{ij}^k(t) = \frac{\left[\tau_{ij}(t)\right]^{\alpha}\left[\eta_{ij}(t)\right]^{\beta}}{\sum_{m=1}^{M_i}\left[\tau_{im}(t)\right]^{\alpha}\left[\eta_{im}(t)\right]^{\beta}} \quad (5)$$

where τ_{ij} and η_{ij} are the pheromone intensity and the heuristic information between node i and node j, respectively. α is the relative importance of the trail and β is the relative importance of the heuristic information η_{ij}: The problem specific heuristic information used is:

$$\eta_{ij} = \frac{1}{C_{ij}} \tag{6}$$

where C_{ij} represent the associated cost. That is, the level of link with smaller cost has greater probability to be chosen.

(ii) Global updating rule

During the construction process, no guarantee is given that an ant will construct a feasible solution which obeys the reliability constraint. The unfeasibility of solutions is treated in the pheromone update: the amount of pheromone deposited by an ant is set to a high value if the generated solution is feasible and to a low value if it is infeasible. These values are dependent of the solution quality. Infeasibilities can then be handled by assigning penalties proportional to the amount of reliability violations. In the case of feasible solutions, an additional penalty proportional to the obtained solution is introduced to improve its quality.

Following the above remarks, the trail intensity is updated as follows:

$$\tau_{ij}(new) = \rho\tau_{ij}(old) + \Delta\tau_{ij} \tag{7}$$

ρ is a coefficient such that $(1-\rho)$ represents the evaporation of trail and $\Delta\tau_{ij}$ is:

$$\Delta\tau_{ij} = \sum_{k=1}^{m} \Delta\tau_{ij}^{k} \tag{8}$$

where m is the number of ants and $\Delta\tau_{ij}^{k}$ is given by:

$$\Delta\tau_{ij}^{k} = \begin{cases} Q \cdot penalty_k \cdot C_k & \text{if the } k^{th} \text{ ant chooses level } j \text{ for link } i \\ 0 & \text{otherwise} \end{cases} \tag{9}$$

where Q is a positive number, and $penalty_k$ is defined as follows:

$$penalty_k = \left(\frac{C_k}{C^*}\right)^a \tag{10}$$

C_k is the cost obtained by ant k, C^* is the best obtained solution. Parameter a represents the relative importance of penalties.

IV. Numerical Results

To assess the feasibility of the ACO approach, two cases studies of ED problems with nonsmooth objective function considering valve point effects and multiple fuels.

Each optimization method (GA, TS, PSO, and ACO) was implemented in MatLab®. All the programs were run on a Pentium 4, 2.6 GHz personal microcomputer with 256-MB RAM under Windows XP.

In each case study, 30 independent runs were made for each of the optimization methods, involving 30 differential initial trial solutions for each optimization method.

A) Case studies and simulation results

***Case 1*:** The system contains 13 thermal units of generation with valve-point effects whose characteristics are given in [8]. The load demand is 2,520 MW. In TABLE 1, the best generation powers are obtained by ACO, PSO, TS, and GA. TABLE 2 shows the best, average, worst cost, the standard deviation and computational time achieved by GA, TS, PSO and ACO in 30 runs.

Case 2: The developed ACO has also been applied to the ED problem with 10 generators where the multiple-fuel effects are considered. In this case, the objective function is represented as the piecewise quadratic cost function. The input data and related constraints of the test system are given in [8]. In this case, the total system demand is 2700 MW. In TABLE 3, the best generation powers are obtained by ACO, PSO, TS, and GA. TABLE 4 shows the best, average, worst cost, the standard deviation and computational time achieved by GA, TS, PSO and ACO in 30 runs.

TABLE 1. Best results obtained for case study 1 (13 unit system)

Unit	Po (MW)	Unit	Po (MW)

ACO	624.11	623.96	623.83	0.07	5.38

B) Comparison of four Methods

i) Solution Quality:

For 13 units system with valve point effects for 2,520 MW load demand and 10 units system with multiple fuels for 2,700 MW load demand, after performed 30 trials; the best solutions of four methods are given in TABLE 1 and TABLE 3, respectively. The results of proposed ACO method are compared with GA, TS, and PSO in terms of worst, average, best generation cost, the standard deviation, and average computational time are provided in TABLE 2 and TABLE 4, respectively. Obviously, all methods have succeeded in finding the near optimum solution presented in [8] with a high probability always satisfying the equality and inequality constraints.

In order to demonstrate the efficiency of the proposed ACO method, the distribution outlines of the best solution of each trial are considered. Fig. 2 showed the distribution outlines of the best solution of each trial in case 13 units system with valve point effects for 2,520 MW load demand. Almost all generation costs obtained by the ACO method were lower, thus verifying that the ACO method has better quality of solution.

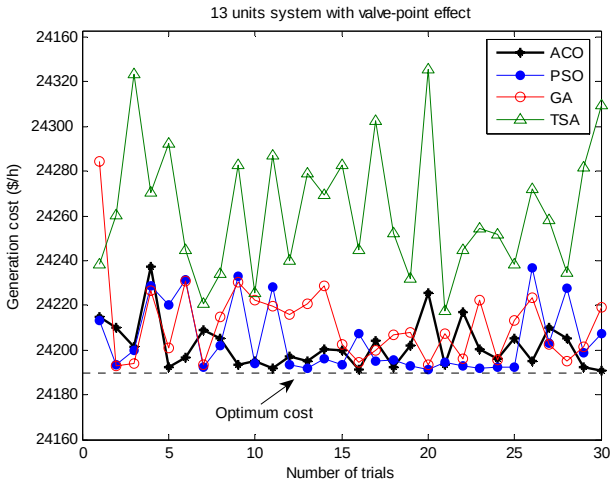

Fig. 2 Distribution of generation cost of four methods (13 unit system)

ii) Computation Efficiency: the convergence characteristics of the proposed MTS method compared with other methods for two case studies. Furthermore, the comparisons of computation time of four methods when applied on three case studies are shown in TABLE 2 and TABLE 4. Obviously, the proposed ACO method has better computation time than other methods for three examples. As seen that, the proposed ACO method converge to optimum solution faster than other methods.

V. Discussion and Conclusions

In this paper, we have successfully employed the proposed ACO method to solve the dynamic ED problem with the valve-point loading effects and multiple fuels. The proposed ACO algorithm has been demonstrated to have superior features, including high-quality solution, stable convergence characteristic, and good computation efficiency. Many nonlinear characteristics of the generator such as valve point effect are considered for practical generator operation in the proposed method. The results show that the proposed method was indeed capable of obtaining higher quality solution efficiently.

In addition, in order to verify it being superior to the GA, TS and PSO method, many performance estimation schemes are performed, such as solution quality and convergence characteristic and computation efficiency.

Relevant Factors for Failure Rate Estimation of Overhead Distribution Feeders

N. Teera-achariyakul and D. Rerkpreedapong
Department of Electrical Engineering
Kasetsart University, Bangkok 10900 Thailand

***Abstract* – This paper proposes relevant factors that can be used in estimating failure rates of overhead distribution feeders. These relevant factors represent how surrounding features of feeders influence their failure rates. The studied features include tree and cleared-tree areas, types of conductors such as bare and insulated conductors, and types of insulators including line-post and other types. 39 distribution feeders of the Provincial Electricity Authority (PEA) are surveyed to collect required data associated with these features. Once the relevant factors are found, they are used as a multiplier to scale up/down the mean failure rate in estimating the failure rate of an interested feeder. The estimation procedure is illustrated step by step with case studies in the paper.**

I. INTRODUCTION

SAIFI and SAIDI are the most widely used reliability indices that indicate the service quality of electric utilities. In assessing the system reliability, the utilities compute the SAIFI and SAIDI from the past performance by using the historical outage data collected by their operators. However, to predict the level of reliability for the future planning, the SAIFI and SAIDI are normally determined based on the system failure rates.

The failure rates of overhead distribution lines in different areas are varied due to a variety of surrounding conditions and types of equipments installed on utility distribution feeders [5-7]. In this paper, the relevant factors (K) associated with the above features are first introduced, and are developed from collected data including distribution feeder surveys and feeder failure rate database.

Three significant advantages resulted from the relevant factors are as follows: (1) they show an influence of studied surrounding features of feeders as a multiplier to scale up/down the mean failure rate, (2) such scaling factors can be straightforwardly used in estimating an interested failure rate of distribution feeders which locate in different surrounding conditions, and (3) in planning on reliability improvement for feeders with poor failure rates, these relevant factors can be useful for choosing an appropriate maintenance activity to heal the feeder weaknesses.

In this paper, the mean failure rate (λ_M) is first obtained from the Provincial Electricity Authority (PEA) technical report including failure rates of over 2,000 overhead distribution feeders in Thailand [3]. These failure rates are determined from the sustained outages database which contains more than 600,000 events in PEA distribution systems during 2001-2005 [1]. Next, feeder surrounding surveys are conducted on three selected local utilities of the PEA including Saraburi, Bangpakong and Rangsit offices. In section II, the data collected from the surveys, for 39 feeders, contain feeder length, percent of trees along the feeder length, percent of bare and insulated cables used along the feeder length, percent of line-post insulators installed on the feeder, and failure rate of the feeder.

In this research, six different surrounding features of distribution feeders are studied, and the relevant factors of these features are as follows:

(1) Tree factor (K_{tree})
(2) Cleared-tree factor ($K_{cleared}$)
(3) Bare-conductor factor (K_{bare})
(4) Insulated-conductor factor ($K_{insulated}$)
(5) Line-post-insulator factor ($K_{linepost}$)
(6) Other-insulator factor (K_{other})

The above relevant factors are determined in Section III. The estimation formula for feeder failure rates is developed, and the tests with case studies are illustrated in Section IV. Finally, conclusions are given in Section V.

II. FAILURE RATES AND SURROUNDING SURVEYS

A. Mean Failure Rate

The mean failure rate of over 2,000 feeders in Thailand is computed from the sustained outage database of the PEA during 2001-2005. The study of uptime of overhead distribution lines has found that most of feeders have a Weibull distribution [2,4], and the mean failure rate of all feeders is found at 17.38 times per 100 circuit kilometers-year [3], and it is used as the mean failure rate (λ_M) in this paper.

B. Feeder Surrounding Surveys

To analyze the impact of the surrounding features on feeder failure rates, field surveys are conducted on three selected local utilities of the PEA including Saraburi, Bangpakong and Rangsit offices. In TABLE I, the data collected from the surveys, for 39 feeders, contain feeder length, percent of trees along the feeder length, percent of bare and insulated conductors used along the feeder length, percent of line-post insulators installed on the feeder, and failure rate of each feeder.

TABLE I
FEEDER SURROUNDING FEATURES VS. FAILURE RATES

III. RELEVANT FACTORS

From TABLE I, the studied relevant factors are trees, types of feeder conductors, and types of insulators. In more details, the trees associated factors include 2 features, which are tree area and cleared-tree area. Next, the type-of-conductors factors consist of bare-conductor and insulated-conductor (Space Aerial Cable; SAC and Partial Insulated Cable; PIC) features. Finally, the factors regarding types of insulators include two features, which are line-post insulators and the other types of insulators (Pin-type insulators and pin-post-type insulators).

According to the six features as described above, the feeders in TABLE I, which are fit to the feature descriptions, are categorized in TABLE II. The averages (λ_i) of feeder failure rates for each category are also given in TABLE II. The feeders that do not match any categories are highlighted, and they are not included in calculating the average failure rates.

TABLE II
AVERAGE FEEDER FAILURE RATES
(TIMES/100-CIRCUIT-KILOMETERS-YEAR)

	Feature Descriptions		Number of Feeders	Average Failure Rates
FEATURE CATEGORY	Tree	More than 75% of trees along feeders	16	19.42
	Cleared	Less than 25% of trees along feeders	6	16.75
	Bare	Bare conductors installed more than 75% of feeder length	5	19.16
	Insulated	Insulated conductors installed more than 75% of feeder length	17	16.61
	Line post	Line post insulators installed more than 75% on feeder	18	17.47
	Others	Line post insulators are installed less than 40% in feeder	2	20.72

TABLE III
RELEVANT FACTORS

K_{tree}	$K_{cleared}$	K_{bare}	$K_{insulated}$	$K_{linepost}$	K_{other}
1.12	0.96	1.10	0.96	1.01	1.19

The relative factor (K_i) for each feature as shown in TABLE III can be determined from (1)

$$K_i = \frac{\lambda_i}{\lambda_M} \quad (1)$$

where
K_i is the relevant factor due to feature i
λ_i is the average failure rate of feeders in category i
λ_M is the mean failure rate of all PEA feeders.

The relevant factors given in TABLE III illustrate how each surrounding feature influence the failure rate of overhead distribution feeders. The factors that are greater than one generally result in adverse effects on feeder failure rates. For instance, an overhead distribution feeder that utilizes bare conductors is more likely to be faulted by tree and animal contacts. As another example, a feeder placed along the line of growing trees is not safe from contacts between trees and electrical equipments on distribution feeders.

However, when types of insulators are considered, the line-post insulators, which are the best type of insulators, are found the most during the surveys. As a result, the relevant factor $K_{linepost}$ is near one because almost all feeders use line-post insulators as a majority. In addition, the PEA has a plan to replace other types of insulators with the line-post insulators in a little while. Consequently, the relevant factors regarding types of insulators may not be required in the future.

The relevant factors $K_{cleared}$ and $K_{insulated}$ are less than one because they represent the features that decrease the failure rates. For example, a feeder that uses insulated conductors and is located in cleared-tree areas would have a very low rate of power outages.

IV. Failure Rate Estimation

After all relevant factors are determined in Section III, they can be used in estimating the failure rate of an interested feeder using (2).

$$\lambda = \lambda_M \times K_T \tag{2}$$

where

λ is the failure rate of the interested feeder.

λ_M is the mean failure rate of all PEA feeders equal 17.38 times per 100-circuit-km.-year.

K_T is the total relevant factor calculated by (3).

$$K_T = (K_{tree} D_{tree} + K_{cleared} D_{cleared}) \times (K_{bare} D_{bare} + K_{insulated} D_{insulated}) \times (K_{linepost} D_{linepost} + K_{other} D_{other}) \tag{3}$$

where

K_{tree} is the relevant factor for tree-area feature.

$K_{cleared}$ is the relevant factor for cleared-tree-area feature.

K_{bare} is the relevant factor for bare-conductor feature.

$K_{insulated}$ is the relevant factor for insulated-conductor feature.

$K_{linepost}$ is the relevant factor for line-post-insulators feature.

K_{other} is the relevant factor for other-types-insulators feature.

D_{tree} is the ratio of tree-area distance to feeder length.

$D_{cleared}$ is the ratio of cleared-tree-area distance to feeder length.

D_{bare} is the ratio of bare-conductor distance to feeder length.

$D_{insulated}$ is the ratio of insulated-conductor distance to feeder length.

$D_{linepost}$ is the proportion of line-post insulators of feeder.

D_{other} is the proportion of the other types of insulators of feeder.

For example, an overhead distribution feeder in a rural area has a feeder length of 68.3 km. The length of bare conductors used in this feeder is 37.6 km. About 60% of insulators installed in the feeder are line-post insulators. The total length of feeder portions over tree areas is about 33.3 km. The failure rate of such a feeder can be estimated step by step as follows.

Step1. Find D_i i.e. D_{tree}, $D_{cleared}$, D_{bare}, $D_{insulated}$, $D_{linepost}$, and D_{other} (0.49, 0.51, 0.55, 0.45, 0.6 and 0.4 respectively),

Step2. Calculate the total relevant factor K_T by substituting all D_i found from step1 and K_i from TABLE III in (3). So,

$K_T = (1.12\times0.49 + 0.96\times0.51) \times (1.10\times0.55 + 0.96\times0.45) \times (1.01\times0.6 + 1.19\times0.4)$

$= 1.16$

Step3. Estimate the feeder failure rate, λ, by substituting K_T obtained in step2 in (2). So, $\lambda = 17.38\times1.16 = 20.20$ times per 100-circuit-km.-year.

The actual failure rate of this feeder calculated from PEA interruption data during 2001-2005 is 21.16 times per 100-circuit-km.-year. A difference between the estimated failure rate and the actual one is around $|21.16\text{-}20.20| \times 100 / 21.16 = 4.52\%$.

The estimated failure rates of 39 surveyed feeders are plotted to compare with the actual values in Figure 1.

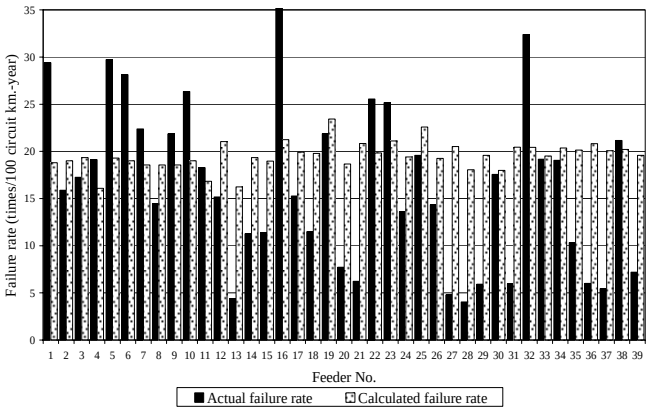

Figure 1. Estimated failure rates vs. actual values of surveyed feeders.

According to the above results, the median of estimation errors is about 30%. It indicates that a few additional relevant factors (animal density, contamination, etc.) besides what presented in this paper may be taken into account for better estimation performance, which could lead to further research. Nevertheless, a worthy advantage of the proposed estimation is that the failure rate of interested feeders can be easily determined without involving any sophisticated mathematical analyses. This estimation method helps electric utilities to approximate their feeder failure rates in no time, when surrounding features of their feeders change in the future.

On reliability improvement using relevant factors, utility engineers can plan to reduce the failure rate of interested feeders to an expected value with an appropriate maintenance activity. For example, an overhead distribution feeder uses 100% of bare conductors (K_{bare} = 1.10). If the bare conductors are totally replaced by insulated conductors ($K_{insulated}$ = 0.96), this maintenance activity will result in a decrease of failure rate by (1.10-0.96)/1.10×100 = 12.7%.

V. CONCLUSIONS

This paper introduces the relevant factors that can be used in estimating failure rate of overhead distribution feeders. These relevant factors represent how surrounding features of overhead feeders influence the failure rates. The studied features include tree and cleared-tree areas, types of conductors such as bare and insulated conductors, and types of insulators including line-post and other types. 39 distribution feeders of the Provincial Electricity Authority (PEA) are surveyed to collect required data associated with these features. Once the relevant factors are found, they are used as a multiplier to scale up/down the mean failure rate in estimating the failure rate of an interested feeder.

The estimation procedure of failure rates are illustrated by case studies. A key advantage of the proposed estimation is its simplicity. Since no sophisticated mathematical analyses are involved, it makes this method practical to be applied by electric utilities. On reliability improvement, an appropriate maintenance activity can be planned to achieve the targeted feeder failure rates using the relevant factors presented in this paper.

***Abstract*- A congestion management (CM) framework for a competitive electricity supply industry is proposed in this paper. The proposed framework manages the congestion separately between power pool and bilateral market. The MVA thermal limit of transmission lines is used associated with various means, i.e. generation re-dispatch, interruptible loads and distributed generations, to relief the congestion. The problem is tested with a 6-bus system and solved by a linear programming.**
